These experiments also indicate that within certain limits the number of bacilli introduced into the water plays no great part in increasing the total longevity. Frankland[1] suggests that among a large number of bacteria taken from a given source there may be some individuals capable of resisting a particular adverse influence, whereas with a smaller number there might not be any such individuals. While this is conceivably possible, my own results do not lend unqualified support to the view. I have found, for example, that after from 50 to 60 days, in such an experiment as I have described (*cf., e. g.,* Flasks A and B after 40 days), the numbers are substantially the same when the initial number was three times as great in one case as in the other (6000 and 18,000). If it were attempted to increase the disparity of numbers to a greater extent than this, I think some risk would be run of introducing sufficient nutrient medium to complicate the experiment. There is at hand, moreover, a plausible explanation for the *apparent* influence of number in certain experiments recorded by other investigators. The number of living bacilli taken up by the loop from a 48-hour culture of freshly isolated typhoid-bacilli is for some reason larger, often very much larger, than the number obtained in a similar way from a 48-hour culture of typhoid-bacilli that has been under artificial cultivation for some months. There is here, therefore, a concurrence of two factors, namely, large numbers and short exposure to the influence of artificial cultivation. I believe, for reasons that I shall bring forward presently, that this last factor is of great importance. Large numbers of bacilli, then, are usually introduced from the very typhoid-culture that possesses great vitality, whereas when long cultivation has rendered the bacilli less able to survive in water smaller numbers are likely to be introduced. This fact, I think, is sufficient to explain the apparent connection between numbers and longevity that some experimenters believe to exist. In those cases in which very large numbers are dealt with (*e. g.,* over 100,000 per c.cm.) the influence of food-substance obscures the whole course of events, and inevitably leads to discordant results.

That the length of time the bacilli from a given culture are able to live in water is dependent on the length of time during which the culture has been under cultivation we have the result of the following experiment as evidence: A few days after I had isolated the typhoid-culture already mentioned, the bacilli were introduced into sterilized tap-water (Lake Michigan); in this instance living bacilli were found to be present after 93 days. From that time onward for thirteen months this particular typhoid-stock was under observation, and bacilli from it were introduced into sterile Lake Michigan

[1] Proc. Royal Society, vol. 56, p. 172.

water at frequent intervals. Care was taken by frequent transfers (agar-tubes) to maintain the vitality of the stock, as far as might be, unimpaired. For two or three months no very noticeable change was observed; but after that time the vitality of the bacilli in water began to wane. Through the whole series of thirteen months a fairly steady decline went on. In the last trial I have made the bacilli lived but 12 days. Intermediate periods were 83 days, 55 days, 41 days, 22 days, etc., the diminished vitality in each case corresponding with the time that had elapsed since the first isolation of the typhoid-stock. We cannot, therefore, if this culture be regarded as typical, escape the conclusion that *the age of the stock-culture employed in experiments upon longevity of the bacilli in water is a factor of prime importance.*

The water that was used in the experiments already described, as well as in those to follow, is drawn from Lake Michigan through the Sixty-eighth Street Tunnel, which supplies the southern part of the city of Chicago. The average composition for the summer and early autumn of 1893 was as follows:[1]

Parts per 100,000.			Average.
Total solids	14.6	to 18.6	15.7
Loss on ignition	3.0	" 3.7	3.4
Chlorin	0.21	" 0.31	0.26
Oxygen consumed	0.07	" 0.10	0.08
N as ammonia (albuminoid)	0.0090	" 0.0127	0.0112
N as ammonia (free)	0.0011	" 0.0039	0.0021
N as nitrites	0.0001	" 0.0009	0.0003
N as nitrates	0.0030	" 0.0070	0.0048

The composition of the water is subject to this not inconsiderable fluctuation, because the sewage that enters the lake is liable to vary in quality and quantity, and is more or less unevenly distributed by the currents and winds. I have not been able, however, to discover what influence, if any, these daily and weekly variations in the composition of the water have upon the life of bacteria introduced. The multiplicity of factors involved renders such a task almost hopeless.

All experiments have been conducted in the dark; the flasks have been kept at the ordinary room-temperature; and, in order to insure uniformity of conditions in each experiment, the flasks have been always placed close together in the dark closet. Through the winter months it has been found possible to keep the temperature fairly constant, from 18° to 21° C., but in summer the temperature of the dark closet has risen on some occasions to 25° or 26° C., and I have reason to suspect that this range of seven or eight degrees is sufficient to lead to disparate results. I have, consequently, included in this paper only such experiments as were carried out under similar temperature-conditions, deferring a discussion of special temperature-influence to a second paper. In all cases, except when very high numbers were present (see Flasks D and E), one cubic centimeter of the infected water was used for plating.

Steam-sterilized lake-water. Proceeding now to a consideration of the results obtained with the typhoid-culture already described, we may first take up the case of steam-sterilized surface-water. Waters of this character have hitherto been the subject of the greater part of the experiments undertaken, but whether because of inaccurate and non-comparable methods, or because of diversity in the composition of the waters employed by different investigators, the results show a singular lack of concurrence. The longest duration of vitality observed by Hochstetter[1] in sterilized Berlin tap-water was seven days, and Mattei and Stagnitta[2] report a longevity of only four days, while, on the other hand, Straus and Dubarry[3] found that the typhoid-bacillus lived eighty-one days in the sterilized water of the polluted Ourcq, and Frankland[4] records a duration of life of "upward of seventy-six[5] days in steam-sterilized Thames water. Between these widely separated extremes many other periods of longevity in water have been recorded, but it is the extremes that concern us most.

The greatest longevity shown by the typhoid-culture with which I have worked was manifested in one of the early experiments soon after isolation, and extended over a period of ninety-three days.

Immediately after inoculation	6435
After 28 hours	4840
" 3 days	5390
" 10 "	4136
" 26 "	3800
" 50 "	1165
" 77 "	49
" 90 "	15
" 93 "	16
" 110 "	0

Succeeding trials showed, as I have already stated, a progressive decline of vitality. To take instances in which the initial numbers were low:

	4 months after isolation.	6 months after isolation.	13 months after isolation.
Initial number	800	1540	1815
After 7 days	660	935	1320
" 10 "	660	364	78 (12 days)
" 20 "	288	18	0

There is, moreover, considerable variation in the results of experiments made with exactly similar

[1] Arbeiten aus dem kaiserlichen Gesundsheitsamte, 1887, ii.

[2] Annali dell' Instituts d'Igiene Speriment di Roma, 1889. I have not seen this paper, and only quote from Frankland's summary.

[3] Arch. de Méd. Expt., 1889.

[4] Proceedings Royal Society, 1894, vol. 56.

[5] Inspection of the tables of dates and longevity given by Frankland, on pp. 330 and 331 of his work, suggests a suspicion that the influence of the age of the culture may be traced in his experiments also.

numbers under similar conditions. (See, *e. g.*, p. 338, Flasks A and B.) This variation shows itself for the most part toward the end of the experiment in the more persistent vitality of a few individuals, and may cause so large a difference in the "period of longevity" as three weeks. A like variation, due without doubt to the variable hardiness of individual bacilli, has been observed by other experimenters. This individual difference shows itself at its true value in the numerical tables, and it is noteworthy that the general course of the diminution of numbers is not altered, as it plainly is altered in the cases just tabulated, in which the age of the culture has modified the general vitality.

The behavior of the *Bacillus coli communis* in the steam-sterilized tap-water is in contrast to the behavior of the typhoid-bacillus. A culture of the *B. coli communis* freshly isolated from normal human feces, when introduced into a flask of water under the conditions just described, soon undergoes considerable multiplication. The following experiments, conducted at the same time, and parallel with the ninety-three-day experiment with the typhoid-bacillus already recorded, illustrate this point:

	D.	E.
Immediately after inoculation	1,925 B. coli.	1,925 B. coli. 6,435 B. typhi.
After 28 hours	2,035	6,160
" 3 days	1,815	6,215
" 10 "	77,000[1]	299,750[1]
" 16 "	93,500[1]	209,000[1]
" 22 "	66,000[1]	200,750[1]
" 26 "	57,550[1]	
" 50 "	22,000[1]	
" 90 "	5,379	25,344[1]
" 127 "	7,260	
" 184 "	148	660
" 262 "	5	0

Therefore in ability not only to multiply but also to maintain vitality in water, *B. coli communis* differs from the typhoid-bacillus. Frankland[2] has recorded an experiment with steam-sterilized Thames water, similar to D, and giving a similar result; but the initial number of colon-bacilli is much larger (69,000) than I employed, and there is a more sudden falling off (from 117,000 to 1500 between fifty-six and sixty-eight days) than is shown in my experiment. The record of his experiment covers only seventy-five days. The result with Flask E is particularly interesting in this connection, as it shows a somewhat larger increase in numbers than Flask D. It is probable that this is due to the additional nutrient medium conveyed into the flask along with the 6435 typhoid-bacilli. This infinitesimal amount of organic matter is, as has been shown, not sufficient to affect the typhoid-bacillus, but experiment E appears to indicate that the *B. coli* is more sensitive than the *B. typhi* to slight increments of food-material. The primary object of experiment E was to determine whether possibly symbiotic relations might obtain between the *B. coli* and the typhoid-bacillus, but the great multiplication of the former rendered this undertaking futile. On the first and third days a few colonies of typhoid-bacilli were identified on the plates (glucose-agar test), but on the tenth day and thereafter not a single typhoid-colony could be detected, although examinations of a large number of colonies were made repeatedly.[1] This, so far as it goes, indicates perhaps that the presence of the *B. coli* in water is hostile to the continued existence of the typhoid-bacillus, but the chance is obviously very great that typhoid-bacilli, if present (say 4136 among 299,000), might be entirely missed.[2] Guimbert states that the sowing of the *B. coli* and *B. typhi* together in water results in the disappearance of the latter (indol-test) after two or three days, but full details of the experiment are not given, and there are grave difficulties in the way of gaining satisfactory evidence on this point.

As a supplementary inquiry to these experiments with the colon-bacillus, a set of flasks, F, G, and H, were infected, two weeks later, with colon-bacilli derived from different sources, the other conditions being precisely similar to those in D and E.

The culture of the colon-bacillus with which F was infected was obtained from the spleen of an individual dying with typhoid fever. The spleen was procured for me through the kindness of Dr. A. P. Ohlmacher, who also sent me the following autopsy-notes:

"The patient was a male, aged twenty-four years. Death after six weeks from hemorrhage and sepsis due to perforation of ileum. Old adhesions around spleen, which was torn in removal on this account. Intestinal contents in abdomen and about the spleen."

From this spleen a typical colon-bacillus, agreeing in all respects with that isolated from normal fèces, was obtained in pure culture and used for infecting Flask F.

The colon-bacillus used in infecting G was obtained from the fresh feces of the lion by Mr. J. M. Flint, and did not differ in any respect from the typical *B. coli communis* from the other sources.

Flask H was infected with a culture of the colon-bacillus, for which I am also indebted to Dr. A. P.

[1] In these cases 1 c.cm. of the infected water was diluted 1:50 with sterilized distilled water and 1 c.cm. of the mixture plated; the counts made from these plates were, of course, multiplied by 50.

[2] Loc. cit., p. 140.

[1] The Würtz-agar-method has not proved available in this connection because the large number of colonies of the *B. coli* on each plate have speedily reddened the whole medium and rendered the search for typhoid-colonies hopeless.

[2] La Semaine Médicale, 1894, No. 29, p. 230.

Ohlmacher. This was isolated from the pus in a case of appendicitis, and agreed in character with the cultures already described.

The results are as follows:

	F. Inoculated with B. coli from spleen.	G. Inoculated with B. coli from feces of lion.	H. Inoculated with B. coli from appendicitis pus.
Initial number	10,065	2,695	2,255
After 2 days .	9,900	2,420	2,915
" 8 " .	17,600	2,850	6,000
" 12 " .	18,400	46,750	8,900
" 22 " .	14,750	96,250	5,650
" 36 " .	35,400	60,500	5,670
" 134 " .	5,940	10,890	1,295
" 248 " .	Not continued	4,675	Not continued

In two respects there is perfect agreement between the cultures of the *B. coli communis* from the four different sources, namely, they all exhibit multiplication and they all show long-continued vitality. The interesting difference in the amount of multiplication that occurs may be referable to racial variation, and suggests, in the cases of F and H, an approximation toward the typhoid-bacillus. I have not yet been able to make a trial of the behavior in water of the "varieties" of the typhoid-bacillus. It is likely that experiment in this direction would add to the number of varying "grades of vitality" in water. It is possible that there may be discovered a graded series of forms intermediate between the true typhoid-bacillus on the one side, which perishes in water under one-hundred days and never multiplies, and, on the other, the true colon-bacillus, which undergoes a very considerable multiplication in water and may maintain its vitality for upward of two-hundred-and-sixty-two days. The more tenacious vitality of the "typical" colon-bacillus, obtained from whatever source, together with its ability to thrive and multiply on very small quantities of nutrient material, is, however, a characteristic that separates it from the "typical" typhoid-bacillus and emphasizes the functional difference known to exist in other respects.

Steam-sterilized distilled water. Experiments upon the vitality of the typhoid-bacillus in sterilized distilled water have not led to more harmonious results than those with sterilized potable waters, although the more uniform quality of the water might have led us to anticipate greater uniformity of results. Hochstetter[1] records five days as the longest duration of vitality that he observed, while Straus and Dubarry[2] record a longevity of from thirty to thirty-five days, and Slater[3] has recently found living typhoid-bacilli in water fifty days after inoculation.[4]

In the last-mentioned two cases, however, the importation of considerable quantities of organic matter renders the results nugatory. Straus and Dubarry, indeed, find practically no difference between longevity in potable water and in distilled water, a fact in itself sufficient to arouse suspicion of some obscuring cause. My own experiments leave no doubt of the fact that, when the same typhoid-culture is introduced under the same conditions into ordinary surface-water and into distilled water, the bacilli invariably perish more rapidly in the latter than in the former. The longest duration of vitality in distilled water that I have observed is eighteen days. In this work with distilled water I have used both the method of direct plating and that of adding sterile bouillon to the infected flask, without, however, any difference in outcome. Four months after isolation of the typhoid-culture the mortality in distilled water was very great:

Initial number	2090
After 1 day	197
" 3 days	1
" 6 "	0

Twelve months after isolation the difference between the behavior in tap-water and in distilled water was still manifest:

	Distilled water.	Tap-water.
Initial number . . .	1815	1815
After 7 days	0	1320
" 12 "	0	78

The striking difference between the behavior of the typhoid-bacillus in ordinary potable water and in distilled water led me to search for the cause, as it is clearly important to attack the problem from this side, as well as by experiments under "natural conditions." That the typhoid-bacillus is able to retain its vitality and virulence for a long time in unsterilized water is a point amply established by the history of epidemics, as well as by laboratory-experiments *in vitro*. The latter have so far chiefly been confirmatory of the evidence from epidemiology. The specific conditions of water that favor or hinder infection have remained, however, very obscure.

One conspicuous difference between distilled water and ordinary surface-water lies in the absence of organic nitrogenous matter (organic nitrogen or albuminoid ammonia) from the former. With a view to discovering more precisely what effect organic matter in sterilized water has upon the

[1] Arbeiten aus dem kaiserlichen Gesundsheitsamte, 1847, ii.

[2] Archives de Méd. Expt., 1889, p. 1.

[3] Journal of Pathology and Bacteriology, June, 1893, p. 468.

[4] Frankland, in the tables already spoken of, refers to Braem as asserting that the typhoid-bacillus lives for 188 days in distilled water. This is certainly an error, for Braem explicitly states (Ziegler's Beiträge, 1890, vol. vii, p. 11) that the large numbers of bacilli, and the concomitant food-material, which he found it necessary to use in his experiments, must have influenced materially the longevity. His observations, moreover, were purely microscopic, not cultural, and he expressly disclaims any implication as to the viability of the "tief dunkeln, dicken Stäbchen," which he found "nach 196 Tagen in sehr reichlichen Menge."

typhoid-bacillus the following experiments were undertaken. I hope to supplement them in a short time with similar experiments upon unsterilized waters.

In order to secure uniform conditions, a standard peptone-solution was prepared by dissolving one gram of peptone in 500 c.cm. of redistilled water. In this solution analysis showed that there were present 12.6 parts per 100,000 of organic nitrogen (Kjeldahl method).[1] Accurately measured quantities of the peptone-solution were added by means of graduated pipets to a series of flasks each containing exactly 1000 c.cm. of sterilized distilled water. These were inoculated with typhoid-bacilli in the usual way. The organic nitrogen-content of each flask (parts per 100,000) is indicated by appended decimals:

	Z^1 (0.0126 org.N).	Z^2 (0.0252 org.N).	Z^3 (0.063 org.N).	Z^4 (0.126 org.N).	Z^5 (0.0 org.N).
Initial number	2090	2090	2090	2090	2090
After 1 day .	216	600	880	2585	197
" 3 days .	1	51	175	2100	1
" 6 " .	0	0	13	495	0
" 10 " .	...	...	0	3	
" 17 " .	...	...	...	4	

Other experiments gave in the main confirmatory results, as:

	Z^6 (0.0126).	Z^7 (0.0252).	Z^8 (0.063).	Z^9 (0.126).	Z^{10} (0.252).	Z^{11} (0.0).
Initial number	1925	1925	1925	1925	1925	1925
After 1 day .	935	275	2475	4950	2035	990
" 3 days .	87	26	2035	3300	2365	
" 18 " .	1	0	2	15	468	2

The addition of one or two c.cm. of the standard peptone-solution (0.0126 and 0.0252 organic nitrogen) appears to be in general without effect upon the longevity of the bacilli, although the first experiment that I have recorded showed grades of vitality singularly adjusted to the rising increments of organic matter (*cf.* Z^1–Z^5). There is a slight multiplication of the typhoid-bacilli, when from 5 to 20 c.cm. of the peptone-solution (0.0630–0.252 organic nitrogen) are added, and some experiments even seemed to indicate that with 10 and 20 c.cm. this multiplication might give rise to very large numbers. These latter experiments, however, were complicated by the effects of summer temperature, and I shall pass them by for the present.

Without entering upon a catalog of the large number of experiments of this kind that I have made, it will suffice to state that the results are similar throughout: *the bacilli invariably live longest in those waters containing the largest amount of organic nitrogen.* It is a noteworthy fact that this holds true *even when no appreciable multiplication occurs.* (*Cf., e.g.*, Z^3 with Z^5, and Z^8 with Z^{11}.) This latter interesting circumstance is open to the interpretation either that the lives of individual bacilli are conserved by the presence of the organic matter, which acts as a kind of elixir of life, or that the more hardy bacilli are able to multiply for one or two generations on the slight amount of peptone supplied them, a multiplication that, however, is masked by the mortality occurring among their less resistant companions. For obvious reasons the second explanation seems to me the more plausible.

These results, showing the influence of organic matter upon the longevity of the typhoid-bacilli in distilled water, suggested a similar series with ordinary surface-water. My earliest experiments in this direction demonstrated that a quantity of peptone-solution (1 c.cm. = 0.0126 organic nitrogen) insufficient to affect the longevity in distilled water brought about considerable multiplication in the tap-water, and led to a long-continued persistence of vitality.

	X^1 (0.0126 org. N).	X^2 (0.063 org. N).	X^3 (0.0 org. N).
Initial number .	1,540	1,540	1540
After 1 day . .	1,500	1,925	1650
" 6 days .	ca. 20,000	Countless	935
" 10 " . .	26,730	456,500	364
" 23 " . .	19,800	170,500	18
" 80 " . .	1	0	0

In following up this result an unexpectedly delicate reaction upon the addition of the peptone was observed. The introduction of 0.5 c.cm. and even of 0.1 c.cm. of the peptone-solution (0.0063–0.0012 organic nitrogen) brought about multiplication.

	X^4 (0.0126 org. N).	X^5 (0.0063 org. N).	X^6 (0.0012 org. N).	X^7 (0.0000).
Initial number	605	605	605	605
After 3 days .	6,160	3,190	500	358
" 6 "	ca. 20,000	?	15,000	342
" 9 "	ca. 30,000	15,000	...	288
" 94 "	29	0	0	0

The course of these experiments was broken into by the complication caused by summer temperature, and the inquiry was not resumed until the typhoid-culture was weakened by twelve months of artificial cultivation. The results at this time, however, fully substantiated the earlier conclusions, and, indeed, imparted to them additional emphasis. With this weakened culture no appreciable multiplication was detected, but the addition of 0.0012 part per 100,000 of organic nitrogen was still sufficient to affect the longevity of the bacilli.

	X^8 (0.c).	X^9 (0.0012).	X^{10} (0.0025).
Initial number . .	1815	1815	1815
After 7 days . .	1320	1925	
" 12 " . .	78	...	990
" 15 " . .	0	165	385
" 64 " . .	...	0	2

These experiments demonstrate that the amount of organic nitrogen of a certain kind in a given

[1] This determination was kindly made for me by Mrs. R. H. Richards, of the Massachusetts Institute of Technology.

sterilized water plays an important rôle in lengthening the life of the typhoid-bacillus in that water. In this connection it is interesting to note that Frankland[1] found in his comparative experiments with sterilized Thames water, Loch Katrine water, and deep well-water that the longevity of the typhoid-bacillus is distinctly greatest in the Loch Katrine water, and that this contains the most organic matter. "Not improbably," he says, "these circumstances are connected together." The difference between distilled water and ordinary surface-water, however, shows that other factors, presumably those concerned with the mineral content of the water, may be involved.[2]

The upshot of the experiments recorded in this paper may be stated briefly as follows:

1. The age of the typhoid-stock influences greatly the life of the bacilli introduced into water, a freshly isolated stock possessing distinctly greater vitality than one that has been under cultivation for some months.

2. The typhoid-bacillus, when introduced with proper precautions into sterilized Lake Michigan water, does not multiply, but may, under certain conditions, maintain its vitality for upward of ninety-three days.

3. The colon-bacillus, on the contrary, under similar conditions undergoes rapid multiplication and may remain alive for upward of two-hundred-and-sixty-two days.

4. In redistilled water the typhoid-bacillus perishes much more speedily than in the water of the lake.

5. The quantity of organic matter (peptone) in redistilled water influences fundamentally the life of the typhoid-bacillus; so small an increment as 0.0126 organic nitrogen (parts per 100,000) causing a perceptible lengthening of life.

6. In sterilized lake-water the addition of a still smaller quantity of organic nitrogen—0.0012—affects the longevity of the typhoid-bacilli introduced.

A NEW METHOD OF BANDAGING THE THUMB.[3]

BY JULIUS SELVA, M.D.,
OF BOSTON, MASS.

THE art of bandaging was born with the fathers of medicine, Hippocrates, Galen, Soranus, Glaucus, and other eminent physicians; and although in ancient times bandages were "plainly intended more for parade than use,"[1] yet we must look at those rudimentary appliances as the foundations of our present system of bandaging. The "scapha," or boat-like bandage; the "gallia gladiatoris," or bandage like a gladiator's helmet; the "regium," or bandage like a crown, have all gone into disuse; but from these antique forms were developed, by the process of evolution, in the course of centuries, the more efficient and simpler bandages of modern times.

The essential rules of bandaging remain always the same: a roller is turned around a limb, trunk, or head, either in circular, spiral, reverse, recurrent, or figure-of-8 form.

It is not necessary to emphasize in this paper the great use and importance of bandages, as there is hardly any one operation in surgery practicable without their assistance.

I have devoted much time to the application of bandages during my experience as a surgical interne to the Boston City Hospital and the Children's Hospital, and about a year ago I devised a new method of bandaging the thumb. Before describing this method, an account will be given of the different thumb-bandages that have been used by various authors.

The thumb-bandages that are on record may be classified into four different types: (1) The spiral. (2) The reversed. (3) The spica or figure-of-8. (4) The combination of these forms.

The spiral bandage for the thumb is probably the oldest variety. It is described in the works of Heister,[2] and also in recent times by Gross[3] and others.

Thillaye,[4] Gerdy,[5] Liston,[6] Velpeau,[7] Jamain,[8] Guillernin,[9] Heath,[10] Leonard,[11] Smith,[12] Mears,[13] and others, described later on a bandage of the thumb, which is practically a simple spica of the thumb and wrist. It begins by two circular turns round the wrist. After the last turn, which should be terminated upon its radial side, the head of the roller is to be directed from the external to the internal side of the thumb, passing between this and the index-finger, to return and cross its base, and be carried again about the wrist. These double circulars are repeated to form a spica, till the whole bandage is exhausted. This bandage makes no provision for covering the distal phalanx of the thumb.

Wales'[14] crossed bandage of the thumb is about the same as the preceding ones. It begins by circular turns at the wrist, and then a successive number of spica turns are made to cover in the thumb, forming an *ascending spica*. When the turns are made from the base downward the spica is said to be *descending*. The bandage terminates at the wrist. The end of the thumb is left uncovered.

Hopkins'[15] bandage does not differ from that of Wales.

[1] Loc. cit., p. 251.

[2] The evidence adduced by Frankland (Proc. Roy. Soc., vol. lvi, pp. 225–227) to support the view that typhoid-bacilli can be educated for aquatic life is inadequate. The quantity of organic matter inevitably introduced in such experiments as he has described is, perhaps, sufficient to account for the phenomena that he is inclined to attribute to "a prolonged and gradual training in more and more aqueous culture-media."

[3] Demonstrated before the Boylston Medical Society, March 29, 1895.

Pye's[16] spica of the thumb is begun with a few turns round the wrist from within outward if the outside of the thumb is to be most supported, and in the opposite direction if the ball is the part requiring the firmer pressure.

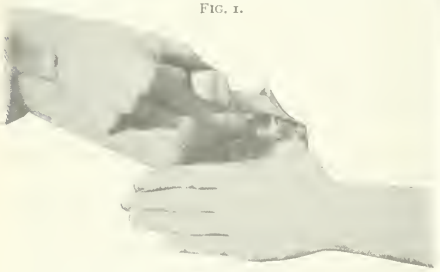
Hill,[17] Hunter,[18] Wyeth,[19] Wharton,[20] and others describe a bandage of a characteristic type. It commences round the wrist, but the first turn is carried at once beyond the last joint, turned once or twice round the last phalanges, then returned by *spiral* turns or spiral reverses to the metacarpo-phalangeal joint, where the ball of the thumb is covered by spica turns round the thumb and wrist, each figure-of-8 *alternating* with a *circular* turn round the wrist. Thus this bandage is a combination of the circular, spiral reverse, and figure-of-8 turns. The end of the distal phalanx is not covered.

In the *American Text-book of Surgery*[21] is described a similar spica of the thumb, which starts at the wrist. According to the figure, it ends at the wrist and does not cover the pulp of the thumb.

The *gauntlet* and *demi-gauntlet* bandages described in ancient and modern text-books are applied to the wrist and finger, and they are not especially adapted to the thumb. No mention is made of thumb-bandages in the classic works of Bell,[22] Castle,[23] Symes,[24] Cooper,[25] Smith (Stephen),[26] Esmarch,[27] Hamilton,[28] Bryant,[29] and others.

Inasmuch as all the bandages that have been used for the thumb are connected with the wrist, their efficiency is more or less impaired by the motions of this joint. Their application presents the following features: (1) They begin at the *wrist.* (2) They end at the *wrist.* (3) The distal phalanx of the thumb is not completely covered. (4) The hand—*i. e.*, the *metacarpus*—does not participate in the bandage.

FIG. 1.

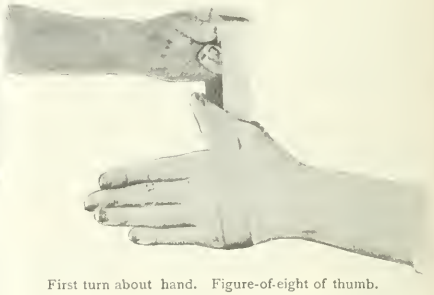


Beginning of bandage—application to abducted thumb.

The new method of bandaging the thumb that I have devised is as follows: The length of the bandage is from 4 to 6 meters and the width from 2½ to 3 centimeters, according to the size of the hand.

Application. The hand is held in a position of semipronation, the thumb pointing upward and being *abducted* at an angle of about 50°, so that the end of the distal phalanx is in line with the heads of the second and fifth metacarpal bones. The first stage of the application of this bandage consists in completely covering the terminal phalanx. The initial end is applied to the outer lateral surface of the second phalanx of the thumb, near its base, and the roller is carried along this surface, over the palmar side of the pulp of the distal phalanx, to

FIG. 2.



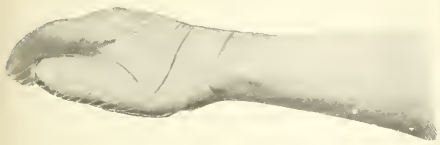
First turn about hand. Figure-of-eight of thumb.

the inner lateral surface of the second phalanx; this turn is held in place by means of the index-finger and thumb of the left hand of the operator, as shown in Fig. 1; then the roller is returned in a *recurrent* form to the place of origin; this last turn should overlap the preceding one, and should be placed in as dorsal a position as possible; then the roller is directed downward and inward over the dorsum of the terminal phalanx and is turned around the very tip of the pulp (Fig. 1), forming a loop that will cross at a point corresponding to the center of the nail. Having thus covered the terminal phalanx, the roller is carried over the dorsum of the hand as low down as the head of the fifth metacarpal bone, the thumb all the time being held *abducted;* it is then turned over the palm of the metacarpus to the dorsal surface of the terminal phalanx, at the point of the first crossing, thus forming a figure-of-8 turn (Fig. 2). This turn can be repeated over itself if the first one is not firm enough for starting. Then a series of successive figure-of-8 turns are made, each overlapping its predecessor and being about half a centimeter apart, forming an *ascending spica;* these turns are carried as high as the carpo-metacarpal articulation, and the bandage is ended by pinning it at the palmar surface of the ball of the thumb, or by splitting and tying it around the metacarpus.

This bandage is essentially a figure-of-8 form, the *smaller* or *lower* loops of which go around the first and second phalanges and part of the ball, and the *larger* or *upper* loops pass and overlap each other around the metacarpus and upper portion of the

ball of the thumb. The bandage can be applied as high as necessary, and in order to completely cover the very highest portion of the ball the lower loops should be applied nearer together, or they can be repeated over themselves at the palmar surface of the base of the second phalanx, whereas the upper loops can be applied successively in an ascending form over the surface of the ball. Of course, if there is no indication, the *recurrent* portion of the bandage may be omitted, in which case the roller is started by one or two circular turns around the *end of the distal phalanx*, and then the rest of the bandage is applied as before. If, after starting, the roller should be directed first over the *palmar* surface of the metacarpus, in making the upper loop, the crossings of the figure-of-8 turns will be situated on the palmar side of the thumb. Fig. 3 shows the thumb-bandage applied.

Fig. 3.



The bandage completely applied.

It will be noticed that these figure-of-8 turns not only overlap themselves, but they also exert an *ascending compression*, which adds strength to the bandage and produces efficient immobilization of the thumb. As these turns are being applied, the thumb, which originally was in a position of *abduction*, is gradually approached to the metacarpus and it becomes more and more *adducted*.

This bandage, unlike the others that have been previously described, does not begin or end at the wrist; it is a bandage that is applied to the phalanges of the thumb and to the metacarpus, and consequently the motions at the wrist-joint do not interfere with the efficiency of the appliance. Provision is made by this bandage for completely covering the terminal phalanx of the thumb.

Uses. 1. To apply dressings to any portion of the thumb, or to the dorsal or palmar surface of the metacarpus.

2. For immobilizing fractures, dislocations, or sprains of the thumb, in which cases the application of strips of sticking-plaster, in the shape of the bandage described, is useful.

3. For the retention of splints.

4. To arrest hemorrhage.

[Note.—In bandaging the arm to the thorax, and the leg to the pelvis I have used a method similar to that described.]

TONGUE-TRACTION AS A CARDIAC STIMULANT.

By H. A. McCALLUM, M.D.,
of London, Ontario,
Professor of Physiology and Lecturer on Clinical Medicine in Western University.

In June, 1892, Dr. J. A. Mullin, of Hamilton, in a discussion on chloroform before the Ontario Medical Association, said that he regarded forcibly pulling on the tongue several times as the most powerful excitor of respiration. I determined to make use of the suggestion at the first opportunity, and the manipulation was, therefore, resorted to in all anesthetic accidents with animals used in the physiologic demonstrations during the following winter sessions.

We soon learned to place considerable confidence in this novel measure. It was about one year thereafter that I first saw the recommendation of "rhythmic tongue-traction" in asphyxia by Laborde, of Paris.

Early last session, after some successful demonstrations of "blood-pressure" on a large dog, the sternum was rapidly cut away and the thoracic organs exposed. After stimulation of the vagus, to note the effect on the exposed mammalian heart, the dog was allowed to die by asphyxia. While my associate Dr. O. Weld (now of Vancouver, B.C.,),

was chloroforming a rabbit, to show the effect on the blood pressure of depressor-nerve stimulation, the class clamored for an exhibition of tongue-traction.

The dead dog was brought into service, the tongue was grasped with an artery-forceps and violent rhythmic traction was practised. The result was a surprise; instead of the diaphragm undergoing the expected rhythmic movements, the apparently dead heart, which was exposed, commenced to beat and underwent vigorous movements for some time. A number of dogs, cats, and rabbits were anesthetized and similarly experimented upon. Drs. Weld, Williams, and Neu were present at some of these experiments, and it was soon determined that tongue-traction is a powerful cardiac stimulant.

In the cat, tongue-traction stimulates diaphragmatic more readily than cardiac movements; in the dog and rabbit the effect is more marked on the heart.

Tongue-traction increases not only the rate of an exposed and failing heart but also the vigor of its contractions. It appeared at first that this method might stimulate the heart by lowering the blood-pressure, through the tissues of the neck acting as a pump on the carotids and aorta, or through inhibition of the vasoconstrictor center. To determine the truth or falsity of this theory some animals were allowed to die of hemorrhage and the effects of tongue-traction noted. The effects on these hearts were, if anything, more marked than in animals dying with cardiac distention.

On some animals both vagi were divided, but the results of tongue-traction on the heart were unaltered. We were therefore led to conclude that its mode of action was on the cardio-accelerating center in the medulla. This view was supported by the fact that, especially in the cat, the respiratory movements were also excited. Marey[1] has made some investigations to determine how tongue-traction stimulated the respiratory movements. He could abolish the results on the diaphragm by cutting either the sensory nerves of the tongue or the phrenics.

Laborde speaks in the most confident terms of the superiority of this method of restoring cases of asphyxia, and I am satisfied it is a method that will succeed, even when other methods fail, because it acts as both a respiratory and cardiac stimulant. It could and should be combined with some good method of artificial respiration in anesthetic accidents, cases of drowning, asphyxia and syncope from any cause.

On several occasions we were able to restore animals by the combined method when we otherwise failed. It is easy to exhaust this effect on the medulla, so that if tongue-traction be practised on the animal before the heart ceases to beat, no amount of traction can restore the contractions when the heart-beat has ceased.

CLINICAL MEMORANDA.

NEPHRECTOMY FOR TUBERCULOSIS OF THE KIDNEY IN A PATIENT ALWAYS A RESIDENT OF COLORADO.

BY WILLIAM S. BAGOT, M.D. (Dublin University), OF DENVER, COL.;
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF DENVER; GYNECOLOGIST TO ST. LUKE'S AND ST. JOSEPH'S HOSPITALS; FORMERLY SENIOR ASSISTANT PHYSICIAN TO THE ROTUNDA LYING-IN HOSPITAL, DUBLIN; FELLOW OF THE BRITISH GYNECOLOGICAL SOCIETY, ETC.

MRS. P., aged twenty-two years, who had been married six months and had had no miscarriages, was sent to me by Dr. James A. Hart, of Colorado Springs. It was learned that her paternal grandfather had died of pulmonary tuberculosis. Her father, a German by descent, began to complain of pulmonary trouble when in his twentieth year, and was sent to Colorado on account of pulmonary tuberculosis nine years afterward. He died at the age of forty-nine years. As far as can be ascertained no other immediate relative has suffered from tuberculosis.

Mrs. P. was born in Colorado. When three years old, she had a severe fall, attended with some injury to the right knee, after which the part remained swollen and inflamed. For seven years her parents consulted physicians without receiving any definite diagnosis or obtaining relief for the condition. At the end of this time they consulted Dr. Sandford, of Colorado Springs, who diagnosticated the trouble as tuberculosis of the knee-joint, and performed the operation of erasion, with a successful result. From that time, her tenth year, the patient remained in apparently perfect health till about Christmas, 1893, when she had an attack of influenza, after which she suffered from some trouble with her bladder and kidneys. For the latter trouble she was treated by Dr. James Hart during February and March, 1894, but soon discontinued treatment, as she felt much relieved. She was married in the following June. In September she began to feel ill and noted frequent urination, with fever, and suffered from severe pain in the region of the right kidney, which radiated up toward the right shoulder and down into the thigh on the same side. She then sent for Dr. Hart, who examined her and found a large tumor in the right hypochondriac and lumbar regions.

On November 81, 1894, I saw the woman in consultation with Dr. Hart and corroborated his opinion that she was suffering from tuberculosis of the kidney. She was then extremely emaciated, being reduced from 160 to about 100 pounds in weight; the evening temperature was 101.5° F., the pulse 116 per minute. A large tumor occupied the right renal region, and a greatly thickened ureter could be felt crossing the brim of the pelvis. Through the vagina the ureter could be felt to be thicker than one's little finger. The urine was loaded with pus. On palpation the left ureter and kidney seemed normal. Examination of the lungs revealed slight consolidation of the right apex.

The patient was admitted to St. Joseph's Hospital on November 24, 1894, her temperature on that evening being 101.5° F. and her pulse 108. She was kept in bed, given a milk-diet and iron (Blaud's pills) in an endeavor to build up her strength, as she was extremely anemic and so weak that I did not think she could stand any operative interference. After six days had elapsed, during which her condition had become, if anything, worse, her evening temperature still reaching 101.6° F., and her pulse 112, I decided to operate. Accordingly, on December 1, 1894, I performed nephrectomy, using ether as the anesthetic.

The kidney was exposed by means of Czerny's incision; then, in order to gain more room, as the organ was very much enlarged, measuring 10 inches by 6 inches, a second incision was made somewhat obliquely from the center of the first downward and forward for about three inches, without opening the peritoneum. On exposing the kidney, the tuberculous process was found to have transgressed the tunica propria and to have invaded the perirenal fat. While enucleating the kidney, which was very adherent in places, it ruptured, and a large quantity of pus escaped. This was at once washed away by flushing the wound with sterilized salt-solution. Before securing the pedicle the ureter, which also was tuberculous and thicker than a little finger, was separated as far down into the pelvis as possible and resected. The renal vessels were then ligated with catgut and the kidney removed. A small rubber drainage-tube was inserted into the proximal end of the ureter and by a suture secured into the lower end of the Czerny incision. The wound was flushed out with sterilized salt-solution and all tuberculous foci in the perirenal fat scraped as thoroughly as possible with a sharp curet. The incisions were then closed with silkworm-gut, leaving sufficient space to pack the cavity with strips of plain sterilized gauze, interspaced with strips of iodoform-gauze (5 per cent.). After this a sterilized gauze dressing was applied.

For the first seventeen hours after the operation the temperature gradually rose from 92.2° F. till it reached 103° F.; *i. e.*, 1.4° higher than it had been the evening before operation. During the next twelve hours it dropped to 100.4° F., this being the highest point reached during the remainder of the convalescence. The temperature became normal on the tenth day. The wound was dressed and the packing renewed on the third day. After this the dressings were renewed every second day, the stitches being removed on the twelfth day. Recovery was somewhat retarded by the appearance from time to time of small tuberculous foci in the wound. These were scraped away with a sharp curet and dusted with flowers of sulphur, which seemed to act better than balsam of Peru or iodoform, both of which I had tried. The patient left the hospital February 3, 1895, a small sinus still existing. When last seen, in June, 1895, this sinus had almost closed; all symptoms had disappeared and weight had increased to 157 pounds.

This case is of interest from the fact that it is, as far as I can learn, the first case of nephrectomy for tuberculosis of the kidney contracted in Colorado.

Dr. L. Galassi, Professor of Special Pathology in the University of Rome, died on August 31st, of a cardiac affection.

LOSS OF CONJUGATE DIVERGENCE, OR PARALYSIS OF EXTERNAL ROTATION OF THE EYES.

BY HOWARD F. HANSELL, M.D.,
OF PHILADELPHIA;
CLINICAL PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE, ETC.

IN a somewhat hasty search through accessible literature I have been unable to find a case analogous to that herewith described. Writers on mental and ocular disease refer briefly to conjugate deviation of the eyes and paralysis of lateral movement as associated conditions in hemiplegia when the lesion has been either determined, or is supposed, to be in the pons, corpus striatum, or optic thalamus, or the cortex of the brain. The case to be reported differs essentially from other cases of conjugate deviation in that, while there was an utter inability to turn either eye outward a single degree beyond the median line, there was no deformity or abnormal turning of either eye—that is, there was no paralysis and no conjugate deviation. Schieff and Adamuk claim that the corpora quadrigemina regulate in part the eye-movements: "Of the posterior pair the right one governs the movement to the right, the left one that to the left. Irritation of both bodies of the same side causes deviation of the eyes to the opposite side of the anterior bodies in the median line upward, and of the posterior downward and inward." Graefe assumes the existence of a separate center for the associated movements to explain "co-ordination-spasm," or co-ordination-paralysis, or a different action of each eye—thus, one up and the other down, a "disjunction of co-ordination."

Dr. F. X. Dercum, under whose care the patient was, and to whom I am indebted for the opportunity to make the ocular examination, has kindly furnished me with his notes.

Cerebellar Disease presenting Unique Ocular Symptoms. A. P., an unmarried young woman, aged seventeen years, presented a negative family history. The patient is the youngest of three children, and was healthy at birth. At the age of six months she was severely ill with scarlet fever and diphtheria, making a "poor recovery." She had a persistent discharge from both ears and numerous abscesses in the glands of the neck. She was under medical attendance almost constantly until she was seven years of age, but improved somewhat at this time. Two years ago she began to menstruate, and since that time has noticed difficulty in walking, first referred to the right leg. When she came under observation the girl presented excessive ataxia in all her movements, and swayed greatly on standing. The muscles generally were weak, but no localized paresis could be detected. The knee-jerks were increased on both sides. There was no tendency to spastic rigidity, and the legs were perfectly flaccid. There was no anesthesia anywhere. The pupils were large and responsive to light. Marked deafness existed, a watch being heard only on contact.

Examination of the ears by Dr. S. MacCuen Smith revealed a perforation of both drums. It was found that the patient was unable to turn the eyes to the right or the left. She could readily fix all objects in the median line; convergence was maintained, and was normal in range. As soon as the object was moved to one or the other side and the girl was requested to look at it,

she utterly failed to direct the axis of either eye toward it. Many attempts were made, so that no misunderstanding could arise, but all were fruitless. There was no diplopia and no squint, either manifest or latent. Conjugate deviation was absent. The eyes were turned neither to the right nor to the left, but steadily maintained a position of parallelism or convergence. None of the muscles was paralyzed; the pupils were equal in size and normal in action; refraction presented a low hyperopia; vision was equal, 20/70; accommodation, 10 D.; exophoria for distance, 2°; abduction, 10°; adduction, 20°; there was no limitation of the fields for white or colors, and no evidence of inflammation; the media were clear and each fundus was normal. The discs showed no peculiarity or sign of previous or present neuritis or papillitis.

Extended observation will be necessary to determine the pathology. The diagnosis lies between hysteria and intracranial disease. If the former is present, no explanation so well fits the case as that offered by Allen Starr[1] of the presence of a lesion, microscopic it is true, in the nerve-cells or fibers, resulting probably from impaired nutrition from an altered condition of the blood or of the bloodvessels, and secondary changes in the excretions. If intracranial disease exists, the location of the lesion is extremely uncertain. The absence of paralysis and the loss of co-ordination point to the cerebellum or to the cerebral cortex as the site of the lesion.

Risien Russell[2] concludes that probably all ocular movements are represented in the cerebral cortex. The ocular effect produced by ablation of part of the cerebellum is paralytic, but whether from the direct influence of the cerebellum on the muscle or indirectly through the loss of the cerebellar influence over the cerebrum is uncertain.

EXCISION OF THE COCCYX FOR CONSTANT PAIN RESULTING FROM AN ununited FRACTURE.[3]

BY LEWIS H. ADLER, JR., M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE RECTUM IN THE PHILADELPHIA POLYCLINIC, ETC.

IN presenting the history of the following case, I by no means do so with the idea of advocating so radical a procedure as an incision in all, or even in the majority, of patients suffering with pain in the region of the coccyx. In the present instance, in which all other means had been tried and proved futile, and in which pain was induced by every movement of the bone, I think that the operation was fully indicated.

The particulars of the case are as follows:

Mrs. A. W., aged forty-three years, was brought to my office February 21, 1895, by Dr. I. Grier Barber, of Danville, Pa. The family history was excellent. The patient had always enjoyed the best of health until six years ago. In December of that year (1889) she slipped and fell on the edge of a board-walk, striking the lower portion of the spine. She was unconscious for a short while. Ecchymosis developed slowly over the region of the sacrum. Extreme pain was experienced and a sensation of something moving when she attempted to stir, which was especially marked in making an effort to sit. The bowels would not move without an enema, and at such times the pain was so severe as to produce faintness. About four months after the accident the woman was hardly able to walk a distance of three or four squares. During all this time she had consulted no physician.

A year-and-a-half after the reception of the injury she was examined under chloroform-anesthesia, and the coccyx was found to be united to the sacrum at a right-angle. The bone was refractured, but the operation was unsuccessful in diminishing the woman's suffering. About this time she lost flesh and had a purulent discharge from the bowel every week or so, the quantity averaging from one to two tablespoonfuls.

For about a year previously to consulting Dr. Barber the patient had been under the care of a physician who had been treating the bowel-trouble with local measures, but without any appreciable relief. Upon consulting Dr. Barber (a week before I saw her), he had Dr. Hoffa and Dr. P. C. Newbaker, both of Danville, examine the patient. As a result of their investigation they wrote me that the rectum was very painful and sensitive, principally at the lower end of the coccyx. A segment of the coccyx about an inch long was quite movable, as though there was an ununited fracture. It was thought possible that the bone might be necrosed and that an internal fistula might exist, but these suppositions could not be confirmed.

Upon making a digital examination of the rectum I found about an inch of the coccyx very freely movable, and the structures overlying the lower portion of the sacrum were adherent to the bone.

On February 22d the patient was etherized, the sphincters were stretched, and a curvilinear incision was made over the sacrum and around one side of the coccyx. The tissues were dissected so as to expose fully the seat of trouble. The upper portion of the fractured end of the coccyx was found to be necrosed, and the entire bone with the exception of the tip was removed.[1] The structures surrounding the bone were denser than usual and were firmly adherent to the coccyx, so much so, in fact, that considerable care was necessary in order to avoid wounding the rectal wall.

A rubber drainage-tube was introduced into the wound and the incision was closed with silkworm-gut sutures. Iodoform was dusted over the part and the usual antiseptic dressing applied. It was necessary to catheterize the patient for some ten days after the operation. On the third day the bowels were moved by the administration of fractional doses of calomel and sodium bicarbonate, followed by a saline. On the fourth day the wound was found to be infected, presumably from contact with fecal matter. The stitches were all removed, as well as the drainage-tube. The wound was washed with a mercuric-chlorid solution (1:2000), followed by a 2 per cent. solution of creolin. The cavity was packed with iodoform-gauze.

On March 4th a sinus full of pus was discovered at

[1] The Western Reserve Medical Journal, May, 1895.
[2] Journal of Physiology, 1894 vol, xii, i.
[3] Read before the Philadelphia County Medical Society.

[1] Dr. H. Augustus Wilson, of this city, first proposed to me the idea of allowing the tip of the coccyx to remain if possible, when excising the body of that bone, for the reason that the muscular and ligamentous attachments thereto maintain their usefulness much better than when the entire bone is removed.

the lower angle of the wound. This was opened freely under local anesthesia induced by ethyl chlorid. From this time on the patient's recovery was uninterrupted though somewhat slow, and she was discharged, practically free from pain, on April 17th. Since then the patient has written to say that she has gained in weight about sixteen pounds.

1610 Arch Street.

HEMATEMESIS IN A CHILD TWO YEARS OLD.

By HENRY M. FISHER, M.D.,
of Philadelphia.

About midnight of August 23, 1895, J. P. began to vomit blood, about "a cupful," at first bright red. The vomiting recurred at intervals of half an hour for two or three hours. At 9 o'clock on the following morning a considerable amount of entirely undigested green corn was ejected, and with it blood-clots and some black liquid blood. When I saw the child, two hours later, he was not markedly prostrated, with a pulse of 120. There was no nasal obstruction, and there were no signs of recent epistaxis. The blood actually vomited had not been saved, but the sheet upon which the child lay was deeply stained, and there were also numerous clots upon it. I ordered a milk-diet, with lime-water, and one-half dram of magnesium sulphate every hour till a free movement of the bowels occurred, and directed the mother to take the child to a hospital in case of recurrence of the hematemesis.

Five days later the parents reported that the magnesium sulphate had caused several black movements, and that there had been no further bloody vomiting.

It seems that the child had partaken freely of green corn and cantaloupe on the evening before the bloody vomiting took place.

BACTERIOLOGIC NOTE.

THE USE OF THE AUTOCLAVE FOR STERILIZING NUTRIENT GELATIN.

By WYATT JOHNSON, M.D., and J. E. LABERGE, M.D.,
of Montreal, Can.

[*From the Laboratory of the Board of Health of the Province of Quebec.*]

An impression seems to exist in many bacteriologic laboratories that the sterilization of nutrient gelatin by means of the autoclave is impracticable, owing to the tendency of this medium to lose its power of setting firmly when exposed to a temperature above the boiling-point of water. Our experience has shown the contrary to be the case, and the results obtained by a single sterilization in the autoclave have been fully as satisfactory as those obtained by fractional sterilization at 100° C. on successive days, so that we now employ the autoclave by preference to avoid delay and uncertainty. The steam-pressure employed is 3/4 of one atmosphere (equal to 115° C.), saturated steam for fifteen minutes, after the gelatin has been filtered and filled into tubes.

In a series of comparative tests in which half of the nutrient medium was prepared by fractional sterilization in an Arnold sterilizer, that prepared in the autoclave was equally transparent, retained the desired degree of alkalinity (usually 2 per cent. acid to phenolphthalein), and remained firm in plates or roll-tubes at a temperature of from 24° to 25° C. In no case have we had any spontaneous growth in the tubes after this sterilization.

We claim no priority for these observations, as the autoclave at 105° C. seems to have been employed for some years in several French laboratories for sterilizing gelatin,[1] though this fact does not appear to have become as generally known as it might be. In the laboratory of the Board of Health of the Province of Quebec attention was first attracted by the fact that some gelatin, sterilized in the autoclave through a mistake, retained its power of setting. In our experience a temperature of 105° C. has not always been sufficient to insure perfect sterilization.

With reference to the temperature we employ, it may be well to mention that the test-tubes and small bottles which we use are made of very thick glass, so that the heat penetrates slowly. In working with thinner ones a lower pressure or a shorter time may be found to give the best result. We have employed gelatin giving a firm jelly, as considerable difference exists between the different brands in respect to their melting-points.

MEDICAL PROGRESS.

Tubercle of the Optic Thalamus with Intention-tremor and Tetanoid Rigidity.—Edwards (*Lancet*, No. 3753, p. 260) has reported the case of a boy, six years old, who seven weeks before coming under observation was noticed to drag his right leg in walking. Two or three days later it was observed that in taking food the child held his spoon in the left hand, and upon his mother insisting upon the use of the right hand for that purpose this latter began to tremble. The trembling was at first slight, but gradually grew more marked. For three weeks there had been severe frontal headache and for four days vomiting. For a short time vision seemed to be impaired. The tremor in the right arm was a coarse and jerky movement, disappearing entirely when the arm was at rest. The movements came largely from the shoulder. There was no nystagmus or syllabic speech. The right arm and leg were distinctly weaker than the left. There was no facial paralysis. There was well-marked ankle-clonus on the right side, but none on the left. The wrist-jerks, as well as the epigastric, abdominal, cremasteric, and plantar reflexes were alike on both sides. There was marked rigidity on passive movement of the right knee-joint. The patient had difficulty in standing unsupported, but not increased by closing the eyes; nor was there any sign of reeling in one or other direction. With assistance he was able to walk and the gait was distinctly ataxic. Sensation was universally normal. The functions of the bladder and rectum were normal. The vomiting was controlled upon the administration of bismuth, but the headache persisted. While under observation well-marked optic neuritis developed in the left eye. There appeared to be also inflammation of the right nerve, but the observation was interfered with by a conjunctivitis, with slight clouding of the cornea, and concomitant blepharospasm. The other cranial nerves

[1] See Thoinot: Précis de Microbie, p. 83.

appeared to be normal. Toward the close of the ophthalmoscopic examination, which was somewhat prolonged, the patient was suddenly seized with an attack of tetanoid rigidity. He became unconscious, with the head bent back, the spine arched, and the whole body extremely rigid, the teeth clenched, and the eyes turned to the right. The face preserved its natural color. This condition persisted for about three minutes, when the muscles gradually relaxed and there was a return to complete consciousness. No clonic contractions followed. It was now learned that the child had had three similar attacks the night before. Large doses of potassium iodid were administered, in conjunction with mercurial inunction. At a later date three more attacks of tetanoid rigidity occurred, the patient falling asleep, worn out, after each. On awaking he moaned constantly and complained of his head. On another occasion five attacks occurred in rapid succession, and upon the following day death ensued. At the post-mortem examination, held sixteen hours after death, rigidity was very marked. The skull-cap was normal; the membranes were congested, but did not show any signs of inflammation. A distinct, firm tumor could be felt on the left side of the brain. On opening the left lateral ventricle in the usual way a very considerable quantity of clear, serous fluid gushed out. There was no excess of fluid in the right lateral ventricle. The tumor was about the size of a large walnut and was found to be situated in the left optic thalamus. A vertico-transverse section through the tumor and the left cerebral hemisphere showed that the growth was pressing on the left internal capsule. The floor of the fourth ventricle presented no signs of pressure, and sections through the medulla and the upper cervical region of the cord appeared normal. Microscopic examination of the growth showed it to be undoubtedly tuberculous.

Acute Rheumatism in the Sequence of Tattooing.—WILLIAMS (*British Medical Journal*, No. 1800, p. 1440) has reported the case of a militiaman, seventeen years old, who, three days after an extensive tattooing of the left forearm, complained of pain, swelling, and tenderness of the left wrist. A day later acute left-sided pneumonia developed, but rapidly subsided. The left shoulder, knee, and ankle were successively involved in the inflammation, and a cardiac bruit developed. Finally, chorea appeared as a complication, limited for a time to the left side, but shortly spreading to the right, where rheumatic inflammation was attacking the joints. The last, however, quickly subsided, leaving a general though mild chorea and a permanently damaged heart.

THERAPEUTIC NOTES.

The Treatment of Malignant Neoplasms with the Toxin of Erysipelas.—CZERNY (*Münchener medicinische Wochenschrift*, 1895, No. 36, p. 833) cites two cases of carcinoma in which a favorable influence was exerted by an intercurrent attack of erysipelas, and four cases of sarcoma in which a similar result was brought about by injections of the toxin of erysipelas. The following conclusions are offered: Injections of sterilized, but not filtered, mixed cultures of the streptococcus erysipelatosus and the bacillus prodigiosus induce rapid elevation of temperature, often with rigor, gastric disturbance, fulness in the head, and delirium; sometimes with labial herpes, and almost always without local inflammatory manifestations. The intensity of the reaction varies with the individual, the amount of toxin injected, and as to whether the fluid enters the interstitial tissues or the bloodvessels. These manifestations subside in the course of a few hours without permanent disturbance of the general condition. Frequently repeated injections are followed by loss of appetite, emaciation, anemia, and general apathy. The injections are capable of exerting a specific influence upon the sarcomatous growths, and under favorable circumstances may lead to recovery. The neoplasms become saturated with serum and then disintegrate and are absorbed, or soften, with necrosis and exfoliation. As the result in the individual case is uncertain, this mode of treatment cannot replace the operative method or render this superfluous. It is, therefore, for the present indicated only in cases of inoperable or recurrent neoplasms. It is possible that the method may be useful after operations for sarcoma, to prevent recurrence. In cases of carcinoma the injections appear at most to retard the growth of the tumor, but not to lead to recovery.

Apolysin is the name given by NENCKI and JAWORSKI (*Allg. med. Centr.-Ztg.*, No. 60–62; *Centr. für die ges. Ther.*, Sept. 1895, p. 528) to a new antipyretic and analgesic belonging in the same chemic group as phenacetin. The substance appears as a whitish-yellow, crystalline powder, of slightly acid taste, of feeble odor, difficult of solution in cold but readily soluble in hot water, and melting at 72° C. It is also soluble in alcohol and in glycerin. The drug was employed in a wide range of cases, in doses of from 7½ to 22½ grains, up to 45 grains daily. In febrile cases it acts as an antithermic, the decline of temperature being attended with the disappearance of other symptoms, especially pain. In cases of neuralgia it acted as an anodyne, diminishing the hyperesthesia, shortening the duration of the individual attack, and often causing disappearance of the symptoms. The action of the drug was rapid and certain and was unattended with unpleasant effects. Its use is contraindicated when the stomach is empty and when secretory hyperacidity is present.

The Treatment of Whooping-cough.—ULLMANN (*Jahrb. f. Kinderheilk.*, B. 40, H. 1; *Centr. f. ges. Ther.*, Sept. 1895, p. 560) undertook to determine the influence of the treatment in the open air of children suffering with whooping-cough, as compared with treatment indoors. In one case the interval between the attacks of coughing averaged one-and-a-half hours in the open air and forty-eight minutes indoors. In another case the child coughed one-and-a-half times and in a third two-and-three-fourths times oftener indoors than out. In a further case observed for nineteen days it was found that the cough was twice as frequent during the day indoors as out-of-doors, and nearly as frequent during the day out-of-doors as during the night in well-ventilated apartments. Other good effects of the treatment out-of-doors were observed in the less intensity of the attacks, the improvement of appetite, the infrequency of vomiting, and the betterment in the general condition.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

CONCERNING SPECIALISM.

WE have lately been treated in numerous articles to criticisms of specialism in medicine, varying from placid censure of its most obtrusive extremes to violent denunciation of the very fact itself and of all its important illustrators. At first we were inclined to sing in chorus. The recent hypertrophy of specialism, the outrageous extremes to which certain exponents have driven it, especially in America, with our orifacialists, graduated tenotomists, female castrationists, ossicle-excisionists, and all the rest, have always loomed big before our eyes. Assent would therefore be an easy task, especially when the impertinent exaggeration of morbid extremists seems to delight in thrusting itself upon the attention, and insulting all sense of self-control with examples of manifest evil. It may, however, very properly be asked if there is no good to be extracted even out of things most woful. All evil has its uses—at least for purposes of warning.

The first and most obvious answer to the critics—we mean the critics *sans phrase*, the *delendo est Carthago* fellows—of specialism is that the contempt poured upon the greatest extremists does not apply to the vast majority of specialists. It is unjust to single out the maniacal hobby-riders and sneer *ex uno disce omnes*. All are not alike. The hobby-riders are few and exceptional; the preponderant majority do not deserve the strictures and are not affected by them. It is sheer nonsense to say that the great body of specialists know nothing of general diseases, that "a man who looks only into the ear cannot see far into the nose," that "they who view female life through the vagina will have little respect for the stomach," that the surgeon will cut rather than cure, and that for stricture of the rectum the oculist will apply glasses or snip eye-tendons. The people who say such things are cantankerous, and try to say sharp things instead of true things. Argument by epigram may be amusing, but, like government by epigram, it ends nowhere or worse than nowhere. The makers of *mots* never say the truth, only the error they impale. Their desire is not to instruct or to be honest, but to make people say, "How smart!" But if they wished to be truthful instead of supercilious, careful instead of captious, they would take special examples or at least types of extremism and pour upon them the vials or larger vessels of justifiable wrath, and not rain it upon the just and the unjust alike, thereby in themselves logically and literally illustrating the very indiscrimination of which they so bitterly complain in others.

The *tu quoque* argument is usually a weak one, but in the present contention it is exceptionally strong and convincing. There is not a specialist in the land but sees every day instances of mistaken diagnosis (and hence of treatment) upon the part of the general physician. What oculist, from examination of the eyes alone, has not pointed out to the general physician the existence of hitherto unsuspected nephritis or circulatory disease? The aurist is constantly emphasizing the facts of ear-disease as a cause or medium of communication of septic cerebral disease, or as a result of respiratory abnormalism. The daily rehearsal of tragedies in the specialist's office, plainly due to errors in diagnosis of the general physician, is pitiable. "My doctor told me my headaches were due to congestion and anemia, and never to let any oculist meddle with my eyes;" "he didn't tell me to have my teeth looked after;" "he didn't examine my urine, although I've had pain in the back for a year;" "he didn't examine my sputum, although I've had a hacking cough for a long time," etc., etc. We do not mean, nor do we think, that the general phy-

sician makes more errors than the specialist; we mean that the specialist is not the only medical sinner. It is our conviction that the average specialist is as much alive to the symptoms and importance of systemic disease as is the average general physician, and certainly no one would deny that he is also as much alive to the abnormalisms of special organs *other than those of his specialty*. We sharply emphasize the word *average* as applied to both classes. A recent diatribe against specialism tirelessly reiterates that the present-day variety is empiric. The charge is, of course, too true of all medicine, but to say that is particularly true of specialism rather than of general practice is topsy-turveyism and squarely opposed to a proper reading of the facts. What is the very stronghold of empiricism, what the enemy that the most extreme specialism is heroically fighting to carry by storm —what but general therapeutics?

But if, as vehemently averred, the specialist is the superficial empiricist and faddist, why does the general physician not annihilate him? Why, instead of annihilation, does he encourage the ever-increasing custom of sending the specialist his patients to treat for their special diseases? The specialist's fate lies at the disposal of the family physician. Without reference-cases the specialist would soon languish and die his supposably deserved death. A homely saw says, "The proof of the pudding is in the eating." Is it not plain that the family physician is learning that the specialist has his uses, that he has special ability and excellence gained by special application and experience, and that in our day of the infinite division of function and profundity of research he must often be called in to supplement the general therapeutist? Has the family physician not learned by bitter experience that never again can one mind encompass more than a small fraction of the knowable, and that his duty to his patient is henceforth to learn where and of what nature is the root of the evil, and, beyond a certain range of ailments, he must advise consultation with the specialist?

There still linger about the fringes of our scientific world some wonderful specimens of an antediluvian age, strange stranded relics of megalosaurean vanity, or of slimy avarice—the quacks—we mean those within the profession—who "treat all diseases," they who "turn no patient out of their own office." Heaven help them—or, rather, help their patients! In the meantime, heaven not helping, the "empiric" specialist must patch up the bungler's work as best he may after the "all-round man" has finished with his ignorance and mistakes. It is simply maudlin nonsense to contend that any one mind can longer compass or master all branches of medical science. It is painfully evident that any one specialty demands the most devoted application of the very best mental ability and training in order to keep abreast of the giant-progress of the time. The inevitable and ruthless march of scientific progress has divided and will continue to divide the practice of medicine into departments or specialties. There are undoubtedly unfortunate aspects and results of this subdivision of work; they are most glaring as well in other sciences as in medical science, but the law, *divide et impera*, is as predestined and inobviable as gravitation, and to rail at it is utter fatuousness. It is wiser to guide it rightly and utilize it shrewdly.

All critics say the specialist should enter upon special work only after thorough training in general medicine, and that is true; but it goes without saying, and in its final analysis it means that the schools must give a far more thorough grounding in general medical essentials than they do. If it means that every person must practise general medicine for ten years before taking up a specialty —then there is something to say on both sides of the question. We are unable to see how the delivery of a thousand women or the treatment of five hundred cases of typhoid fever can much help one to be a better aurist, or bacteriologist, or ophthalmologist. It is easy to demand much of the young physician, ambitious, short-lived (*ars longa, vita brevis*), and eager to be at his real life-work. He certainly should be consulted a little about it all. The advice savors a little of the old maxim about learning to swim without going near the water, or in another aspect it looks like advising an *experimentum in corpore vili;* but mistakes in specialty-practice are hardly more expensive than those in general practice. We are not advising the young graduate to plunge into a specialty at once; we are contending for the due weighing of circumstances, ability, training, and all that.

And what does one mean by specialism? Where will one draw the line? Should every family physician be also a surgeon? Assuredly not! It is simply impossible. It is to-day truer than ever that no man can serve two masters, much less a dozen

or two. Should every physician rely upon his own judgment as to refraction? Should he treat obscure aural diseases? Should he be his own bacteriologist? Not in any case if he have a particle of modesty, or honesty, or interest in his patient's health.

Beyond all question and despite all abuses, the rise of specialism has been the condition of medical progress. How many thousands, nay millions, of people are there to-day blessed with ocular health and ability to carry on the duties of civilization by reason of the work of Graefe, Helmholtz, Donders, and their followers. Would any of the discoveries in ophthalmology and their applications have been made without the specialist? What has revolutionized surgery but specialism? What is now revolutionizing all medicine but the work of the specialist in bacteriology? Has there been a single great discovery in modern medicine that is not the work of the specialist, or of men who, if living, would to-day be specialists? Is specialism not the absolute *sine qua non* of promised discovery in the future?

Finally, mark it well, the family physician is now quite as much a specialist as anybody else, and this whole pother of discussion is a mere meaningless war of words and misunderstandings. The general physician does not treat more diseases, perhaps even less, than the physician who confines himself to a single organ. In the progress or process of subdivision the generalist has become the veriest specialist. Moreover, almost every disease has or may have its effects upon every special organ, and no specialist who ignores general diseases, and diseases of other organs, will henceforth be able to hold "the pace" set for him by his broader-minded and more comprehensive rivals. Thus the evils of specialism—evils that we acknowledge and deplore—are in a fair way of curing themselves. The way as advised by high authorities should not be backward, but on through! Specialists will not, cannot renounce their peculiar work, and become general physicians; science and humanity cry out against such an absurdity; and the way through is the right way. The specialist is already becoming the general physician in the sense that he knows the limits of his own knowledge, and does not try to do what he cannot do, but advises consultation with those who can and who do know. This also the specialist family-physician is fast learning, and so he is broadening also into general practice, and no longer puts "drugs of which he knows little into a body of which he knows less, for a disease of which he knows nothing."

Theoretically the essence of the controversy and of the whole matter consists in the attainment of the vantage-ground of accurate knowledge of at least one organ, and of the diseases of that organ. From this standpoint one cannot worse but better survey the whole field of medicine.

But the practical lesson of it all is that every one —*i. e.*, every "specialist"—shall learn to confine himself to the work he is competent to do, and beyond that to advise consultation with others more competent to treat certain organs or diseases; and the advice to consult the specialist family-physician has been, is, and will remain that very frequently given by his co-worker in other specialties.

EDITORIAL COMMENTS.

The Culture-test in Diphtheria and the Question of Quarantine.—The examination of the throats of persons convalescent from diphtheria has revealed the presence of the Klebs-Loeffler bacillus even as late as three months after all clinical manifestations of the disease had ceased. In the majority of cases studied the bacilli have been found virulent up to the fourth week of the disease. Not only in persons who have just recovered from an attack of diphtheria, but also in the throats of nurses and caretakers virulent bacilli have been discovered in the absence of the least symptom of disease.

Hitherto it has been the custom in Philadelphia among officials who have to do with contagious diseases to fumigate the premises of persons suffering with diphtheria as soon as the attending physician pronounced the patient able to leave his room, and the physician usually allowed this when the membrane had disappeared from the throat and the individual seemed in good health. The placard was removed forty-eight hours after fumigation, and though children were kept out of school for two weeks longer, they were allowed to mingle freely with their comrades and relations.

Since the inauguration of bacteriologic laboratories and the use of culture-tests, fumigation has been delayed in such cases in which cultures have been made, until the bacilli are no longer found; the placard is left for the same period of time, and the patient is confined to the house and isolated from the other children.

In a large, roomy house, with garden-space, prolonged confinement of a healthy child can hardly be considered a hardship, either for the individual or his family; but for the poorer classes, who occupy seldom more than three rooms, and whose families are usually large, isolation for a period of from four to six weeks is not only difficult of execution, but is also a very serious matter for the little patient. Yet just here the quarantine is most needed, because the street is the playground of the poorer children, the contact with playmates is close, and children are numerous. It is difficult to make the parents understand that the danger is not yet over when

the child seems to be in a perfectly healthy condition, and they will be less rigid in maintaining a quarantine.

Unfortunately but a small number of the cases of diphtheria that occur in a city are submitted to the culture-test; and as the Board of Health of Philadelphia at least accepts the attending physician's statement that the house is ready for fumigation, the children of one family may be allowed to leave the house two weeks earlier than the children of another family, living, perhaps, in adjoining houses, simply because no cultures were made in the one case and were made in the other.

The neighborhood will soon discover that the first doctor dismisses his cases much sooner than the second, and will, of course, sound his praises above the other. The children of the former will be able to attend school two weeks earlier than those of the latter, the new rule or Act of Assembly simply stating that a period of thirty days shall elapse "after the discharge by recovery or death of the person last afflicted" and "the thorough disinfection of the premises," and as disinfection of the premises does not occur in culture-cases until the bacilli have disappeared, the thirty days date from the end of such time.

The intent of the law evidently was to exclude all cases until the danger of infection was past; if by bacterial examination the danger is proved to be over, then surely the purpose of the law is fulfilled and the child should be allowed to enter upon his school-duties.

The proper thing to do, it seems to us, would be to require the culture-test in all cases, and to refuse to raise the quarantine until the bacilli are no longer found present.

This would put the matter on a scientific basis, and would not allow those physicians who make use of the test to be placed at a disadvantage for doing so. If this were carried out, the accommodations at the Municipal Hospital would probably have to be increased, as more children would be sent there, owing to the impossibility of effective isolation in private houses for so long a time, whereas at the hospital the convalescent children have the use of the grounds and porches, and therefore do not suffer because of their confinement.

In the therapeutics of diphtheria much attention will in future have to be paid to expelling the bacilli in as short a period of time as possible. In the July and August numbers of the *American Journal of the Medical Sciences* Dr. F. H. Williams reports the results of investigations in this direction, and claims to be able to cause the bacilli to disappear from the throat on or before the nineteenth day of the disease. The antitoxin-treatment has not as yet been shown to have any direct influence in shortening the time of residence of the bacilli, although the membrane usually disappears earlier with its use. The bacilli persist after the membrane has left, and they may be present without the formation of membrane.

In justice, therefore, to the community, to the patient, and to the doctor, we repeat that the Health-Inspector should require a culture-test in every case before raising the quarantine; otherwise those who make use of this test will be unfairly discriminated against. Apartments occupied by diphtheria-patients could be disinfected and fumigated as heretofore, but the placard should remain and isolation continue until the bacteria can no longer be detected.

As Others See Us.—It is not given to any but rare and beautiful minds to speak such delightful words of his own profession as those uttered by DR. C. ELLERY STEDMAN, of Dorchester, Mass., in his altogether admirable address to the Norfolk District Medical Society last June, and published in the *Boston Medical and Surgical Journal* of August 22d. The way we are looked at by the public, "the People with a large P," the taunts, deserved and undeserved, we have to bear, the answers we might or should make thereto—these things are touched upon with a combination of wit and pathos, a hand as light and yet as firm as that of the Autocrat's own. We had almost expressed the thought, or the wish, why does he not take up the Autocrat's function? For example, is not this a gem?

"One of our best men, whom all of us respect and many of us love, was called to a young woman in one of his families, and to his vast surprise found the maiden—whom he had known from her birth—in the throes of a miscarriage. After scolding briskly for some minutes, he proceeded to relieve her of her chorionic encumbrances. As he worked red-handed an aunt came in, and rising to the situation, exclaimed, 'So you *are* in the business after all.' The rage of the good-hearted and honorable man may be fancied. He now devotes himself to the infernal gods if he ever attends a woman in that trouble again; and if he finds himself caught at the bedside, he abandons the case."

We regret that we cannot quote the whole address. These are the closing words:

"I believe there are none whose work is of better quality or more conscientiously done than that of the general practitioner, who represents the body of the profession. It ill becomes those whom they serve, to doubt their capacity or to depreciate their work. The doctor may scold, he may even swear when he turns out of his warm bed of a cold night; but he turns out, he plods or drives through the snow and the mud and the cold—too often for no other remuneration than the glow of satisfaction if a knotty diagnosis be cleared up, or if remedies have steered Nature into a safe port. All over the world are men in laboratories, in the dead-house, in the hospitals, in the hovel, striving to wrest her secrets from Nature, satisfied if, after days and nights of toil, they may elucidate one point—forge one link in the chain of evidence that shall establish a truth or expose an error. They live among the dead and dying, in an atmosphere charged with disease and death; and, as Dr. Holmes says, 'They have tasks to perform which the chambermaid and the stable-boy would shrink from undertaking.'

"Yes, we are ignorant; but it is not because the way to knowledge is closed or unfrequented. The old roads are thronged with travellers; and new ones are opened every day, in which one timidly steps at first, another enters and goes farther on the path, more join them, and soon there is a crowd which thickens and presses on. Nature hides her jewels deep; and we must sweat and dig and bore and wash before she will yield her treasure. Much can be told of what has been done, but that is just the line of thought which we avoid to-day.

"To sum up—needless though it be to say it to this company—let us reflect that it is easy to give offence even when we least intend it; that even on the low ground of self-interest we prosper when we keep to the straight path; that in dealing with those not of our own communion, whatever they may do, no one of us can afford for one moment to forget that he is a gentleman. If we are told we do not know much, we confess it with shame and confusion of face; but we know as much, if not more, than those whom we pay for working for us.

We do our best work when no one is watching us; and—thank God!—ours is the only profession that at any time does its work for nothing."

Yale University Medical School.—In commenting upon the subject of medical education in the United States in THE NEWS of August 31st, p. 246, we took occasion to say that Yale University was one of the four-year medical schools. We find, however, that we rested under a misapprehension. The corporation has lengthened the medical course to four years, but the change will not take effect until the fall of 1896; in the meantime this year's matriculants may graduate in 1898. The explanation given by the dean for the existing state of affairs is that the corporation of the University could not be assembled in time to take action on the recommendation of the medical faculty to extend the course at once to four years. The reason given seems to us quite inadequate and will not at all redound to the credit of the school. If a university of the standing of Yale allows a mere technicality to stand in the way of higher medical education, how can smaller schools be blamed for holding back.

"Cellular Altruism" and "Physiologic History."—For these suggestive and appropriate terms we are indebted to Professor S. H. Gage, of Cornell University, who used them first in his exceptionally able address as President of the American Microscopic Society (*Science*, August 23, 1895). We elsewhere reproduce a few scattered selections from the paper, regretting that want of space prevents us from producing it entire. From a veteran and practical physiologist and microscopist such clear statements show plainly the fast-changing attitude of science as to the more recondite problems of life. With Lombroso acknowledging his defeat, and a "degenerate" follower giving it the *coup de grace* by a personal *reductio ad absurdum*, we trust the anatomic and materialistic position of psuedo-science has reached its inevitable end, and that henceforth physiology and pure induction may be the order of the day.

SELECTION.

"PHYSIOLOGIC HISTORY" AND "CELLULAR ALTRUISM."

THERE is another fact in Nature that the microscope has revealed, and that fills the contemplative mind with wonder, and an aspiration to see a little further into the living substance, and so perchance discover the hidden springs of action. This fact may be called *cellular altruism*. In human society the philanthropist and soldier are ready at any time to sacrifice themselves for the race or the nation. With the animals the guards of the flock or herd are equally ready to die in its defence.

. . . . . .

Into the veins of the *necturus* was injected some lampblack mixed with water, a little gum-arabic, and ordinary salt, an entirely non-poisonous mixture. Thousands of particles of carbon were thus introduced into the blood, and could be seen circulating with it through the transparent gills. True to their duty, the white corpuscles in a day or two engulfed the carbon particles, but for several days more the leukocytes could be seen circulating with the bloodstream, and carrying their load of coal with them. Gradually the carbon-laden corpuscles disappeared, and only the ordinary carbon-free ones remained. Where had the carbon been left? Had it been simply deposited somewhere in the system? The tissues were fixed and serial sections made. The natural pigment was bleached with hydrogen dioxid, so that if any carbon was present it would show umistakably. With the exception of the spleen, no carbon appeared in the tissues, but in many places the carbon-laden leukocytes were found. In mucous cavities and on mucous surfaces, and on the surface of the skin, were many of them; in the walls of organs were many more apparently on their way to the surface with the load—that is, the carbon is naturally carried out of the tissues upon the free surfaces of the skin and muous membranes, where, being outside of the body, it could no more interfere in any way with it. But what was the fate of the leukocytes that carried the lampblack out of the tissues? They carry their load out and free the body, but they themselves perish. They sacrifice themselves for the rest of the body as surely as ever did soldier or philanthropist for the betterment or the preservation of the State.

. . . . . .

In brief, it seems to me that the present state of physical and physiological knowledge warrants the assumption, the working-hypothesis, that life is a form of energy different from those considered in the domain of physics and chemistry. This form of energy is the last to appear upon our planet, last because more conditions were necessary for its manifestations. It, like the other forms of energy, requires a material vehicle through which to act, but the results produced by it are vastly more complex. Like the other energies of Nature, it does not act alone. It acts with the energies of the physicist, but as the master; and under its influence the manifestations pass infinitely beyond the point where for the ordinary energies of Nature it is written "thus far and no further."

It can be stated without fear of refutation that every physiological investigation shows with accumulating emphasis that the manifestations of living matter are not explicable with only the forces of dead matter, and the more profound the knowledge of the investigator the more certain is the testimony that the life-energy is not a mere name. And, strange to say, the physicist and chemist are most emphatic in declaring that life is an energy outside their domain.

. . . . . .

The sure way, it seems to me, is the study of structure and function together; the function or activity serving as a clue and stimulus to the investigator for finding the mechanism through which function is manifested, and thus give due significance to structural details which, without the hint from the function, might pass unnoticed.

This kind of microscopical study, it seems to me, may be well designated as Physiological History. It is in sharp contrast with ordinary histology, in which too often the investigator knows nothing of the age, state of digestion, or of fasting, nervous activity, rest or exhaustion. Indeed, in many cases it is a source of congratulation if he knows even the name of the animal from which the tissue is derived. Such haphazard observation has not in the past, and is not likely in the

future, to lead to splendid results. If structure, as I most firmly believe, is the material expression of function, and the sole purpose of the structure is to form the vehicle of some physiological action, then the structure can be truly understood only when studied in action or fixed and studied in the various phases of action.

Indeed, if one looks only for form or morphology in the study of histology, the very pith and marrow is more likely to be lost.

[Professor Simon Henry Gage, Presidential Address, American Microscopic Society.—*Science*, August 23, 1895.]

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held in Detroit, September 3, 4, 5, and 6, 1895.

(Continued from page 336.)

DR. GEORGE W. CALE, of St. Louis, read a paper entitled

TWO SUCCESSFUL OPERATIONS FOR TRAUMATIC INSANITY.

He pointed out that insanity due to injuries of the head is of rather infrequent occurrence. In 2200 cases of insanity treated by Kiernan, 45 were of traumatic origin; while Hays records 61 due to the same cause out of 2500 cases. Schläger reports 500 cases of insanity due to concussion of the brain.

The case was reported of a carpenter, twenty-six years of age, with a good family history. No case of insanity or of serious nervous disease had ever been present in the family. In June, 1885, the patient received a blow from a club in the hands of a negro, the wound inflicted being midway between the fissure of Rolando and the external occipital protuberance, slightly to the left of the median line. It was treated as an ordinary scalp-wound, as it suppurated for three months. Four years after the inception of the wound the man complained of severe pain in the left parietal and occipital regions. In October, 1888, he was sent to an insane-asylum, where he remained sixteen months. His condition improved, he returned home, but he was again sent back to the asylum, where he was detained for five months. Four months later he was brought to Dr. Cale, who diagnosticated traumatic insanity, and advised operation, which was consented to. Recovery ensued.

The second case was one of acute mania following a trauma. In this also operation was performed and recovery ensued.

DR. WILLIAM FULLER, of Grand Rapids, Mich., related that he had operated in two cases of insanity due to traumatism, one in Montreal in 1870, after the patient had been discharged from an insane-asylum as incurable. When the dura mater was opened some serum escaped. A few days subsequent to the operation the patient was rational, but as soon as the wound closed the hallucinations returned. The brain was then punctured in two or three different directions, but with no result except to establish drainage. The man died two months later, and a post-mortem examination revealed a tuberculous abscess in the fissure of Sylvius containing about two teaspoonfuls of pus. The other case was due to syphilis, and was relieved by the removal of pressure due to that disease.

DR. J. FRANK, of Chicago, reported an interesting case of insanity in which he trephined, removing a large piece of bone. A piece of the brain, excised for examination, seemed to be healthy. The patient, after being in an insane-asylum for five years, made a complete recovery and took up the thread of life where she had left it. She continued in this way for one year, then relapsed. What was the reason of her recovery? In opening the dura there was a gush of cerebral fluid. Dr. Frank firmly believes that it is not the depression of the skull that produces the bad results, but that at the time of the injury there is a chronic inflammation of the meninges, or a slow inflammatory process, which throws out cerebral fluid. This fluid may be in the ventricles between the dura and the brain or in the tissues of the brain itself, and the theory of concussion held by the profession Dr. Frank believes to be erroneous. He has repeatedly made experiments on dogs by rapping them on the head and rendering them insensible, and immediately thereafter effusion was found.

DR. MAAS, of Detroit, stated that we are in the dark as to the exact cause of the insanity in many cases, and that there is evidently some vasomotor disturbance.

DR. F. MAAS, of Detroit, read a paper, which was largely a statistical one, in which he pointed out the comparative value of the medical and surgical treatment of appendicitis.

DR. WILLIAM E. WIRT, of Cleveland, read a paper on

THE USE OF DRY HEAT OF HIGH TEMPERATURE IN THE TREATMENT OF JOINT DISEASES.

He cited a case of rheumatoid arthritis in which he resorted to this method of treatment. Great improvement in the motion of the joint and in the comfort felt by the patient followed. He also reported a case of rheumatism of a year's standing in which there was more or less fixation. He broke up the adhesions, made use of dry heat at a high temperature, up to 290°, and increased ease with which the patient could move the joint and relief of pain followed.

DR. CARTER S. COLE, of New York, read a paper entitled

ULCERS OF THE LEG; ALL CAN BE CURED.

Constitutional conditions that favor morbid states, or that return to a healthy state, should receive proper treatment, whether or not ulcers exist. For systematic purposes ulcers of the leg were designated, according to their appearance, as healthy, irritable, indolent, etc. In intractable cases thorough washing with soap and water and good scrubbing with a stiff bristle bairbrush were conceded first place. If the ulcer be inflamed, irritable, or painful, anesthesia may be required for this and subsequent steps. The next step is a thorough cleaning out of all soft granulations and the base of the ulcer with a sharp curet. The edges of the ulcer are freed from their attachment, and in many cases with a curved sharp bistoury the circumference is nicked at intervals of about one-quarter of an inch. If much hemorrhage follows, a pad of gauze wrung out of a 2 per cent. solution of carbolic acid is placed over the wound and a firm compressive bandage applied from the toes to the knee, the wound

having previously been thoroughly cleansed with the carbolic solution. The dressing, when used, is allowed to remain for twenty-four or forty-eight hours, after which the ulcer will have become a simple one, and be amenable to treatment as follows: No further lotion is used. The wound is wiped with dry cotton, and over and completely covering it are placed strips of diachylon-plaster to protect the ulcer. Over the surgeon's plaster is applied a pad of sterilized gauze, held in place by strips of rubber adhesive plaster, or often simply by a bandage. Then a firm muslin bandage is applied from the toes to the knee, making equable compression. Bandaging should be carefully done. Sometimes two bandages three inches wide and eight yards long are used. The bandage is not removed unless it becomes loose or saturated with the discharge, or the leg becomes painful. In redressing the ulcer dry absorbent cotton is again used to cleanse the wound, and the steps detailed are repeated. Often after two or three dressings the bandage may remain from five to seven days without being disturbed. In some cases a thin scum forms on the ulcer, which must be removed by going over the surface lightly with a curet. With this treatment, in ordinary cases, about three weeks will suffice for the cure of an ulcer of even a dozen years' standing. In extraordinary cases as long as six weeks may be necessary.

Dr. Eugene Fuller, of New York, read a paper entitled

HOW TO DIAGNOSTICATE SEXUAL DERANGEMENTS IN THE MALE.

He dwelt on the fact that in the majority of instances sexual derangements in the male are caused by pathologic processes in or about the seminal vesicles, and, further, that they accomplish their results by interfering with the mechanism of ejaculation. He called attention also to the fact that this side of the question has been almost wholly neglected by preceding writers on sexual disorders, who have devoted themselves largely to psychologic causes in this connection, the result being that the great majority of the profession associate sexual disturbances with some radical mental defect. Sexual derangements in the male should be diagnostically arranged in four classes: (1) Those dependent on seminal vesiculitis. (2) Those dependent on neuroses. (3) Those dependent upon primary mental disease or degeneration. (4) Those dependent on general malnutrition and debility. The order of this classification corresponds to the frequency with which these different forms of disease are encountered in practice.

When seminal vesiculitis exists there is generally a previous history of urethral or vesical inflammation, sexual abuse, and the like, all of which are agents tending to produce localized inflammation in the seminal vesicles.

The causes of the second class either inhibit or excite the sexual center by means of reflex nervous action.

The third class of causes includes the different forms of paranoia, in which the sexual sense exists in a perverted form.

The fourth class of causes is a small one. It includes individuals, generally young or middle-aged, who make complaint that they are capable of little sexual exertion, and that feelings of prostration and exhaustion result whenever coitus is attempted.

Reference was made to the different appearances that the varying grades of seminal vesiculitis present to the sense of touch, and attention was directed to the fact that in cases of extensive perivesiculitis involving both sacs an inexperienced examiner is liable to err in diagnosis, mistaking the condition for hypertrophy or inflammation of the prostate. It was pointed out that to become perfected in the feel of the seminal vesicles the finger needs as much practice as does that of the gynecologist in palpating the ovaries and tubes. To obtain the necessary practice the genito-urinary surgeon was advised to examine habitually in this manner every male case coming into the clinic until all normal and pathologic conditions can be fully appreciated.

Dr. S. P. Collings, of Hot Springs, Ark., read a paper on

CHRONIC SEMINAL VESICULITIS WITH HEMORRHAGE.

He said that the usual cause of this trouble is the extension of gonorrheal inflammation from the prostatic urethra through the ejaculatory duct into the vesicle itself; at least there is usually a history of a former gonorrhea, with a chronic deep urethral trouble remaining. The vesicles are sometimes involved in very acute and severe gonorrheal inflammation, with or without the implication of the cord and epididymis. They may also be involved in tuberculous inflammation, although practically never primarily. A case has been reported in which after death the vesicle was found to be primarily involved. The most important symptom is the disturbance of the sexual function. The character and appearance of the seminal fluid are more or less changed. Its consistency is so increased at times that it is gelatinous. The diagnosis of subacute or chronic seminal vesiculitis would be difficult were dependence placed entirely upon the symptoms in reaching a conclusion. They are vague and, at times, misleading, except the appearance of blood in the seminal fluid, which, if thoroughly admixed, would at once indicate a diseased condition of one or both vesicles. It was recommended that if inflammation of the vesicles occurs in one whose urethra is strictured, the stricture must be cured before hope can be entertained of permanent results in vesical treatment.

Dr. C. T. Drennen, of Hot Springs, Ark., read a paper on

SYPHILIS AND ITS TREATMENT.

He spoke of the treatment of this disease in connection with the use and abuse of certain so-called antisyphilitic remedies. He said that from the most recent researches it is not possible as yet to form definite conclusions as to the usefulness of sero-therapy in the treatment of syphilis. But the reports are quite encouraging, and there is hardly a doubt that it possesses value in at least the tertiary lesions. Fournier believes the good effect to be due not to any specific, but to its rehabilitating influence upon the system.

It was pointed out that the hot water at Hot Springs was well known to exert an influence peculiar in its effect for good, and this resort constituted therefore a veritable Mecca for syphilitics; that the action of the water is eliminative, stimulating, and antiseptic, and that larger doses of mercury and potassium iodid can be given without harm, have been demonstrated by experience

and observation; that its exact or specific action is unknown, and that its value is attested to by the multiplied thousands throughout the country are propositions that are incontrovertible.

DR. WILLIAM T. BELFIELD, of Chicago, described and presented an instrument for the purpose of securing asepsis in operations upon the bladder and prostate.

DR. THOMAS H. MANLEY, of New York, read a paper entitled

THE ELEMENT OF VASCULAR COMPRESSION IN FRACTURE-TREATMENT.

He stated that the extent of damage borne by the vessels in a given case of fracture will primarily depend upon the degree and quality of force applied and the line of treatment adopted. In a series of experiments made during the past year on the blood and blood-vessels, under a multiplicity of conditions, in the lower animals under anesthetics, one question that Dr. Manley took pains to determine definitely was whether, as a general rule, the circulation of the distal part of the limb was retarded in cases of fracture. Without entering into detail as to the great diversity of vascular phenomena observed in a frog's webbing under the microscope after single, multiple, and compound fractures were produced, it will suffice to say that with but few exceptions, immediately and for a considerable period of time after the bone was broken, the circulation in the capillaries and the smaller arteries was completely arrested. In several it was found that for several days all of the smaller vessels were motionless, and in a few they so remained until the fractured ends of the bones united. These experiments were extended to the mammalia—the shafts of the limbs of pups, kittens, and adult dogs, of different ages and of various sizes.

DR. H. O. PANTZER, of Indianapolis, Ind., read a paper entitled

THE SIGNIFICANCE OF FISSURE-FRACTURES OF THE ARTICULAR ENDS OF THE LONG BONES.

He reported a case of fissure-fracture involving the outer third of the head of the radius, having loose attachments to its body. Excessive callus had developed without effecting union. The splinter and the callus were removed, when reposition of the joint was easily attained. The crepitus felt at the first examination and the failure to find it again, it was thought, should have suggested fissure-fracture. When the first dressing was removed, the limb seemed to present a perfect condition and to promise full restoration. These prospects were changed as soon as passive and active mobilization was begun. The probability is that the attempts at mobilization for this kind of injury were made too soon, and that they were at least partially responsible for the subsequent unfavorable developments. The conclusion was reached that when undue painfulness and subsequent swelling, with no gain or even a loss of mobility, attend the efforts of mobilization after kindred lesions, further efforts at mobilization should be deferred. The possibility of a fissure-fracture should be considered in determining the diagnosis and treatment of all cases of joint-injury.

DR. E. W. ANDREWS, of Chicago, contributed a paper entitled

IMBRICATION OR LAP-JOINT METHOD—A PLASTIC OPERATION FOR HERNIA.

He maintained that the principle of imbrication or overlapping the several aponeurotic layers of the abdominal wall may also enter into other abdominal operations to advantage. The present paper referred only to its use in inguinal hernia. Here it is to be employed to supplement and reinforce existing methods, without losing sight of their good qualities. While based upon the best modern, open method, and while confessedly an outgrowth of experiences with the Macewen, Bassini, Halsted, and similar operations, yet the carrying out of the imbrication-idea so far changes the technic as to make it as different from them all as they are from each other.

The interlocking or overlapping principle of uniting the musculo-aponeurotic layers of the abdomen has been an outgrowth of clinical experience with Dr. Andrews rather than of theory. He adopted it at first as an expedient in cases in which the Bassini operation seemed difficult and needed supplementing, but of late the value of the principle had seemed to him more and more evident, and he had used it in all his cases. The following conclusions were presented: Any successful method of radical cure of hernia must be a true plastic operation upon the musculo-aponeurotic layers of the abdominal wall. Cicatricial tissue and peritoneal exudates are of no permanent value; a large, strong flap is needed, of sufficient size to fill the internal ring, together with triplicate layers of aponeuroses; interlocking of the layers, giving broad surfaces of union; shortening of the anterior as well as the posterior wall of the canal, making them mutually supporting, and relieving tension on deep sutures; and ample protection of the cord.

DR. CHARLES A. L. REED, of Cincinnati, read a paper entitled

FURTHER OBSERVATIONS ON THE RADICAL CURE OF RUPTURE BY THE INTRAPELVIC METHOD, WITH ILLUSTRATIVE CASES.

The method described differs from the several methods of radical operation now in vogue; differs, in the first instance, in the fact that it is intrapelvic, while the others—Bassini's, Halsted's, McBurney's, Macewen's—are extrapelvic.

The essential point of differences between Dr. Reed's operation and that of Bassini's consists (1) in leaving undisturbed the extremely tense fascia composing the anterior wall of the ring; (2) in leaving the cord in the position that Nature designed for it, entirely protected by the normal fascia; (3) in closing the internal ring on the inside of the pelvis and in protecting it by a strong peritoneal pad; (4) in avoiding the menace to virility arising from a transplantation of the cord, its possible constriction by an artificial ring of tense fascia, and its necessary investment by an inflammatory exudate; (5) in increasing the resistance of the parts by fortifying the fascia comprising the anterior wall of the ring, and by increasing and making permanent the obliquity of the cord within its normal canal.

The advantages of the operation consist in securing, by the unfolding of the redundant but attenuated median fascia, the formation of a column that, when consoli-

dated by inflammatory adhesions, has a certain retentive and supportive power, the influence of which is of value in preventing recurrence. The anchorage of the recti in the median line destroys the retentive power of the wall.

DR. HENRY O. MARCY, of Boston, followed with a paper entitled

SURGICAL TREATMENT OF HEMORRHOIDS.

This paper was in the nature of a reply to the strictures cast upon the Whitehead operation by Dr. Edmund W. Andrews, of Chicago, in a paper read before the Illinois State Medical Society. Dr. Marcy believes that if, in the statistics given by Dr. Andrews, the names of the operators were mentioned, most of the disastrous results would be found to have followed the work of incompetent men. His results have been excellent in those cases in which he has performed the Whitehead operation, slightly modified by himself.

DR. JOHN RIDLON, of Chicago, read a paper on

CLUB-FOOT,

which he defined as a distortion of the foot in its relation to the leg. The simple and compound varieties of club-foot were dealt with. Nearly all of the congenital cases present the compound variety—equino-varus; a few present equino-valgus; rarely there is seen a simple calcaneus. Of simple equinus Dr. Ridlon had met with but a single instance, and of simple varus and simple valgus he had seen none. Of the acquired variety, simple equinus is by far the most frequently found; next in frequency is simple valgus, then equino-varus, calcaneo-valgus, equino-valgus, simple varus, and varus in one foot and valgus in the other. The acquired deformity occurs more than three times as frequently as the congenital form. The etiology of the congenital forms was next dealt with, as well as that of the acquired forms. Then followed the symptoms, diagnosis, and prognosis.

The treatment of club-foot is mechanical or operative, or both mechanical and operative. Both these measures were dealt with at length.

DR. E. E. TULL, of New York, read a paper on

VAGINAL CASTRATION,

in which he claimed for this method a lower mortality, a shorter convalescence, and a wider adaptability, as it may be employed in cases too weak for abdominal section.

DR. F. G. GRONER, of Grand Rapids, Michigan, read a paper entitled

A NEW PHASE OF CELIOTOMY.

He related a suit for malpractice which had just been terminated in Grand Rapids. The suit was commenced against a doctor some time ago, and was for $50,000. The defendant died, but the court held that the cause of action survived, and that the suit could be brought against the estate. The jury returned a verdict for $10,000. It was contended that there was no malpractice, and fault was found with the laws that permitted a suit against a doctor to survive his death, and be a menace to his widow and children. It was thought a remedy should be provided by the Legislature.

DR. J. FRANK, of Chicago, read a paper entitled

RESULTS OF FIVE YEARS' EXPERIENCE WITH INTRA-ABDOMINAL SHORTENING OF THE ROUND LIGAMENTS.

He related that since November, 1889, he had had the opportunity of performing this operation seventeen times, with only one failure, and without any deaths. In these cases the operation was performed for retroversion, prolapsus, and retroversion with prolapsus of the uterus.

The median incision is made a trifle lower than in ordinary celiotomy. The round ligament is caught up anteriorly with a sharp or a blunt hook, and is then held taut by an assistant. A small, full-curved needle threaded with fine silk is then passed through the loop of the round ligament and is brought back in the reverse manner through the other half of the loop. No portion of the broad ligament is included in any of the sutures. Too much stress cannot be placed upon this particular procedure of passing the needle through a part of the cord and not around it, for in passing the needle around the cord there is danger of strangulation, as the blood-supply and the nerve-supply would be thus entirely shut off.

About fifty per cent. of the cases have remained under observation since the time of operation, which, in some instances, has been as long as two years, and in all of these the uterus retains its corrected position. This operation should be performed in preference to any other in all cases in which the uterus is prolapsed or immediately falls back upon replacing it with a uterine sound, and in which pessaries and tampons afford no relief, clearly showing that there must be some force that does not permit the uterus to remain in its normal position.

DR. THEODORE A. MCGRAW, of Detroit, delivered the Address on Surgery. He selected for his subject

THE PRESENT STATE OF OUR KNOWLEDGE OF CARCINOMATA AND OTHER TUMORS.

He said that a comparison of the ideas that prevailed relative to these diseases thirty years ago with those the profession holds to-day would show a change that marks rather a clearer view of the nature of the problem than any actual gain in its solution. Before Virchow the subject of tumors and carcinomata was wrapped in greatest confusion. Tumors were divided and classified in that era according to their clinical histories. They were divided into the innocent, which were looked upon as purely local, and the malignant, which were regarded as due to dyscrasiæ, the seat of which is in the blood. Under the influence of the new cellular pathology faith in so-called dyscrasiæ was abandoned and supplanted by a new doctrine, which taught that tumors and carcinomata resulted ever and always from aberrations in cellular nutrition, development and growth. It may be said that during this time the energies of the profession, as far as tumors are concerned, have been confined almost solely to this channel. The most successful attempt to account for the origin of tumors and carcinomata was that of Cohnheim.

The arguments offered in defence of the parasitic theory of carcinomata are (1) the microscopic evidence; (2) the frequent occurrence of auto-inoculation, and the evidently infectious course of the disease in the human

body; (3) the endemic occurrence of carcinomata in certain localities, and in rare instances in the same houses; (4) occasional successful inoculation of the disease in animals. The arguments against it are the many instances of hereditary tendency; the general failure of experiments of inoculation, and the fact that metastases occur, not through the transfer from one point to another of parasitic germs, as is usual in parasitic diseases, but by the transmigration of cells bearing the same characters as the cells of the original tumor, and the subsequent proliferation of the migrating cells; the fact that not only carcinomata but tumors of all kinds have a greater or less tendency to produce metastases; the tendency exhibited by embryonic remains and histoid tumors to become malignant.

Dr. McGraw closed by saying that physicians should be better instructed in the means of diagnosis and in the necessity of early operative treatment. And last, but not least, the laity could be induced to assist, not only by liberal contributions of means, but by that intelligent co-operation which would lessen the difficulty of collecting evidence and making post-mortem examinations and keeping the sufferers out of the hands of the quacks.

(To be concluded.)

AMERICAN ORTHOPEDIC ASSOCIATION.

Ninth Annual Meeting, Held in Chicago, September 17, 18, and 19, 1895.

THE Society was called to order by the President, DR. JOHN RIDLON, of Chicago.

After the transaction of some routine business, the President delivered his address. He selected for his subject

THE GROWTH AND PROSPERITY OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

He said, if one thing more than another had been instrumental in bringing about the present healthful organization, it was a wisely framed Constitution and By-Laws and a strict adherence to their requirements. To become a member the candidate must be personally known by at least two members of the Association, who voluntarily nominate him for membership, and he must have a creditable record of orthopedic work either as a writer, a teacher, or a clinician.

The generous expenditure of practically the entire income of the Association in the annual publication of its volume of *Transactions* has played no unimportant a part in the development of the Society. In this regard there was urged upon the members the serious consideration of the publication of a monthly or, at least, a bi-monthly journal, which shall contain all the papers read and discussions held before the Association and abstracts of all other worthy publications upon orthopedic subjects, whether first appearing here or abroad. Such a journal could be issued at little, if any, increase upon the cost of the present *Transactions*, and in the hands of an enterprising editor could within a year or two be made almost self-supporting.

The address was closed with a tribute to the memory of Drs. Little and Detmold.

DRS. R. W. LOVETT and JOHN DANE, of Boston, contributed a joint paper entitled

FLAT FOOT.

They submitted the following conclusions: 1. That the feet of the infant at birth are not flat; that a tracing made at that time resembles that of the normal adult foot. 2. That a body of fat develops under the arch which gives the appearance of flat foot for some years, and that at the age of four or five years this is absorbed. 3. That the carbon-tracing is not a perfect method of studying abnormalities of the arch of the foot, because it fails to detect the slighter abnormalities or to record pronation. 4. That the element of pronation is more constant than breaking down of the arch of the foot and may be entirely separated from the latter. 5. That the condition of pronated foot without breaking down of the arch of the foot should be recognized and not confused with flat foot. 6. That the treatment of pronated and of flat foot is the same, and consists in the use of proper boots, the application of a pad or plate, the stretching of the gastrocnemius muscle when it is shortened, and in the routine use of massage, and always of exercises to develop the muscles that hold up the arch.

DR. S. L. MCCURDY, of Pittsburg, read a paper on

CONGENITAL ABSENCE OF THE RADII, WITH OPERATION.

He detailed the case of an infant five months old, born at full term after a normal presentation, presenting complete absence of the radii, with abnormal relationship between the bloodvessels and the soft structures of the forearm. Otherwise the child was perfectly developed. Operative interference was at first not advised, for the reason that no successful method had been invented. In the worst cases, in which there is much bony deficiency, the choice lies between amputation and doing nothing. Bardenheuer two years ago proposed a new method for the operative treatment of these deformities. His operation on the forearm consisted in replacing the defect at its lower part with bone, and thereby permanently correcting the deformed position of the hand.

By a longitudinal incision the distal end of the ulna and the carpus are exposed, and the first isolated from its attachments. The ulna is then split through its middle into a radial and an ulnar section. These are separated by allowing the carpal bones to come up between them. By means of a nail passed through each side the ends are fixed to the carpus. A plaster bandage is applied, and left on for four or five weeks. This operation is easily carried out. It has been performed by Bardenheuer three times, and the results in each instance were good, from both a functional and a cosmetic point of view. In all, the deformity was permanently corrected. The same principles may be adopted in the treatment of other defects. In cases of congenital defects of the tibia or fibula the same operation has been performed once for each variety. The best result was obtained with the fibular defect. In the case reported, operation was eventually undertaken, the desire being to adhere to the method described as nearly as possible. It was not possible, however, to follow the method. The soft structures, tendons, etc., were so much shortened that to attempt to shift the end of the ulna across to the center of the carpus would have been impossible except by a virtual amputation of the arm. To have split the ulna and wire the carpal bones between these ends

would have been impossible. The only method was to sever the ulna at a point where the free end of the upper fragment could be brought to the semilunar bone. The semilunar was curetted and drilled, and after drilling the ulna the two bones were adjusted with silkworm-gut. It was necessary to divide the tendons upon the radial side of the forearm before the hand could be straightened. A number of arteries were severed and required ligation. The cut through the soft tissues was made obliquely across the forearm, beginning upon the dorsum of the wrist and passing upward and around under the forearm, the object being to allow the structures to slide upon each other. These were then sutured in the corrected position, thus avoiding the gap that would otherwise have been left after a cross-section. After dressings were applied the hand was put up in plaster-of-Paris. The wound healed by primary union. The operation was first performed on the left hand, and a second operation was planned for the right arm, but the patient died from pulmonary tuberculosis five months afterward.

A case was also reported of congenital deformity, with a decided history of a maternal impression. A woman, whose husband was a railroad-conductor, was startled, when about six weeks pregnant, by the appearance of a crowd of men carrying on a stretcher a man, whom she thought was her husband. She had a habit when startled or in grief of grasping the fingers of the left hand, including the thumb just below the knuckles, with the right hand. While the injured man was not her husband, the impression was imparted to her unborn child, and manifested itself in the peculiar attitude of the hand.

DR. A. M. PHELPS, of New York, reported a case of congenital dislocation of the shoulder-joint, and described an operation for its relief.

DR. JAMES E. MOORE, of Minneapolis, read a paper on

REMOVAL OF THE ASTRAGALUS FOR TALIPES VALGUS.

He said that the modern non-operative treatment of talipes valgus was so satisfactory that it is rarely necessary to consider operative measures. In acquired flat foot, several operations have been tried in extreme cases, and among them Ogston's, which has probably been performed more frequently than any other, although at present it does not seem to have any enthusiastic advocates. The scaphoid has been removed, but the operation has not been followed by flattering results. The case was reported of a woman, twenty years of age, who had cut the internal lateral ligament of the ankle when she was a child by stepping on a piece of glass. An examination showed that the uninjured foot manifested a natural tendency toward flat foot, and the injured member showed extreme flat foot, with the inner side of the great toe turned almost directly downward. The condition had grown gradually worse for some years, so that when the patient came under observation she had been obliged to give up her employment as a domestic on account of the severe pain produced by standing or walking. Chloroform was administered, with the hope of forcibly correcting the deformity. Owing to the extreme rigidity of the foot, failure was feared; so the patient's consent was gained to resort to a cutting-operation if it should be necessary. It was found impossible to overcome the deformity by manual force, and an operation was decided upon. The displaced astragalus formed the bulk of the deformity, and was the keynote of the trouble. This was removed through a longitudinal incision on the inner side of the foot, which could be immediately placed in a very satisfactory position. The usual surgical dressing was applied, and the foot held in proper position by a plaster-of-Paris bandage. The healing was prompt and satisfactory, and in about two months the patient began to walk. Marked improvement in the position of the foot followed. About one year after the patient began to walk the ankle, which was atrophied, had developed considerably. The result of the operation was more satisfactory from a practical than from an esthetic point of view. The patient still complains of some pain. When she stands much or walks more than usual the foot is somewhat swollen in the evening, but she is now at work. While she is in every way better than before the operation the result is not perfect, but it is hoped that eventually she will be quite well.

DR. JOEL E. GOLDTHWAIT, of Boston, read a paper entitled

TENDON-TRANSPLANTATION IN THE TREATMENT OF DEFORMITIES RESULTING FROM INFANTILE PARALYSIS.

Attention was called to the possibility of furnishing better mechanical attachments for certain non-paralyzed or only partially paralyzed muscles as a part of the treatment of infantile paralysis. A certain number of cases were reported with results that were most gratifying, and from which it appears not unreasonable to class tendon-transplantation with tenotomy and the other surgical procedures that have a place in the treatment of this condition. At the knee undoubtedly tendon-transplantation can be employed to advantage in a certain limited number of cases, and possibly at some of the other articulations, although the best results are to be looked for in those portions of the body where the tendons are well formed and lie superficially. The operation is not to be attempted upon the tendons of muscles that are wholly paralyzed, except possibly in rare instances, for the purpose of furnishing additional support of a purely tendinous character. It is conceivable that in the foot, for instance, if the tendons on the inner side are more atrophied and offer less resistance than those on the outer side, these tendons might be attached to the inner side, and thus increase the lateral support. This is merely a suggestion, however, not having been tried practically, and the benefit to be derived therefrom would undoubtedly be slight. There is also a question as to whether or not two atrophied tendons would unite firmly, although from watching the other cases it is doubtful if there would be any trouble on this account.

The best results from tendon-transplantation are to be obtained in cases in which one group of muscles has been destroyed, leaving the antagonizing or accessory muscles very little, if at all, impaired. Such a condition results in a definite deformity, which becomes more marked as age increases. The best illustration of this is to be found in the condition so commonly seen in the

foot when the gastrocnemius and the muscles at the inner side of the foot have been destroyed, the peroneal muscles retaining their normal contractility. The result is a valgus which constantly increases, both from the muscular contraction and from the faulty mechanical position in which the weight of the body must be received upon the foot in walking or in standing. The same result is also seen in connection with the anterior muscles of the foot; the anterior tibial and the extensor pollicis so often being destroyed, the peroneus tertius and the extensor communis digitorum are the only muscles left for flexing the foot at the ankle. This also results in a valgus which steadily increases.

To correct these mechanical conditions and to use the non-paralyzed muscles to the best advantage, Dr. Goldthwait has operated upon four cases, providing new attachments for the tendons of the muscles.

The first case was in a young woman, nineteen years of age, who complained of trouble in the left foot. When nine months old she became paralyzed, the palsy partially clearing up, and leaving the foot very weak, so that walking had always been difficult. The difficulty had been growing worse and there had been considerable pain referred to the inner side of the foot under the inner malleolus. The left leg was an inch shorter than the right. There was marked atrophy of the left calf, and the foot was in the position of extreme calcaneo-valgus. In walking the weight was borne upon the inner edge of the heel, the anterior portion of the foot being turned outward at an angle of fully 40° with the normal axis of the ankle-joint. The posterior muscles were all paralyzed with the exception of the peroneus longus and brevis, and the tendons of these muscles, instead of lying in the groove behind the external malleolus, had been drawn forward, so that they rested on the outer surface of the malleolus near its anterior edge. With the tendons in this position, the action of the muscles caused extreme valgus and slight flexion at the ankle, instead of extension, as should be the case. The anterior muscles were practically normal, and, having no posterior muscles to antagonize them, their contraction caused such extreme flexion that the dorsum of the foot rested against the anterior surface of the leg.

An oblique incision four inches long was made, so that it crossed the tendo Achillis about an inch above its insertion into the os calcis. Through this wound the peroneal tendons were exposed and divided at the lower edge of the malleolus. The tendo Achillis was then freed and the tendon of the peroneus brevis passed under this and attached to the tendon of the flexor longus pollicis. The tendon of the peroneus longus was then attached to the tendo Achillis, after which the wound was closed and a plaster-of-Paris bandage applied, holding the foot extended in order to relieve the strain as much as possible from the sutured tendons. One month later a valgus-plate was applied, and this has been worn since.

The method of attaching the tendons to each other is of great importance, and unless they are firmly joined the benefit of the operation is lost. The tendon to which the attachment is to be made is split and the end of the severed tendon is drawn through this slit, and securely held by two quilted sutures, which are so placed that when tightened the outer tendon is spread out, furnishing a broad surface for union. In the case reported the valgus has largely been corrected, and what remains is controlled by the plate, so that the tread of the foot in walking is quite normal. As a fair test of the result the patient has during the last five months been doing general housework and has suffered no inconvenience from the foot.

DR. ROYAL WHITMAN, of New York, read a paper entitled

A STUDY OF THE WEAK FOOT WITH REFERENCE TO ITS CAUSES, ITS DIAGNOSIS, AND ITS CURE; WITH AN ANALYSIS OF ONE-THOUSAND CASES OF SO-CALLED FLAT FOOT.

He emphasized the importance of looking on the foot as a mechanism, and on the flat foot not as a deformity only, but rather as a weak or disabled machine. Attention was called to the fact that the normal foot is not only a support, but also a lever. If this activity or leverage be diseased or lost, the foot will be subjected to great mechanical disadvantage. Particular stress was laid upon the component elements which made up the weak or flat foot. These are (1) the improper distribution of the weight upon the foot because of the pronation or valgus; (2) the displacement of the line of strain by the abduction of the foot; and (3) secondary lowering of the arch.

The various predisposing and exciting causes of weakness were enumerated. The importance of the early recognition of the weakness and of the training of children, in order that future disability might be avoided; the importance of the proper shoe, in both childhood and adult life; and the treatment for the various grades of weakness and deformity were then discussed and illustrated by diagrams and casts.

In conclusion, the following points were emphasized: Flat-foot, in its surgical sense, is a compound deformity, of which the elements of valgus and abduction, the improper distribution of the weight and strain, are of vastly greater importance than the depth of the arch. The weak and flat foot can be cured, but only by the application of the simple principles that any mechanic would apply to a disabled machine whose structure and use were known to him; in other words, there can be no permanent cure of weakness and deformity unless normal function is regained, nor effective treatment unless it has this end in view. The term weak foot has at least this advantage, that it implies nothing that the student must unlearn; it is because of the misapplication and misapprehension of flat foot, and because of the associations that have so long obscured the rational treatment of the deformity, that the term is to be discarded.

DR. L. A. WEIGEL, of Rochester, N. Y., contributed a paper on

METATARSALGIA.

DR. ROSWELL PARK, of Buffalo, N. Y., read a paper on

THE DEFORMITIES AND MALFORMATIONS RESULTING FROM ACUTE INFECTIONS IN BONE.

He said that clinically there are three locations in which bone-infections are most commonly met with—beneath the periosteum, in the epiphyses, and in the diaphyses. From the pathologic side infections are of four main varieties: (1) tuberculous; (2) staphylococcous; (3) streptococcous; (4) pneumococcous. To these may be added rare instances in which other

organisms are primarily or secondarily present. Of these, certainly the more common is the tuberculous form, whose manifestations are usually not acute. The other three may be grouped in a general way as pyogenic forms of invasion in which pus is practically invariably produced, providing that only sufficient time have elapsed. Allusion was made to the acute miliary tuberculosis of bone that corresponds in most essentials with similar invasion of the lungs. This variety is not quite so rapid in course as the pyogenic forms, and it may take two or three weeks to produce such destruction of the bone as to necessitate operation. It stands, therefore, in an intermediate position between the acute infections and the slower (usually the tuberculous) lesions. Nevertheless, it is sufficiently acute to demand prompt recognition, and when recognized it may often be relieved by prompt operative interference. The course of a bone-disease will depend first upon the location of the lesion, and secondly upon its character. In 30 cases observed by Kocher the disease occurred 13 times in the tibia and 11 in the femur. In 98 cases collected by Leucke and Volkmann the femur was involved 36 times, the tibia 34, and the humerus 11. Disease in the immediate neighborhood of the hip-joint is about five times as common as in that of the knee. Comparing epiphyses with diaphyses, and accepting Schede's 67 cases, it is found that of 28 cases in which the femur was involved, in half the disease was in the shaft and half in the diaphysis. Of 27 cases in which the tibia was involved only 9 concerned the epiphysis, and of 7 cases in which the humerus suffered 2 involved the epiphysis.

Necrosis concerns orthopedists mainly in that in many instances it produces a weakening of the bone that may lead to fracture, deformity, or curvature. Dr. Park has observed spontaneous fractures of necrotic bone; in one case a necrotic femur broke as he was lifting the patient upon the operating-table. Incidentally there is danger of carcinoma in some of these cases. Volkmann has collected 32 cases in which old and fistulous passages became the site of epitheliomatous changes, and in which carcinoma was the final result.

(To be concluded.)

NEWS ITEMS.

The Vermont State Medical Society will hold its eighty-second annual meeting at Burlington, October 10 and 11, 1895. The program includes the following communications: Obituary of S. T. Brooks, M.D., by H. S. Browne, St. Johnsbury. Our Profession, by W. D. Huntington, Rochester; discussion, F. D. Robertson, St. Albans. Address in Medicine (Vice-President's Address), by F. F. Chaffee, Hartford; discussion, H. R. Wilder, Swanton. Cholelithiasis, by E. H. Martin, Middlebury; discussion, L. W. Hubbard, Lyndon. Intestinal Indigestion: its Dietetic and Rational Treatment, by William H. Porter, New York City; discussion, J. H. Jackson, Barre. Cases of Tuberculosis Treated with Tuberculin and Antiphthisin, by L. M. Greene, Bethel; discussion, J. S. Richmond, Windsor. Diabetes Mellitus, by F. C. Morgan, Felchville; discussion, G. E. Lane, Ludlow. President's Annual Address, J. H. Linsley, Burlington. Subject: Some Suggestions Concerning the Examination of Blood; discussion, J. H. Jackson, Barre; A. P. Grinnell, Burlington; and E. W. Shipman, Vergennes. Address in State Medicine, by C. S. Caverly, Rutland; discussion, O. W. Sherwin, Woodstock. Medical and Surgical Treatment of Appendicitis, by S. C. Gordon, Portland, Me.; discussion, L. M. Bingham, Burlington. Blood-stains, by J. N. Jenne, St. Albans; discussion, O. H. Pettingill, Saxtons River. The Relations of the Medical Profession to Certain Social Conditions, by Charles H. Cook, Natick, Mass.; discussion, F. R. Stoddard, Shelburne. The Border-lines of Insanity, by S. E. Lawton, Brattleboro; discussion, J. M. Clarke, Burlington. Address in Surgery, by J. B. Wheeler, Burlington; discussion, E. M. Pond, Rutland. The Prostate, Some of its Acute and Chronic Conditions, and their Treatment, by L. Bolton Bangs, New York City; discussion, H. D. Holton, Brattleboro. Treatment of Injuries of the Eye, by C. E. Chandler, Montpelier; discussion, George H. Gorham, Bellows Falls. Heredity, by O. G. Stickney, Barre; discussion, C. C. Smith, Gaysville. The Antitoxin-treatment of Diphtheria, by Edward R. Campbell, Bellows Falls; discussion, J. H. Hamilton, Richford.

Suicide in Vienna.—According to returns made by the Central Statistical Commission, the number of suicides in Vienna during 1889–1893 amounted to 1254—3.2 per 10,000 of the population. Among the corresponding returns of some other Continental towns may be mentioned Paris with 3.6, Brussels with 3.29, Berlin with 2.98, Munich with 1.98, and Breslau with 3.91 per 10,000 of population. During the seven preceding quinquennial periods 360 cases of suicide occurred in 1854–1858, 367 in 1859–1863, 565 in 1864–1868, 631 in 1869–1873, 1020 in 1874–1878, 1129 in 1879–1883, and 1196 in 1884–1888. Among 100 cases of suicide 77 were men and 23 were women. Adolescents appear to have every year more frequent recourse to this method of terminating their real or supposed miseries, the highest rate being registered at the age from sixteen to twenty-five years. Among 100 suicides 32.5 ended their days by hanging, 23.5 by pistol-shots, 22.4 by poisoning, and 5.8 by drowning. With respect to the poisons potassium cyanid was resorted to in 12.7 per cent. of the cases, caustic lye in 22.7 per cent., phosphorus in 26.1 per cent., and sulphuric acid in 7.2 per cent. As for seasonal distribution the proportions were: January, 8.5 per cent.; February, 7.6 per cent.; March, 8.9 per cent.; April, 9.1 per cent.; May, 10.5 per cent.; June, 8.7 per cent.; July, 8.1 per cent.; August, 7.2 per cent.; September, 7.4 per cent.; October, 8.3 per cent.; November, 7.8 per cent., and December, 7.9 per cent.—*Lancet*, Sept. 14, 1895, p. 704.

The Revival of the Index Medicus.—The following is a list of additional subscriptions for the *Index Medicus* received by Dr. John S. Billings from September 7th to September 24th:

Albany, N. Y.: Dr. Henry Hun.

Alhambra, Cal.: Dr. Milbank Johnson.

Ann Arbor, Mich.: Medical Department, University of Michigan.

Baltimore, Md.: Dr. Thomas S. Cullen.

Boston, Mass.: Dr. J. W. Elliot, Dr. R. H. Fitz, Dr. M. H. Richardson.

Cleveland, Ohio: Dr. William H. Humiston.

Colorado Springs, Col.: El Paso County Medical Society.

London, Eng.: British Medical Association.

Louisville, Ky.: Index Medicus Club.

Nashville, Tenn.: Dr. J. H. Mills.

New York City: Dr. Robert Abbe, Dr. S. T. Armstrong, Dr. L. Duncan Bulkley, Dr. D. Bryson Delavan, Dr. Alexander Lambert, Dr. Robert T. Morris, Dr. Frederick Peterson, Dr. R. W. Taylor, Dr. W. Gilman Thompson, Dr. F. H. Wiggin.

Philadelphia, Pa.: Dr. John W. Croskey, Dr. Howard F. Hansell, Dr. John H. Packard.

Syracuse, N. Y.: Dr. Henry L. Elsner, Syracuse Academy of Medicine.

The total number of subscriptions equals 105. The additional 95 should be easy of attainment.

An Army Medical Board will be in session at Washington, D. C., during October, 1895, for the examination of candidates for appointment to the medical corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the board will make application to the Secretary of War, before October 8th, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to citizenship, character, and habits. The candidate must be between twenty-two and twenty-nine years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing Dr. George M. Sternberg, Surgeon-General, U. S. Army, Washington, D. C.

The Rush Monument Fund.—Dr. George H. Rohé, Secretary and Treasurer of the Rush Monument Committee, announces that the sum-total of the Rush Monument Fund to date amounts to $3357.39. Among the recent contributions are the following:

Dr. Nicholas Senn, Chicago	$100 00
Dr. Andrew Annan, Emmetsburg, Md.	50 00
Eastern Ohio Medical Association (through Dr. J. C. M. Floyd)	10 00
Medical Society, Wayne County, New York (through Dr. D. S. Colvin)	10 00
Dr. George M. Sternberg, U. S. A.	10 00
Dr. J. R. Buist, Nashville, Tenn.	5 00
Dr. George M. Gould, Phila.	5 00
Dr. Franklin B. Ferguson, Deer Island, Me.	2 00
Dr. George N. Acker, Washington, D. C.	1 00
Dr. John B. Hamilton, Chicago	1 00
Dr. W. H. Marsh, Solomons, Md.	1 00
Dr. Jacob L. Williams, Boston	1 00

Dr. Albert Leary Gihon, Medical Director of the U. S. Navy, having reached the age of sixty-two years, will be retired from the service on September 28, 1895, after a service of more than forty years, eleven of which were spent at sea and more than twenty-seven on shore. He retires with the rank of Commodore (Brigadier-General). Dr. Gihon was graduated from the Philadelphia College of Medicine and Surgery in 1852, and was Professor of Chemistry and Toxicology in that institution in 1853-54. He entered the navy in 1855 as Assistant Surgeon, becoming successively Passed Assistant Surgeon in May, 1860; Surgeon in August, 1861; Medical Inspector in November, 1872; and Medical Director in August, 1879. He has represented the medical department of the navy in many important scientific bodies, in a considerable number of which he has been honored with some official position. He has made numerous contributions to medical literature, the latest of which is a series of articles in the *Twentieth-Century Practice of Medicine*.

John Collins Warren, M.D., LL.D.—At the last commencement of Jefferson Medical College the honorary degree of LL.D. was conferred on Dr. John Collins Warren, Professor of Surgery in Harvard University.

Albrecht Nagel, Professor of Ophthalmology in the University of Tübingen, died July 22d, at the age of sixty-two years.

THE DIAGNOSIS OF LATE CASES OF MULTIPLE NEURITIS.

BY GEORGE J. PRESTON, M.D.,
OF BALTIMORE, MD.,
PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS.

MULTIPLE neuritis in the acute stage, or in the early part of the attack, presents an array of symptoms so characteristic that an error in diagnosis is unwarrantable. In the late cases, on the other hand, especially those that are slowly improving, the diagnosis is often extremely difficult. The class of cases referred to in this paper are those in which the disease has existed for six months or a year.

In certain cases of multiple neuritis sensation may from the first be only slightly involved, and in all cases the sensory fibers regain their function long before the motor. In late cases it is the rule to find little or no disturbance of sensation, while at the same time motor paralysis may be very pronounced. It is most probable that the cause of this difference between motor and sensory fibers is physiologic and not pathologic, as there is no proof that the various pathologic processes at work, toxic or toxemic, would attack by preference or more violently the motor fibers. It is very common to find in ordinary pressure-paralysis little or no involvement of sensation, associated with more or less absolute motor paralysis, and in this case the only way in which the sensory fibers could escape would be that they run centrally in the mixed nerve. Some limited experiments upon animals made a year or two ago seem to show that in dogs and cats the motor and sensory fibers are irregularly distributed in the mixed nerve. Upon physiologic grounds it would be natural to suppose that sensory impulses would be transmitted more readily than motor along a bad conductor. Hyperesthesia is also absent in the late cases, so that a prominent feature of the affection under consideration, sensory disturbance, has disappeared.

All grades of motor paralysis may be present in these late cases, and the legs are involved to a greater degree than the arms, except in cases resulting from metallic poisoning. The paralysis, while usually symmetric, often shows marked differences in the degree of recovery. The deep reflexes are very slow to return, but they sometimes reappear while the paralysis still persists. The superficial reflexes are always present in the late cases, and are frequently not affected in the early stage, even although there may be a decided degree of anesthesia present. A marked feature of the late cases is muscular atrophy, which is commonly symmetric, but may be more pronounced in some regions than in others. A degree of ataxia is sometimes found which is out of proportion to the loss of strength. These are some of the confusing symptoms that contribute to the difficulty of a differential diagnosis.

From a purely clinical standpoint, and without any reference to etiology, there are three or four fairly well-marked types met with in the later stages of multiple neuritis: 1st, atrophic; 2d, paraplegic; 3d, tabetic. Cases not falling under any of these three divisions may be regarded as belonging to a fourth or mixed type.

The atrophic form is likely to be confounded with some of the varieties of chronic poliomyelitis, possibly with syringomyelia. In many cases it is simply impossible to determine whether the case is one of chronic poliomyelitis or of late multiple neuritis, without invoking the aid of history or awaiting the termination of the disease. The wasting of the muscles may be identical, even to the marked atrophy of the muscles of the hand; sensation has returned in the case of neuritis, the electric reaction is *nil* in both affections, and in both the deep reflexes are abolished. The following cases illustrate this form of the disease:[1]

CASE I.—D. G., a woman, aged twenty-five years, was first seen six months after the onset of the disease. From the patient's statement it was evident that the case had been diagnosticated chronic muscular atrophy and a hopeless prognosis given. The muscular atrophy was extreme, resembling that of a case of progressive muscular atrophy in the last stages. The woman had formerly weighed 200 pounds, but when first seen weighed about 100 pounds. The muscles of the face were greatly wasted, though not to the extreme degree as the muscles of the limbs and trunk. There was bilateral wrist-drop and foot-drop. The patient could not feed herself, and was unable to hold her head up or turn over in bed. There was a little blunting of the sense of touch, but no actual anesthesia. Electro-contractility was abolished to the faradic and barely perceptible to the strongest galvanic currents that

[1] Some of the cases related in this paper were described more fully in a paper presented to the Medical and Chirurgical Faculty of Maryland in 1891.

could be used. The patient made a perfect recovery in about a year-and-a-half, confirming the diagnosis of multiple neuritis. It may be mentioned incidentally that upon her recovery she became so violently erotic that she had to be discharged from the hospital.

CASE II.—A woman, aged twenty-six years, presented extreme emaciation, with bilateral foot-drop and wrist-drop, and could not stand or walk without assistance. The reflexes were lost. This case was one of chronic lead-poisoning, white lead having been used as a face-powder.

CASE III.—J. P. McN., a man, aged thirty-eight years, presented wasting of the extremities, especially the lower, with inability to stand or walk. The reflexes were abolished, sensation was impaired and in certain regions lost, the muscular sense was wanting, and irregular pains were present in the limbs. The patient was discharged cured.

Physical examination in these three patients disclosed, with some slight exceptions, a fairly typical picture of chronic muscular atrophy, and it was not until a minute history was obtained and carefully weighed that the diagnosis of late multiple neuritis was arrived at and practically confirmed by the complete recovery in each instance. It is more than probable that progressive muscular atrophy and chronic multiple neuritis are often mistaken for each other, or rather that multiple neuritis in the later stages of the disease is often mistaken for chronic poliomyelitis. There is no pain and no anesthesia in the late cases, or if these symptoms do exist they are so slight as not to attract attention. If marked anesthesia be present, it is a most valuable diagnostic sign. The electric reaction has not in my hands been of any great service as a means of differentiation between the two diseases in question, as electro-contractility has practically disappeared in both in the later stages, or in either case certain groups of muscles may be found that respond to one of the currents. In this connection I would like to add my testimony to the statement recently made by Remak, that sluggish contractility is a more frequent and reliable sign of degeneration than the polar changes so long regarded as classic. In speaking of the atrophic type of neuritis only cases of general, widespread disease are meant, not cases of irregular poliomyelitis or of limited neuritis.

The second class is the tabetic form or type of multiple neuritis. It not infrequently happens that at the onset of the disease the arms are but slightly involved, and later in the course of the affection the disturbances of sensation and altered reflexes are confined to the lower extremities. So closely do these symptoms resemble those of locomotor ataxia that this form of neuritis is spoken of as pseudo-tabes. There is an absence of girdle-sensation and of lightning-pains, though I have recently seen two cases in which there were neuralgic pains of a fugacious nature. Optic neuritis or atrophy rarely if ever occurs and marked pupillary changes are not common. I have seen the Argyll-Robertson pupil once in a well-marked case of multiple neuritis. The bladder and rectum escape in neuritis and the trophic changes do not correspond to the well-known joint-affections of true tabes. Loss of power is, of course, much more marked in neuritis than in the first or second stage of tabes. I have never been able to note the great difference in the gait of the two affections, a point somewhat insisted on by Charcot. When the foot-drop is pronounced, of course the gait will be characteristic; but in the majority of cases of this type the paralysis is very slight and the gait is incoordinate, resembling that of tabes very closely. The following cases will illustrate the similarity in symptomatology between tabes and the tabetic form of neuritis:

CASE IV.—A man, aged forty years, was first seen by my assistant, who made a diagnosis of tabes. There were moderate ataxia, absolute loss of the deep reflexes, slight impairment of sensation, with sluggishness and contraction of the pupils. There was an indistinct history of pains, but no girdle-sensation, no interference with the bladder or rectum, and retention of sexual power. A diagnosis of late neuritis was made, which was confirmed by the subsequent course of the disease, and also by obtaining a more accurate history of the earlier part of the attack, the man having been treated for acute neuritis at another hospital.

CASE V.—J. C., a man, aged forty-five years, presented the clinical picture of a case of alcoholic neuritis, with marked delusions and hallucinations. He complained of pain in legs; the knee-jerk was abolished; the pupils were almost insensitive to light, and but slightly active in accommodation. Ataxia was so great that for a month or more the patient could not stand or walk, though his strength was fairly good. There was slight anesthesia, and great impairment of the muscular sense. The man gradually recovered, with the exception of his mental condition, which was not improved.

CASE VI.—A man, aged thirty-eight years, had been in the hospital a year-and-a-half before, when a diagnosis of locomotor ataxia was made by a well-known physician. The patient, a very intelligent man, gave a history of pain, with loss of knee-jerk, anesthesia, and ataxia at the time the diagnosis of tabes was made. When seen a year after the acute attack there was slight loss of sensation in the lower extremities, with the knee-jerk present, though feeble.

CASE VII.—L. D., a woman, aged fifty-two years, presented pronounced ataxia, with loss of the knee-jerks, irregular anesthesia, Argyll-Robertson pupil, and normal discs. Improvement was rapid under treatment, the knee-jerks returning in the course of some months.

CASE VIII.—R. D., a man, aged thirty-four years, was seen only a few weeks after the onset of his disease. Ataxia was very marked, and the gait was

characteristically tabetic. There was slight loss of strength in the legs. The knee-jerks were lost, and there was slight impairment of sensation. The eyes were normal, except that the pupils were sluggish. Electric examination showed slight reaction of degeneration. A week or two after the patient was first seen there appeared slight tingling and numbness in the hands. Improvement has been rapid, and the diagnosis of neuritis is now clear, though at first there was very considerable doubt as between peripheral and central disease.

In the cases illustrative of the tabetic type, just detailed, it will be noticed that the arms were not affected at all, or only very slightly. In all of these cases the loss of sensation was very much the same as that found in tabes. The deep reflexes were invariably lost in all. Ataxia was marked in nearly all. In one case there was Argyll-Robertson pupil, and in another an approximation of this symptom. The history elicited in regard to pain was uncertain, a fact not very uncommon in veritable tabes. In none of the cases was there a history of girdle-sensation, distinct lightning-pains, interference with the functions of the bladder or rectum, or loss of sexual power. In no case was there optic atrophy, and the trophic lesions were not suggestive of tabes. These negative points are of great value in making the differential diagnosis, but on the whole they are less important than the history of the case. The very fact that we have to rely so much upon the history, a notably uncertain factor, enhances greatly the difficulty of diagnosis.

The third type of neuritis is the paraplegic. It is a little doubtful whether we should regard the cases in this group as instances of multiple neuritis, except by taking advantage of the flexibility of the nomenclature. It is quite probable that in many instances the nerves of the upper extremities are from the first not involved in the inflammatory process. Possibly certain cases of double sciatic neuritis are to be included in this group. There are, however, many cases in which the history shows conclusively that in the beginning of the disease there was a general neuritis, leaving behind it a paraplegia, simulating very closely, in fact often indistinguishable from some of the varieties of myelitis. Sometimes the picture is one of lumbar myelitis; again that of the rarer diffuse myelitis.

Case IX was a man, aged about thirty-five years, whom I had seen a number of times, and without any very careful examination had regarded as a case of lumbar myelitis. When first examined there was paralysis of the lower limbs, with normal power in the arms, with loss of the knee-jerks, bilateral foot-drop, and some edema of the lower extremities, with an approach to glossy skin. An examination made some months later revealed returning knee-jerks, increased power in the legs, with irregular but limited muscular atrophy. A careful inquiry into the man's history elicited the fact that he had been suddenly taken ill a year previously, when he had fever, absolute loss of motion and sensation in all four extremities, with severe pain; and upon following up the case it was found that he had been treated at the University of Maryland Hospital for acute multiple neuritis.

Case X.—M. S., a woman, aged twenty years, was seen some months after the beginning of the attack. There was absolute loss of motion and marked loss of sensation in the lower extremities. The knee jerk was absent and bilateral foot-drop was present. There was a history of great pain in the legs, with gradual loss of strength and muscular atrophy. These symptoms followed a confinement, and may have been due to a myelitis, though the history pointed strongly to a neuritis. The case went on to a speedy recovery.

Case XI.—T. C., a man, aged forty-three years, had a right hemiplegia two years before admission into the hospital, but had recovered sufficiently to do heavy laboring work. In November, 1891, he was suddenly seized with pain in the right side, soon extending to the left, and followed by loss of power in all four extremities. When seen in September, 1892, ten months after the onset of the disease, he was unable to stand. There was very little loss of sensation, with almost complete loss of power in the legs. The arms were very slightly affected. The right side was worse than the left. There was marked atrophy in the legs and forearms. The deep reflexes were lost, the superficial preserved. The pupils were normal. The atrophied muscles showed reaction of degeneration. The patient was discharged, cured, in January, 1893.

The absence of vesical or rectal disturbance, of girdle-sensation, and of spinal tenderness, the temporary character of the anesthesia, in neuritis, together with the history of the onset and course of the disease, will generally enable the diagnosis to be made between multiple neuritis in the late stage and lumbar, or the rarer form, diffuse myelitis.

There are, finally, certain mixed cases that are often very puzzling; the resemblance may be more or less close to one of the three types already given, with certain important variations, or the picture may be a very composite one. All the symptoms, except certain limited paralyses, anesthesias, or atrophies, may have disappeared. All resemblance to the classic symptomatology may have vanished, and the picture that has been effaced by a gradual improvement of the various symptoms has to be reconstructed from very meager remnants. This is comparatively easy when the patient can give an intelligent account of the early period of the disease, or when the family-physician can be called upon to fill in the details; but in hospital-practice, with an ignorant subject, it is often a very difficult matter to obtain anything like a satisfactory history. Sometimes these cases will suggest syringomyelia; some-

times one or the other forms of muscular atrophy; sometimes a monoplegia of central origin, or an affection of the cord.

The cases detailed—and many others could have been added—show how close the resemblance often is between late cases of multiple neuritis and various other diseases. Apart from organic affections, the question of hysteria will often come up, but there is rarely any difficulty in excluding it. There can hardly be any doubt that more mistakes are made in the diagnosis of these late cases of multiple neuritis than in any other one form of organic nervous disease. It is only by the most careful attention to the symptomatology, taken in connection with the previous history of the case, that anything like certainty can be arrived at. It is very important that the case be diagnosticated correctly, as even in the late cases of multiple neuritis proper treatment tends very materially to modify the course of the disease and hasten the recovery. From the standpoint of prognosis the recognition of the true nature of the affection is of even greater importance, as in the one case we can hold out the certainty almost of a cure, while in nearly all the other diseases with which multiple neuritis is likely to be confounded we can offer hardly a hope of improvement.

THE RELATION OF PELVIC DISEASES TO MENTAL DISORDERS.

By ISABEL M. DAVENPORT, M D,
OF KANKAKEE, ILL.;
ASSISTANT PHYSICIAN AND GYNECOLOGIST TO THE EASTERN ILLINOIS HOSPITAL FOR THE INSANE.

THE subject of this paper has been suggested by the fact that out of a large number of female patients admitted to the Eastern Illinois Hospital for the Insane the cause most frequently assigned by the friends and attending physician is "pelvic disease." It would seem that physicians too often fly to this source as a cause, when in reality I am often surprised to find the pelvic organs in these cases in a fairly healthy condition. Only a short time ago I was called to see a woman who was suffering from an attack of acute mania. She had been brought to Chicago by her family physician, who was a man of apparent intelligence, for the purpose of having the uterus and ovaries removed, with the hope of bringing about mental recovery. Upon examination I found the uterus somewhat enlarged and some erosion of the cervix, with a small amount of mucopurulent discharge; but nothing abnormal about the ovaries and tubes could be distinguished—a condition frequently met with, and one that, while somewhat hard to control, is seldom considered serious enough to call for such radical measures, and that the attending physician would not for a moment have considered significant in any other case than one of insanity. In the absence of any history of hereditary insanity, however, he at once seized upon this favorite cause, and advised removal of the pelvic organs, when, as a matter of fact, the disease, being acute mania, the chances for recovery were good without any treatment, to say nothing of such radical measures.

I do not wish to be understood as being opposed to even the most extreme measures in these cases if there is sufficient cause in the organs themselves for the operation; for at the best I think a woman who is or has been insane loses nothing by removal of her uterus and ovaries, if for no other reason than that it prevents an entailment of her awful affliction on another generation. Indeed, when I see women who have returned to the hospital after the birth successively of several children, and see one member after another of a family committed to this hospital, I feel that it would be humane to castrate every woman who is insane. In the light of our present knowledge, however, no amount of pelvic or other physical disease will cause insanity if the conditions for this disorder do not exist in the brain; and yet we know that the sexual apparatus has a profound influence over the life of women. In how far these organs may act as a determining factor in producing insanity is an important question.

The gynecologist has a very useful place in the treatment of the insane in that it is possible to afford much relief and comfort to a class who cannot properly care for themselves; and by removing a source of nerve-irritation render the patient less irritable and restless; by being able to determine the condition of the bowels; in discovering injuries that are often self-inflicted; removing foreign bodies from the vagina and even from the uterus, and last, but not by any means least, by the mental effect upon patients who have been taught to believe that all their ills are due to uterine diseases, and in being treated for these they have confidence and courage to hope for recovery from their mental disorders.

This last is an influence extremely valuable to many, if not curative in itself. Within the past year I have received and attended five women who had undergone radical operations with the hope of recovery from insanity.

CASE I.—Mrs. L., an American of good family and social standing, forty-six years of age, and the mother of five children, gave a history of hereditary insanity. She has had three attacks of mania, the first occurring after the birth of her second child, the second after the birth of the youngest, and this last attack one-and-one-half years ago. She has been treated in two private sanitariums, and in June, 1894, the uterus and appendages were removed because of the presence of an intramural fibroid

tumor of the uterus. The operation was followed by several convulsions, said to have been epileptiform, and also by paralysis of the right side. The woman recovered from these, however, but her mental condition being unimproved she was committed to the Eastern Illinois Hospital for the Insane in April, 1895, where she has continued unimproved; though, from the fact that her case is one of recurrent mania, she will probably recover, and being at the age for the menopause, the prognosis is good for continued mental health.

Case II.—Mrs. P., an American of good family, thirty-four years old, was married, but had never had a child. She gave a history of hereditary insanity, her mother having died of paretic dementia. The patient had always been delicate. Some years ago the tubes and ovaries were removed because of pyosalpingitis and a very erotic tendency, which was supposed to be due to the diseased organs. After recovery from the operation the woman had "queer spells," as the history words it, and became addicted to the use of opium, tobacco, and liquor, with no abatement of the abnormal erotic disposition. Indeed, she became very depraved, and after escaping from her friends and spending three weeks of fearful debauchery in one of the large cities, she was brought to us on June 1, 1895, in a state of acute mania, and she thus continues, unimproved.

An interesting fact in relation with this case is that the patient has continued to menstruate regularly since the operation, though her former physician, who is a reputable gentleman, says he knows to a certainty that the operation was perfectly done.

Case III.—Miss G., an American, thirty years old, of good family and unmarried, had had one miscarriage. From puberty she had been extremely irritable and erotic, at the menstrual periods especially. She had attempted homicide at these times. Some years ago the ovaries and tubes (which were healthy) were removed, with a view to removing the cause of her erotic and irritable tendencies, but notwithstanding this operation the woman continued in the same mental condition until June, 1895, when she voluntarily committed herself to this hospital. In examining her I found the heart enlarged, the apex being displaced downward and toward the sternum, with a harsh, blowing sound at the apex during the systole. I have not been able to learn whether this condition existed before the operation, or, as is sometimes the case, has developed since; but the patient says that she has flashes of heat preceding the irritable attacks, and the irritability is ascribed by her to these "hot flashes." It would appear that the condition of the heart was a sufficient cause for the irritability, which, however, has not manifested itself here, and the patient has been perfectly sane, quiet, and well-behaved since her admission. The abnormal heart-sounds and the hot flashes have become less frequent and severe under ten drops of tincture of digitalis thrice daily, and the patient will be returned to her home in another month if she continues well.

Case IV is that of a young woman recently admitted, who has had epilepsy since puberty, the seizures occurring only at the menstrual period. Her friends were advised that if she married and had a child she would probably have good health and the seizures disappear. This wise (?) advice was acted upon, and when, after the birth of the third child the seizures continued, they were advised to have the ovaries removed. This was done some six months ago, with no benefit, and the patient was then committed to the Eastern Illinois Hospital for the Insane. Now her friends have been told that if a slightly lacerated cervix (which is bound down by inflammatory adhesions) were repaired she would recover.

Case V.—Mrs. B., an American, thirty-four years of age, married and the mother of two children, gives an obscure history of hereditary insanity. She has suffered from an attack of puerperal mania from the birth of her youngest child, in September, 1889. The excitement is greatest at the menstrual periods. She has been an inmate of the Eastern Illinois Hospital for the Insane since December, 1891, during which time the best care that the hospital, with the addition of every aid that her friends (who are wealthy) could procure, had been given her without permanent benefit. The patient suffered from endometritis and an extreme lateral version, with shortening of one broad ligament, and as a last and proper resort her friends wished the operation of ovario-hysterectomy performed. They were advised that her physicians could not hope for benefit from removal of the organs in question, but that there was a bare possibility that the shock produced by so severe an operation, the long-continued rest in bed, and the depletion from loss of blood, with the effect of the anesthetic, might prove beneficial.

In order that a physician who was a relative might perform the operation, and also from a sentiment that she might not die in a hospital for the insane, if she did not recover, she was taken to Chicago, and the operation successfully performed. In one month she returned and steadily grew worse, having been continuously noisy, profane, and destructive—in fact, more excited than she had been at any time after her admission, until on August 15th, when, after being given sulfonal to the point of narcotism, she suddenly became rational, and has continued so up to the present time, having now gone to her home on a visit. Whether or not she will continue well remains to be seen; but, owing to the fact that she had been given no treatment except that which had been given her repeatedly before, it would seem that the removal of the pelvic organs had certainly influenced her recovery to the present extent.

During the past four years Dr. George H. Rohé, Superintendent of the Maryland Hospital for the Insane, has operated for pelvic diseases in women upon thirty-four cases. I have at hand his report of twenty-two cases, covered by the years 1891 and 1893. The twenty-two cases have yielded the following results:

Puerperal mania—6 cases, with recovery in 3 and improvement in 1.

Simple mania—1 case, with slight mental improvement.

Hystero-epilepsy with mania—2 cases, with recovery in 1; operation too recent in 1 to give the result.

Epileptic insanity—3 cases, with 2 deaths and slight improvement in 1.

Periodic mania—3 cases, with decided progressive mental improvement in all.

Paranoia—1 case, with slight but not permanent improvement.

Thus among 22 cases there was recovery in 5 and decided improvement in 7. An interesting fact is that the cases of recovery and decided improvement represented forms of insanity that appear to be strongly influenced if not caused by the sexual organs. On the whole, it appears that removal of the uterus or appendages is beneficial in some cases, and as there is no good and sufficient reason for the usual extreme conservatism of alienists in regard to radical operation in the insane, this conservatism (providing, of course, that there is a sufficient degree or extent of disease in the pelvic organs themselves) is depriving patients of a chance for recovery or improvement that they should have.

OBSERVATIONS REGARDING EYESTRAIN AND ITS RELIEF.[1]

By EDWARD JACKSON, A.M., M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC; SURGEON TO WILLS EYE HOSPITAL.

THERE is a common impression that eyestrain is simply and solely a result of ocular defects—that without some ocular fault there is no eyestrain; and that the discovery of some marked anomaly of refraction, or of the ocular muscles, is the one thing needful to establish the diagnosis of eyestrain; and the correction of that error of refraction or fault of muscular balance is the sole and sufficient treatment of the condition. There are too many physicians who, suspecting a connection between the eyes and a chronic headache, come to the ophthalmologist and ask if the patient has any error of refraction, expecting the answer to settle all questions of pathology, and a pair of glasses to sum up the treatment.

Now, as a matter of fact, ametropia of any degree may be altogether unattended with eyestrain, and eyestrain can exist without any ocular defect. Of course, in a great many cases the two are intimately associated. Ametropia is perhaps the most effective and most common predisposing cause of eyestrain; and the mass of cases of eyestrain present ametropia sufficient in amount to be practically important. Nevertheless, ametropia and eyestrain are distinct conditions. One sees every grade of the various forms of ametropia in persons who use their eyes without eyestrain, and typical severe eyestrain although the eyes may be free from defect.

If eyestrain and ametropia are not invariably connected, what, it may be asked, is their true relation to one another? Ametropia, fault of ocular focus, is one of several factors that by their cooperation may cause eyestrain. It is such an important factor that it should be carefully and completely studied in every case of eyestrain; but it should be remembered always that it is only one factor, and that other factors will in particular cases prove of even greater importance.

The various factors of eyestrain may be summarized thus:

First. Ocular defects, including ametropia, insufficient power of accommodation, and (rarely) faults of muscle-balance.

Second. Improper requirements in the way of eyework, including excessive hours of eyework, excessive minuteness of objects looked at, inferior illumination, imperfect adjustment of optic instruments, wrong position of the object, or wrong arrangement of hours of eyework and recreation.

Third. Defects of general nutrition, including chronic ill-health, the immediate and after-effects of acute specific disease, and diathetic influences.

Fourth. Imperfect organization of the nervous system or degenerative changes in it, including the influence of sudden changes in the amount or kind of eyework, and certain forms of senile decay.

These four classes include a host of individual causes which are to be borne in mind, and their relative importance carefully estimated in the study of a given case. Any narrower routine will at times result in unnecessary failure; but the narrower way of regarding the case is far too common. One needs constantly to remember that an ocular headache is not aggravated only by eyework; it may be aggravated, or even set up, by the recurrence of the menstrual epoch, by hunger, by anemia, by exhaustion of mind or body, or by the lowered character of the general nutrition after exhausting illness. And, conversely, it is not benefited merely by lenses or prisms, atropin, or the dark-room, but by sleep, food, tonics, and all wholesome influences. On the other hand, it is an error equally serious to assume, because a headache is benefited by a hearty meal, or a brisk purge, or rest from business, or a course of iron and strychnin, that eyestrain can have nothing to do with it. And the same is true of the other symptoms that we group under this general head of eyestrain.

The recognition of the broader etiologic relations of eyestrain cannot fail to exert an important influence on our methods of investigating and managing all such cases. For instance, when it is suspected that eyestrain is the central fact in the symptom-group,

[1] Read before the Colorado State Medical Society, 1895.

other lines of study of the case will not be ignored, and the whole diagnosis, prognosis, and treatment founded on the results obtained with the ophthalmometer or the test-lenses. It will still be pertinent to look into the question of diathesis, the usual workings of the nervous system, and every possible influence bearing on the nutrition of the patient, as well as the amount and conditions of his eyework. Again, it is not essential for the general practitioner to have at his command skilled measurements of the refraction of the eyes before making a probable diagnosis of eyestrain. Whether the astigmatism is 0.5 D. or 5.D. will not in itself settle the matter. In either case the decision will rest as much on other evidence as upon this one fact. Eyestrain is recognized by the whole clinical picture it presents, not by a single feature.

To even a greater extent do these factors, other than the mere optic defect, influence the prognosis and the treatment. Age, especially as indicating the evolution or involution, present or prospective, of the nervous system, the tendency of the nervous system as regards habitual or recurrent pain; the state and prospects of general nutrition; the necessary requirements of occupation on the whole organism, as well as on the eye, must all be considered before an intelligent prognosis can be given. And while the removal of the single causative factor will relieve some patients, the proportion of those relieved will rise with the skilful combating of every adverse and depressing influence. Glasses may be of value or essential, but so may be readjustment of eyework, improved general nutrition, or the recognition of those bounds that the constitution of the patient sets on habitual effort.

The next point to which I would ask attention is that the intensity of the eyestrain is not directly proportional to the ocular fault that gives rise to it. The former may even seem inversely proportional to the latter. An ocular defect may give rise either to imperfect vision or to eyestrain, less generally to both. It is the higher degrees of ametropia that necessarily cause imperfect vision, while the lower, in which imperfect vision can be obviated by increased exertion, more commonly cause eyestrain. Then the prognosis as to the continuance of the symptoms complained of is the more unfavorable in proportion to the smallness of the ocular defect sharing in their causation. The factor of ametropia entering into the causation is the only factor that can be always and with certainty removed. In proportion as it is relatively small the share of the other factors less amenable to the measures at our command becomes relatively large, and our ability to give relief correspondingly doubtful.

Particularly after middle life do small errors of refraction or imperfections of adjustment cause severe and persistent strain. When the power of accommodation has so diminished that the correction of 1 D. of hyperopia is quite beyond its range, 0.25 D. of the same error of refraction may prove a constant provocation to painful effort on the part of the ciliary muscle, or an equal amount of inaccuracy in the adjustment of lenses may be equally injurious.

Another point worthy of attention is the complete difference in the effects produced by a perfectly accurate correction of ametropia, as compared with those due to a slightly inaccurate correction. The difference in relief given is often utterly out of proportion to the difference in the refracting power or axial direction of the lenses, but clinically the fact is well established. Perhaps it will help us to understand it to remember that if an emmetrope attempts to work with a pair of 0.5 D. concave lenses, the annoyance experienced is far greater than that usually felt by the hyperope with an error of 1.5 D. The ametropia proves more disastrous to the person not accustomed to it, and if one wears the wrong glasses the fault of focus that he has to contend with is always one to which he is not accustomed. If the inaccuracy be simply in the direction of a lower degree of the original fault, this may not be noticed if the ratio between the two eyes be properly preserved. Yet even then the result cannot be regarded as wholly satisfactory.

Finally, as regards relief of eyestrain through the wearing of glasses, let me call attention to the practical importance of the *period of adaptation* to the use of glasses. In nearly all works on the subject this period of adaptation is slighted or ignored. It is commonly stated that the wearing by young persons of convex lenses correcting their total hyperopia will at first cause blurring of distant vision, and sometimes it is mentioned that strong concave lenses may at first prove unsatisfactory for near work; but no adequate expression is given of the fact that nearly every pair of glasses adjusted, if they be adequate to the needs of the case, and of more than trifling strength, will at first cause discomfort and aggravation of some symptoms of eyestrain, or at least markedly less comfort than they will give when the eyes have become accustomed to working through them. It is a matter of the first practical importance that this period should be borne in mind, and the patient fully warned of its existence and characteristics. Some will remember the story of the African adventurer, who restored his imperilled influence over his native followers by calling them before him, placing on the tongue of each a couple of grains of tartar emetic, and solemnly announcing that they would vomit. According to the account of the native: "He told us we would vomit, and by Allah we did vomit. Great is the prophet!!" So if with the prescription of a pair of glasses full warning is given of the period of

slight gain or increased discomfort, its occurrence will only stimulate confidence in the knowledge and frankness of the oculist, and help to secure a full and fair test of the value of the lenses; while the occurrence of the same train of symptoms, without any previous warning regarding them, has too often by destruction of confidence proved a disaster to both physician and patient.

CLINICAL MEMORANDA.

PROBABLE SEPTIC PHLEBITIS OF THE LEFT SIGMOID SINUS.[1]

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS;

AND

EDMUND J. A. ROGERS, M.D.,
OF DENVER, COL.;
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER; SURGEON TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS; AND CONSULTING SURGEON TO THE COLORADO STATE INSANE ASYLUM.

HISTORY AND NEUROLOGIC EXAMINATION BY DR. ESKRIDGE.

S. C. B., a white, married farmer, thirty-six years of age, born in Indiana, and living in Colorado a few months, was admitted to St. Luke's Hospital January 13, 1895. It was learned that the man's father had died at the age of sixty-two and was demented for ten years previous to his death. His mother was living and exceedingly irritable and nervous. One brother died of pulmonary tuberculosis and one sister had carcinoma of the breast. The patient's health in childhood was good and remained so until four years ago, when after exposure to cold he began to experience severe pain in the back and left side of the head, and this was followed a few days later by a discharge of pus from the left ear. The otorrhea continued for about six weeks. After this all pain subsided and the man was apparently in the best of health until December 24, 1894, when after exposure in the mountains he began to suffer from severe pain in the left mastoid region. Within a day or two the pain appeared in the ear proper, and on the third day from the beginning of the mastoid pain a discharge, consisting of blood and pus, took place from the ear. For several days after the discharge became free the pain was less severe, but instead there was a feeling of numbness and fulness in and around the ear, and for a period of about twenty-four hours immediately after the discharge began the patient experienced severe pain at the front and top of the head. From December 29, 1894, to January 4, 1895, through the day he seemed very quiet and was in a stupor most of the time; but during the night he became violent, emotional, and hilarious. He would laugh, sing, and pray, and make violent contortions with his face. During the two or three days after January 4th he was quite rational, but complained of constant pain in the region of the left ear. On January 6th he came to Denver, from a distance of one-hundred or two-hundred miles. Two days later he suffered from a severe chill, which was followed by a rise of temperature, and for the next five days he was said to have had from one to three chills a day.

I first saw the man in consultation with Dr. Stenhouse on January 19, 1895. I learned that on the previous evening the temperature had reached 105° after a chill. During my first visit, which was made about noon, the patient was suffering from a severe chill, and the temperature in the mouth was 102°. The chill lasted about an hour, and at the end of this time the temperature reached 104°. The man was said not to have perspired any after the chills from which he had suffered before I saw him.

Examination revealed the following condition: The patient was sallow, not much emaciated, but looked depressed. He complained of a dull, heavy pain deep in the left ear and just posterior to it. There was no discharge from the ear; neither was there any odor of an unpleasant nature about the patient. Slight tenderness was found over the upper left posterior cervical triangle and over the left mastoid region, but none in the region of the jugular vein. The knee-jerks were slightly increased; ankle-clonus was absent; the plantar reflexes were greatly diminished; all other superficial reflexes were absent; the deep reflexes of the arms were considerably increased. All general sensory phenomena were normal, as were all the special senses except hearing on the left side, where the watch could not be heard through the air or the bones. The tuning-fork was heard better with the right ear. Percussion over the left mastoid process gave rise to an uncomfortable sensation, but to no distinct pain.

Immediately on admission into the hospital, at 2.30 P. M., Dr. Edmund J. A. Rogers saw the patient in consultation with me. The history of the subacute ear-trouble, the suppression of the discharge from the ear, the repeated and prolonged chills, lasting from one to two hours, followed by a rise of from four to seven degrees in the temperature, the pain and slight tenderness in the superior posterior cervical triangle, the pain in the left side of the head in the mastoid region associated with the affected ear, and the man's depressed condition and sallow appearance pointed to septic infection, most probably of the left sigmoid sinus. There did not seem to be any evidence of meningitis, and we had not watched the case sufficiently to enable us to form an opinion in regard to the presence of cerebral abscess. We decided to give one-half grain of calcium sulphid every three hours. Iron, quinin, and strychnin, together with free administration of alcohol and an abundance of nourishing and digestible food, formed the treatment on which we mainly relied.

Dr. Rogers ordered the left ear to be irrigated with hot sterilized water for a period of ten minutes every hour. At 9 P. M., the temperature was 103°, the pulse 89, the respiration 20. The pulse was full, but not well sustained. At midnight the temperature was 100.6°, the pulse 77, the respiration 20. On January 14th, at 6 A.M., the temperature was 99.4°, the pulse 73, the respiration 20. The man had slept well during the night without a hypnotic. He had taken an ounce of whisky in six ounces of hot milk every three hours while awake since his admission, and was feeling much improved.

On January 14th and 15th the following observations were noted: '*January 14th*, 9 A.M., temperature 98.2°,

[1] Read before the Golden Belt Medical Society at Abilene, Kan., July 11, 1895.

pulse 68, respiration 18; 12 M., temperature 97.4°, pulse 64, respiration 16; 3 P.M., temperature 98.4°, pulse 68, respiration 18; 6 P.M., temperature 98.4°, pulse 68, respiration 18; 10 P.M., temperature 99°, pulse 65, respiration 17. *15th*, 3 A.M., temperature 97.8°, pulse 62, respiration 18; 8 A.M., temperature 98°, pulse 66, respiration 18; 1 P.M., temperature 97.4°, pulse 68, respiration 18.

He was now apparently doing well, took a sufficient amount of nourishment, bore free stimulation well, and was getting a fair amount of sleep. During the evening of January 15th his temperature arose about one degree above normal, and at 2 A.M. of January 16th it was 100.4°, the pulse 82, the respiration 24, but at 7 A.M. of the 17th the temperature had fallen to normal. During the next forty-eight hours the temperature varied from a degree to a degree-and-a-half above normal, and the patient was slightly restless, and did not relish his nourishment as well as he had previously. At 7 A.M. of January 19th, after a restless night, during which the patient had suffered from considerable pain in the left mastoid region and in the posterior portion of the head on the left side, the temperature registered 99°, the pulse 74, the respiration 18. During the day he felt restless, and at 4 P.M he began to feel chilly, and hot bottles were applied to his feet. At 5.30 P.M. the following notes of the case were made:

"The patient has been restless, worried, or emotional all day. His condition does not seem so good as it did yesterday, and he complains of considerable pain in the left upper posterior cervical region. The left posterior cervical muscles are somewhat rigid; they stand out prominently and are slightly tender to pressure. The man is unable to bring the head forward to anything like the normal extent, and the attempt to do so gives him considerable pain in the rigid muscles. There is no pain in the head or ear, and no tenderness over the ear or any portion of the head. The patient points to the attachment of the cervical muscles to the cranial bones as being opposite the site of the uncomfortable feeling that seems to him to lie deep in the parts. There is no paresis or paralysis of any of the external ocular muscles. The pupils are normal in size and respond feebly and slowly to light; accommodation is normal. The ophthalmoscope shows slight haziness of the margin of the optic nerves, more marked on the right side than on the left (in which the veins seem very large). The knee-jerks are greatly increased; the plantar reflexes almost absent; ankle-clonus is absent; the cremasteric reflexes are present but very feeble, while the abdominal reflexes are absent. There is no paresis or paralysis of any muscles. The mind is perfectly clear. The temperature is 99.4°, the pulse 78, the respiration 16." One-and-a-half hours later, or at 7 P.M., a chill occurred and the temperature rose to 101°; the pulse then was 88 and the respiration 18. The chill lasted until 8 P.M., when the thermometer registered 104°; the pulse was 100 and the respiration 24. During the night the temperature descended to 99.8°, the pulse to 84, and the respiration to 16. On January 20th, at 9 A.M., the man felt more comfortable. At a consultation, three hours later, with Drs. Rogers, Parkhill, Lobengier, and Stenhouse, an operation was decided upon for 1 P.M. The opinion was concurred in by most of us that the pathologic condition was a probable infecting focus in the mastoid cells and antrum, and phlebitis of the sigmoid sinus, with possibly meningitis of the posterior fossa of the left side. Abscess was not suspected. The repeated chills, followed by high and vacillating temperature and the pain in the posterior upper cervical triangle, in association with otitis media, were in favor of phlebitis of the sigmoid sinus; the only reason that meningitis was suspected was from the stiffness of the posterior cervical muscles; while the absence of headache seemed to militate against abscess from ear-disease.

SURGICAL HISTORY BY DR. ROGERS.

The operation was begun at 1.30 P.M. Full preparation had been made to wash out the lateral sinus, but as a preliminary step the mastoid antrum and cells were opened by chiselling and were scraped. No pus or indication of disease was discovered. An incision was then made backward, with the intention of trephining, to reach the sinus. In clearing the bone a large vein (mastoid) was cut immediately over the sinus and the blood flowed very freely. This seemed to show that the sinus was unobstructed, and it was decided to try the effect of this free local depletion before going into the skull. Some ounces of blood were allowed to escape and the venous foramen was then packed with coarse silk-thread and the wound closed. At 5 P.M. the patient had a severe chill and the temperature rose to 105.2°. It fell in a few hours below 100° and did not rise again. Rapid convalescence with the disappearance of all serious symptoms followed, without complications, and the patient left the hospital, apparently well, in two weeks.

SUBSEQUENT HISTORY OF THE CASE, WITH REMARKS, BY DR. ESKRIDGE.

During the first month after the patient left the hospital I saw him regularly once or twice each week. He seemed to gain gradually in strength and flesh, but at times, especially at night, he became confused and would do or say foolish things. He did not suffer from severe head-pain, but was conscious of a disagreeable sensation referred to the head most of the time. Mental effort exhausted him. Early in March, or about six weeks after the operation, he became depressed mentally, grew suspicious of his physicians, wife, or of anyone who manifested an interest in him. At this time his headache was often very severe, and sometimes in his desperation he would strike his head against the furniture or walls of his room. He refused to receive any attention from Dr. Rogers or myself. Not infrequently he gave vent to violent outbursts of anger, and would threaten to kill his wife. He made several engagements to visit me at my office, but he never kept any of them. He remained on the street a great deal of the time, both day and night, and on one or two occasions he disappeared and was not heard from for two or three days. He was either unwilling or unable to give an account of his whereabouts during these times. His wife became greatly alarmed about his condition and arranged with me to call on him late on the night of March 20th. I called about eleven o'clock and found him in bed. He received me kindly, answered questions readily, and made no objections to my examining him. He complained bitterly of headache and said he could not sleep well. I did not make a thorough examination that night, as he promised to call at my office the next day.

I found both optic discs congested and apparently a little swollen. The fields were preserved and the pupils were equal, normal in size, and responded readily to light and in accommodation. The knee-jerks were decidedly increased. I did not pursue the examination further, as the man promised to submit to a prolonged examination the next day. He showed no undue irritability during my visit. After I left he became violent and threatened to kill his wife and other inmates of the house, because, he maintained, they were conspiring against him and had arranged for me to visit him when he did not wish to see a physician. He did not visit me the next day, and the day following he left town with his wife. On May 1st I received a letter from his wife stating that he was still suffering considerably from his head and sought relief by bathing it frequently in cold water. At times he was quite dizzy. Occasionally he was attacked with excruciating pains in the head and would often give way to outbursts of anger, when he would threaten to kill his wife. On June 20th I again heard from him indirectly, and my informant stated that he was apparently no better; and that he was still suffering from headache, and was subject to outbreaks of violent temper.

On July 10th and 27th I again heard from the patient. On the date first named his wife called at my office, and said that her husband was less violent, but that he still suffered from headache and had lost considerable flesh. He was still suspicious of everyone and refused to see a physician. They were living about two-hundred-and-fifty miles from Denver, but, as I had to visit Pueblo on July 30th, the woman promised, if possible, to meet me there with her husband on that day. On the 27th of July I received a letter from her stating that it was impossible to get her husband to consent to visit Pueblo, and that he was still suffering severely from pain in the head.

The history of the case subsequent to the operation demonstrates that while the course of the disease was somewhat checked by the surgical procedure, the entire morbid process was not removed. It is probable that partial obliteration of the sigmoid sinus was effected by a septic thrombus, and that the bleeding at the time of the operation relieved the congestion, but that the infective thrombus subsequently invaded the brain-substance.

In the absence of a thorough examination since the beginning of the severe headache and the mental symptoms subsequent to the operation it is impossible to determine the condition of affairs at present. The probabilities are that the man is suffering either from a focal pachymeningitis or from abscess of the brain. It would probably have been better had the sigmoid sinus been exposed and cleansed at the time of the operation, for the history of the case up to that time, with repeated high temperature, the sudden rise in temperature being always preceded by a chill, indicated the presence of a thrombus. In a subsequent case presenting similar symptoms, I should urge that the sigmoid sinus be entered, notwithstanding that the veins leading into it may indicate that the sinus is not completely occluded.

The diagnosis of acute brain-trouble following otorrhea rests between infective thrombus, meningitis, and abscess of the brain. The clinical history of each of these morbid processes, when taken individually, is quite distinct, and the diagnosis is comparatively easy when the symptoms of one of these pathologic states do not obscure or complicate those of the others. Unfortunately we may have two, or all, of these morbid processes existing at the same time in the same individual, when the symptoms of abscess may be totally obscured by those of meningitis or thrombosis. Meningitis is attended with a continual elevation of temperature considerably above normal, and usually also with symptoms of intracranial nerve-irritation, and not infrequently, further, with retraction of the head, while an infective condition of the sinus is marked by repeated chills followed by high temperature and well-pronounced febrile remissions. The pulse is rapid and weak, and tenderness is often present over the mastoid region and posterior upper cervical triangle of the neck and over the course of the jugular vein. The symptoms of an infective thrombosis are so obtrusive as in a great measure to overshadow those of abscess. The affection of the sinus demands the first attention, as a cure would be impossible though the contents of the abscess were evacuated, so long as the condition of the sinus was allowed to go unrelieved; and the abscess should receive attention later, if it is possible to diagnosticate it. The presence of basilar meningitis of the posterior fossa is evidenced by retraction of the head, and of the middle fossa by involvement of the cranial nerves.

NOTES ON A CASE OF LEPROSY.

BY C. F. HERSMAN, M.D.,
OF ST. LOUIS, MO.

DURING the winter of 1894 there entered the City Hospital, in St. Louis, a well-marked case of the mixed form of leprosy. The true nature of the affection was first recognized by Dr. W. L. Russell, at that time Senior Assistant Physician. It is through his kindness that I saw the case.

The brief clinical notes that were made at the hospital give the following information in regard to the case: The patient was a man, sixty-five years old, who was born in the State of Illinois. Most of his life he had followed the trade of a tinner. Save an attack of gonorrhea many years ago, he had never suffered from any illness till his present trouble began. There was no history of syphilis. The man had used alcohol in moderation. A good many years ago (he did not recollect just how long, but thought about twenty years) he lived in South America, associating intimately, even to the extent of sexual intercourse, with persons who had a peculiar spotted condition of the skin. Some of them had lost their fingers; at the time the man understood that these peculiarities were the results of smallpox.

The patient could not tell exactly when his trouble began, but said that it was at least four years ago. He first noticed a red spot on one of his thighs, which, after a time, was replaced by a bleb that left in its wake a superficial ulcer. From this time red spots began to appear over the whole body. On the trunk and limbs there were to be seen many white spots, irregularly oval in outline, from a quarter of an inch in diameter to the size of the palm. The intervening skin was of a dark brownish-red and was evidently hyperpigmented. The white, atrophic-looking spots were most noticeable upon the back and the extensor aspects of the limbs, though there were a number upon the front of the body and the flexor surfaces. For some time the patient had

been anesthetic to such a degree that he burned himself without knowing it.

When admitted to the hospital the man had an irregular fever, which was thought to be malarial. At the end of two weeks the fever declined, and there were noticed in the sacral region some fifteen or twenty nodules, slightly elevated, from a pea to a bean in size. The nodules seemed to be somewhat darker in color than the skin surrounding them, but the difference was so slight that one could scarcely discern the nodules except by looking obliquely across the surface. During the febrile attack the temperature was at one time as high as 103° F.

Physical examination revealed no lesions of the viscera.

The urine had a specific gravity of 1015, and contained neither albumin nor sugar.

On examination as to sensibility it was found that in the white patches touch, pain, and the temperature-sense were equally affected, in the center of the patch to such an extent that all three seemed practically absent. In the skin between the white atrophic patches (that portion of the surface where hyperpigmentation was present) the sense of pain seemed in many places much more affected than touch, while the temperature-sense might be said to occupy an intermediate position, being not so much affected as the pain-sense, but more than touch. In the ulnar nerve above the right elbow could be felt several nodules. The ulnar and peroneal nerves of both sides seemed larger than normal and were quite tender on pressure. There was marked paresis of all the extremities, though no absolute paralysis was discovered. The tendon-reflexes were increased. One of the nodules was removed from the back, and, after hardening in alcohol, sections were made and examined for lepra-bacilli. The sections were heated for a few moments in carbol-fuchsin solution and then decolorized. A surprising number of bacilli were then visible, lying for the most part in masses that were situated in the upper part of the corium. These masses were so large and so numerous as to give a reddish hue to the specimen when viewed with the naked eye. In many portions of the section the bacilli could be seen lying in rows connecting the larger masses, as though lying in the lymphatics of the skin. The chief point of interest in this case seems to lie in the dissociation of sensation that was present. It has been taught that one of the chief points in differentiating syringomyelia from the nervous type of leprosy was that with the former malady dissociation was found, while with the latter the loss of the three senses, touch, pain, and temperature, was uniform. Here we have a case in which there can be no doubt of the diagnosis, in which this symptom, supposed to characterize syringomyelia, was well marked. It is not difficult to imagine that a case of the pure type of the nervous form of leprosy might exist presenting this dissociation and so making the differential diagnosis almost impossible. Petrini[1] has seen a case of leprosy in which the same phenomenon was noted, while Morrow[2] refers to a similar case that he has seen.

FRACTURE OF THE PELVIS.[1]

By W. F. BREAKEY, M.D.,
of Ann Arbor, Mich.

A man, about sixty years of age, while working on a building, fell about ten feet to the ground, in consequence of the breaking of a scaffold, striking on his left side on some stones. He was helped up and stood alone while he urinated, the urine appearing normal in color. He was taken to his home on a dray, where I saw him, soon after, with my son, Dr. James F. Breakey. The man was suffering from considerable shock, but was conscious enough to complain of severe pain in the left pelvic region and in the right forearm, in which latter was found a Colles fracture of the radius, with dislocation of the ulna. He was given stimulants and anodynes. Dr. Nancrede saw the patient at this stage with me. A cursory examination of the pelvis and left lower extremity showed marked flattening of left lateral pelvic and trochanteric outline, with slight apparent shortening of the thigh. There was eversion of the left foot, and abi'ity to move the thigh voluntarily in any direction in but slight degree; though the limb could be moved with abnormal freedom as far as resistance opposed. Movement, however, greatly aggravated the pain. There was crepitus, felt rather than heard, which, with the apparent shortening of the limb and the flattening of the hip, suggested fracture of the neck of the femur, but on rotation of the femur the trochanter described its normal arc. Traction of the limb in the line of extension restored its length, but did not restore the contour of the trochanter and hip, which had the appearance of lateral compression, though the femur seemed to be intact and not dislocated from the acetabulum. Further examination disclosed great mobility of the left pelvic brim and of the spine and ramus of the pubes on the same side, and fracture of pelvis was diagnosticated, though without supposing such comminution of bone as the fragments showed.

The nerve-supply and the cutaneous sensibility of the extremity were not impaired. There was inability to evacuate the bladder after the first effort, and the catheter had to be used. The secretion of urine was not interrupted. There was little to be done in the way of surgical treatment proper. The fractured forearm was appropriately dressed. The treatment of the fractured pelvis consisted chiefly in securing rest and support for the injured parts and the thigh and leg, with slight traction, which favored restoration of the contour of the hip and gave some relief from pain.

Though conscious for two days, the patient did not rally from the effects of the shock, and died on the third day after the injury, becoming partially comatose a few hours before death.

It is rare that the extent of such injuries can be demonstrated by postmortem examination, much less by the fractured bone itself.

The capsular and round ligaments of the head of the femur were intact, though lines of fracture ran through the acetabular socket. There was much bruising of the soft tissues contiguous to the fractured innominate bone, and to the rectum and bladder, though no lesions of

[1] Communication and fragments presented to the Mississippi Valley Medical Association, at Detroit, Mich., September, 1895.

these viscera could be detected. Some small fragments of the ilium were lost in maceration, as also were some fragments of the radius, showing an interesting case of Colles (or more nearly Barton's) fracture. The innominate bone was shattered into about twenty fragments.

The literature of the subject shows that fracture of the crest and processes of the ilium is comparatively infrequent; that of the ischia and one ramus only even more rare; but such extensive comminution as shown by this fracture is very rare.

Holmes gives an illustration of a case in which the head of the femur was driven through the acetabulum, and the appearance of this bone would indicate that a considerable part of the impact had been through the head of the femur.

I have seen two cases of fracture of the crest and processes of the ilium, one in a young person and one in a man of sixty, both of which made complete recoveries.

MEDICAL PROGRESS.

The Etiology of Goiter.—MORRIS (*British Medical Journal*, No. 1801, p. 13) reports that during two-and-a-half years' residence in Hambleden, Buckinghamshire, he has seen fifty cases of goiter among a population of two-thousand, with a possibility that there are others that escaped observation. The district is situated at the foot of one of the spurs of the Chiltern Hills. The soil is excessively chalky, and with few exceptions the water-supply is obtained from deep wells sunk into the chalk. When the water is low the water is drawn and even consumed while still milky in color, for the poor take little trouble to boil it or let it settle. No cases were encountered at the tops of the hills, where the people drink stored rain-water. Of the whole number of cases all were water-drinkers, but only four were males, and the ages ranged from four to seventy-six years. There appeared to be little doubt that the presence of calcium and magnesium carbonates in the water was the sole cause of the disease. In only one instance was there even the slightest suspicion of hereditary transmission. Neither was intermarriage a factor. The amount of iron in the water was infinitesimal.

The Warm Bath as a Diagnostic Measure.—RICHARDSON (*Asclepiad*, vol. xi, No. 43, p. 268) calls attention to the use of the warm bath in the diagnosis of diseased conditions of the abdominal cavity. The water of the bath is brought up to the natural temperature of the body, and the patient is allowed to recline in the water with all parts immersed, except the face and head, for a quarter of an hour before the examination commences. By that time the skin has become flaccid, and the parts beneath, especially the abdomen, are more readily felt through the abdominal walls. The method is applicable not only to emaciated subjects but also to the obese.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—TIMMER (*Deutsche medicinische Wochenschrift*, 1895, No. 37, p. 607) reports the employment of the antitoxin in the treatment of 147 cases of diphtheria between October 24, 1894, and June 1, 1895. There occurred 13 deaths, a mortality of 8.8 per cent. Among 51 cases requiring operation there was a mortality of 18 per cent. Diphtheria-bacilli were found in 117 of the cases, among which number there were 9 deaths, 7.7 per cent. The mortality in previous years, between 1883 and 1893, varied between 31 and 50.5 per cent. During this period the mortality in cases operated upon varied between 51 and 67.5 per cent.

BAGINSKY (*Berliner klinische Wochenschrift*, 1895, No. 37, p. 813) reports a mortality of 15.6 per cent. among 525 cases of diphtheria treated with the antitoxin up to March 15, 1895, as against a previous mortality of 41.1 per cent. From March 15 to August 31, 1895, 224 cases were treated with the antitoxin, the diagnosis being confirmed by bacteriologic examination, with a mortality of 9.37 per cent.

WELCH (*Bulletin of the Johns Hopkins Hospital*, vol. vi, Nos. 52, 53, p. 97) has collected from all accessible sources 7166 cases of diphtheria treated with the antitoxin, showing a mortality of 17.3 per cent., as compared with an estimated mortality of 42.1 in cases treated previously or simultaneously without the antitoxin. In 648 cases treated with the antitoxin in which tracheotomy was performed the mortality was 39.8 per cent.; in 342 in which intubation was practised the mortality was 28.9 per cent.; in 26 in which intubation was followed by tracheotomy the mortality was 53.8 per cent.; in 211 cases in which it is not stated whether tracheotomy or intubation was practised the mortality was 40 2 per cent. The estimated mortality in cases treated simultaneously or previously without the antitoxin was 64.5 per cent. after tracheotomy and 62.4 per cent. after intubation.

Chlorolin.—At a recent meeting of the Société des Sciences Médicales de Lyon, NICOLAS (*Lyon Médical*, 1895, No. 35, p. 15) detailed the results of observations upon a new antiseptic known as chlorolin, the chemic formula of which has not yet been determined. It was found that the addition of this substance in the proportion of 1 to 10,000 to nutritive bouillon prevented the development of diphtheria-bacilli. The addition of 5 per cent. to a bouillon-culture of diphtheria-bacilli was sufficient to destroy these. The agent in the form of vapor also had an injurious effect upon diphtheria-bacilli. In all cases the colonies in the neighborhood of those directly acted upon presented no changes in form or histo-chemic reaction, although their power of growth was interfered with and their virulence was diminished.

Iodoformin is the designation given by EICHENGRUN (*Berl. Ap.-Ztg.*, 1895; *Ph. P., Centr. f. die ges. Ther.*, Sept., 1895, p. 572) to an odorless modification of iodoform, appearing as a fine, white powder, insoluble in water and in the ordinary solvents. It is said to contain 70 per cent. of iodoform, which is set free by contact with the discharges of the wound.

In the Treatment of Furunculosis BROCQ (*Berliner klinische Wochenschrift*, 1895, No. 35, p. 776) has recommended extract of colchicum, in doses of from 2 to 4 cg. (gr. $\frac{1}{3}$–gr. $\frac{2}{3}$), in conjunction with topical applications of spirit of camphor.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, OCTOBER 5, 1895.

THE PATHOLOGIC NOVEL.

PHYSICIANS can no longer complain that the public is not interested in their work. Medical subjects are becoming the rage, not only in the froth—which is too often scum—of the enterprising reporter of the daily press, but also in the pages of our more permanent literature. The latest thing in antitoxins, the fashionable inoculation-cure for carcinoma, the most dramatic development in cerebral surgery, the appalling ravages (and still more appalling theories) of appendicitis fill column after column in our newspapers. The shortest road to fame nowadays is to invent a new remedy, operation—or bacillus.

The alarming increase of insanity, of neurasthenia, of carcinoma (due to the oxalic acid in the toothsome but treacherous tomato), of heart-disease, is bewailed at length. Such headlines as "He Swallowed a Lamp," "Another Victim of the Ghoulish Grapeseed," "Diphtheria Done Up," etc., stare at us from every page. This state of affairs is partly due to the morbid sensation-craze that spares no sanctuary in its ravages, but it is also largely indicative of a genuine interest on the part of the public in the physician and his work. There are drawbacks, it is true, and Koch is not the only medical man who has had occasion to cry "Protect me from my friends."

It is bad enough to see distinguished physicians and their favorite diseases misrepresented and suffering indignities of various description in the ephemeral sheet of the daily newspaper or weekly journal. But when it comes to mistreatment of this sort in the pages of permanent additions to our literature, it is time to lift our voices in protest. The worst offender in this regard is that school of novelists falsely calling themselves "realists." As the avowed apostles of the uncomfortable and repulsive, disease has of course a peculiar attraction for them. A carcinoma or a tertiary ulcer fascinates them as a velvet cheek or a rippling muscle does the true artist. Carrion of any sort, physical or moral, attracts them like vultures; but, like the vulture, they are wretched anatomists and worse pathologists. If the fidelity of their alleged photographs—which they mistake for pictures—of the "human animal" ("*La Bête Humaine*," Zola) is no greater than that of their portrayal of his diseases, their "details" and "studies" are essentially falser than the wildest visions of the romanticist, and this is actually the case, as that most constant and most loving student of his fellowmen, the physician, instantly detects and resents.

To no one is the "seamy side" of life more incessantly revealed or the secret heart of humanity more completely laid bare than to the physician, and yet we are unanimous in declaring that the wider our experience, the greater becomes our respect for and belief in humanity, while these dabblers are pessimists to a man. Their novels are therefore usually "pathologic," even though not dealing avowedly with disease as one of the *dramatis personæ*. One of the most glaring instances of this is the notorious *Kreutzer Sonata*, in which Tolstoi, the founder of the "New Christianity," practically declares through his mouthpiece, the "hero," that everything connected with family-life is a source of wretchedness, shame, and crime. Sexual intercourse, for instance, is in itself sinful and degrading, and involves the loss of mutual self-respect on the part of both husband and wife. "Christ's saying, 'He that looketh after a woman to lust after her hath committed adultery,' applies to a man's own wife." Children are merely a source of infinite worry and anxiety, and family-life is simply the breeding-ground of jealousy, spite, and furious quarrels. This writer finally comes to

the sage conclusion that it were better for the human race to become extinct than to continue to perpetuate itself by the present methods of marriage and the family. The doctor, of course, comes in with the rest for his splash of vitriol in the shape of the foulest insult levelled at the profession since the days of Molière, "the doctor who undressed her *and felt of her all over*, for which precious service I was compelled to pay and thank him, declared," etc. The insinuation is one of which only a *roué* and a Russian would have been capable, and yet its author is the acknowledged high-priest of the "gospel of humanity," of realism.

Of all diseases chosen as factors in the development of the dramatic situation, syphilis is, for obvious reasons, the favorite. It is supposed to combine physical and moral repulsiveness and retribution in a way that peculiarly appeals to these sensation-mongers. Accordingly, it can boast of several novels or dramas devoted exclusively to its exploitation. One of the most celebrated of these is Ibsen's *Ghosts*. In this passionate protest against the conventionalities—and decencies—of civilized life, the keystone of the whole dramatic situation is the appearance of a mysterious disease in the central figure, which his physician is made to declare is inherited from his dissipated father. This furnishes his mother with the necessary cue for a fiercely dramatic outburst against "society" for compelling her, not to marry the father, for this she admits she was under no real compulsion to do, but to remain faithful to him afterward. She hotly reproaches her spiritual adviser for his "cowardice" in not receiving her with open arms twenty years before, when she had fled to him and, with the engaging frankness of the new woman, informed him of her preference for him over her husband.

The situation is a touching one, the dramatic and ethical merits of which are beyond our sphere; but its pathologic elements deserve some comment. Firstly, no such disease as that here described by Ibsen is as yet known to the medical profession, though, now that his much-lauded "marvellous insight" has enabled him to discover, or, rather, invent it, we shall probably hear of other cases being reported. Secondly, Ibsen clearly intimates that he is trying to depict syphilis or some venereal disease; but he has made the trifling mistake (for a realistic photographer) of endowing the avowedly *hereditary* form of the disease with symptoms that can only occur in the *acquired* form. Even in that variety they have never yet been known to occur in the order, combination, and manner, or with the suddenness described. Thirdly, if the son had been the subject of the hereditary form of this disease, he would almost inevitably have presented unmistakable marks of it in his cornea, teeth, or complexion, and, perhaps, in all three. By a curious fatality, Ibsen, in his glowing description of the son's blooming youth and vigor, decking the victim for the sacrifice, as it were, touches upon the facial details in such a way as practically to preclude the presence of any of these signs. Fourthly, any brain-disease, venereal or otherwise, acute enough to destroy vision totally within five minutes, would almost certainly destroy life as well within a few days or weeks; while one of the most harrowing scenes of the play is the fervent pleading of the son with his mother to promise to give him a fatal dose of morphin as soon as his mind is gone, as his omniscient physician has told him that he may live on for years in an idiotic condition.

In short, the verdict of the pathologist upon this drama must be the same as that of both the true literary artist and the sociologist—*Bosh!*

In that recent product of the emancipated woman, *The Heavenly Twins*, we have another apotheosis of venereal disease. In this instance the fault of the drawing is in the perspective; but this is so glaringly incorrect that the effect of the whole is essentially false and unreal. Molehills are literally magnified into mountains. The main burden of the book, that men who have been dissipated in youth are usually incapacitated from becoming the fathers of healthy children, is as inconsistent with the known facts of the case as it is repugnant to common sense. Such disasters as the authoress describes may and do occur; wild oats must certainly be reaped some day, and we cannot be too strenuous in insisting upon a rigid scrutiny of both the record and the physical condition of the prospective husbands of our pure daughters; nor can the standard of male chastity be raised too high; but such results are, beyond peradventure, the decided exception. Ten per cent. would abundantly represent their frequency, even after such marriages; while the impression given through the whole of Mme. Grand's pages is that they are the almost invariable rule.

As to her minor proposition, that the strain and burden of maternity break the spirit and undermine

the health of women, both the records and medical opinion are diametrically opposed thereto. Married women are healthier, happier, and longer-lived than unmarried ones. Indeed, the authoress has by a curious oversight or *gaucherie* actually proved the morbidness of her view of life by letting her extraordinary heroine and mouthpiece develop well-marked symptoms of insanity in later life and disappear from the scene with the shades of the asylum gathering round her.

In *Trilby* we have a charming little story utterly wrecked and ruined by a baleful and ghastly shadow of hypnotic influence, which hangs over it like a pall. Like most such "glooms" it has, happily, no counterpart in real life, not even in the life of the hospitals. There are two absolutely essential elements lacking in the verisimilitude of Svengali's influence over Trilby: Willingness to submit to being influenced on the part of the subject, in the first place, and the original possession of the faculties which she exhibited at his suggestion in the second. Without the first requisite hypnotism can never take place, though, of course, after the hypnotic state has been reached the subject's actions may be entirely beyond the control of her own will. As to the second, an absolutely tone-deaf person, as Trilby avowedly was, could no more be endowed by hypnotic influence with the power of appreciating harmony and distinguishing shades of musical expression than she could be changed from a blond to a brunet. Every physiologist knows that, no matter what her vocal powers might be, she would be utterly incapable of harmonious song unless she could hear and correctly appreciate the tones of her own voice. Deaf mutes, for instance, are dumb, simply because they cannot hear the sounds made by their usually perfect vocal apparatus, and consequently cannot regulate and combine them into articulate speech. No amount of suggestion or mesmerism can draw out of any subject anything more than was in them before. The popular idea that hypnotism is a sort of connecting-tube, through which the moods, will, impulses, and powers of the operator can be poured into the mind of the subject, is entirely unfounded. Finally the mysterious decline and death of Trilby from the "fearful drain upon her nervous force," without pain or symptom of disease, are highly artistic, but extremely unnatural. People do not die that way at thirty-one, except in novels, or from that cause at any age. In short, we are thankful that the painful later experiences and early death of Miss Trilby O'Ferrall not only did not happen, but could not have happened; and we sincerely hope that Mr. Du Maurier will recognize the fact in his forthcoming sequel.

Death and disease are painful and piteous enough; but, like a certain other morbid influence, not half so black as they are painted, and even from the hospital-ward and the postmortem table we may learn that

> "There are nettles everywhere,
> But sweet green grasses are more frequent still.
> The blue of heaven is greater than the cloud."

THE MILK-SUPPLY OF LONDON.

A commission instituted by the *British Medical Journal* has recently reported some results obtained in the examination of milk supplied to the city of London. Both whole milk, as ordinarily sold in the market, and condensed milk in cans, have been examined. The number of samples taken is, however, too small to form a satisfactory basis for judgment as to the quality of the general milk-supply of that large city; only twenty-five of each set, whole and condensed, being examined. The results as to the former indicate the usual conditions, skimming and watering, and the employment of preservatives. There is nothing very novel in this information; indeed, from what is known of the liability of milk to adulteration, and of the methods in common use, one could say without the examination of samples that the supply of any large city is tampered with in certain respects.

Many of the samples of condensed milk were found to have been prepared from milk closely skimmed, so that the proportion of fat was much less than that contained in standard brands of condensed milk. This is also a fact that has been known for several years. Some of the public analysts of England have called attention to the sale of condensed skimmed milk in England. A number of these brands bear on some part of the label a statement, direct or indirect, that the fat has been partly abstracted; but, as is usual in such cases, the indication is so printed as to escape casual inspection.

The special interest that attaches to these examinations is in reference to the probability of similar practices in this country. Examinations of standard brands of condensed milk prepared in Philadelphia and New York have been made during the last year or so for The Medical News, but no marked de-

ficiency of fat has been found. The proportion rarely runs over 12 per cent., and frequently does not go over 9; but even the cheapest brands have been found to yield a fair proportion. It is somewhat surprising that the American manufacturers have not sought to put upon the market condensed skimmed milk, and such products are liable to appear at any moment. The most serious objection to the condensed milk sold in this country is the very large proportion of cane sugar that is added. This ingredient frequently exceeds in quantity the constituents of the milk itself.

It has been stated that the number of samples of whole milk examined by the *Journal* Commission is too insignificant to form a basis for judgment as to the character of the London milk-supply. It is interesting to note that the milk supplied to certain public institutions was of very inferior quality, and it is doubtless true that in many cases the materials supplied to the tables of the officials will be found to be much better than that supplied to the tables of the inmates. This is a point that needs the active interference of the philanthropist, because it is reasonable to assume that a part of the work of improvement in the condition of the delinquent and defective classes will consist in providing them with wholesome food. As an indication of the extent to which, at least, one milk-supply company of London carries its supervision, we may instance the Aylesbury Dairy Company, located in the west end of London, which has for many years maintained an analytic laboratory, in which not only are extensive examinations of the milk and milk-products handled by it made, but also a sanitary supervision over the condition of the farms from which the milk comes is maintained. During the year 1894, 28,455 samples of milk and 2269 samples of cream were examined, in addition to a considerable number of examinations of other milk-products. Of the milk samples, over 12,000 were taken from the railway-churns on arrival at the company's depot. To control the men employed in delivering the milk 13,000 samples were taken before, during, and after delivery, and analyzed comparatively. In this company's work, which is conducted by one of the most distinguished analysts in England, the estimations of fat are all made by a rapid process devised by two Philadelphia chemists. No instance of tampering with the milk was found in all these examinations. Whatever may, therefore, be the general inference drawn from the work of the *British Medical Journal* Commission we must infer that a considerable proportion of the London milk-supply is quite above suspicion, and, as this result was obtained through private enterprise, it emphasizes the point that has previously been made in THE MEDICAL NEWS, that reform in the food-supply, and especially in the milk-supply, will be promoted largely by the development of enlightened business-principles.

EDITORIAL COMMENTS.

Vital Statistics in New Zealand.—New Zealand is one of the most interesting countries of the world. It is one of the latest English colonies. Settlement began in earnest in 1850. According to the official Year-book, the population was, in 1894, 672,265, exclusive of Maoris—357,635 males and 314,630 females. The Maoris number about 41,993. There were also, in 1894, 4044 Chinese, of whom 17 were females. The Chinese are diminishing in number at the rate of about 10 per cent. a year, while the Maoris have diminished 10 per cent. in twenty years.

The population of New Zealand is increasing rapidly by immigration. The population was 32,554 in 1854—17,914 males and 14,640 females; in 1863 it was 164,048—105,978 males and 58,070 females; in 1873 it was 295,948—170,408 males, and 125,540 females; in 1883 it was 540,877—294,665 males and 246,212 females. As the population now stands, a little over half, 393,371, were born on the islands. Only 70.02 per cent. were married in 1891. The excess of births over deaths was 11,420 in 1893, but 14,106 in 1884. During the year 1893 there was a gain of 10,412 by excess of immigration over emigration. The death-rate is marvellously low, between 12 and 13 per 1000 of population in the cities, and 10.23 in the whole colony. The infantile mortality was about 10 to each 100 births in the cities.

During the year 1893, 836 married men died, leaving 3352 children—1577 under fifteen years of age. The average number of children to each father was 4.01; 135 of the 836 fathers were childless.

The most astonishing and inexplicable showing is made in relation to the rate of births. Since 1881, in spite of an increase of population from 493,482 to 661,349 in 1893 and the increase of marriages at the same time from 3277 to 4115 each year, the number of births has fallen from 18,372 (or 37.55 per 1000 population) to 18,187 (or 27.50 per 1000 population). This cannot be due to any error of registration, the compiler of these statistics asserts. This rate is lower than that in any country in the world, except France (22.6) and Ireland (23.1). In the United States the rate is 30.7; in Scotland, 31.4; in Prussia, 37.7; in Austria, 38.1; in Hungary, 40.3.

The male births of New Zealand numbered 9310 to 8877 females, a ratio of 104.80 to 100. There were 188 cases of twins and one case of triplets. One mother in each 101 gave birth to twins. This has been the proportion during the last ten years.

Of the children 673 were illegitimate—37 in every 1000. This is less than in any other country except

South Australia, where the rate is 28.4 to the 1000, and Ireland, where it is 27. In Switzerland the rate is 46; in Italy, 68; in France, 81; in Austria, 147.

There were 30 divorces asked for, and 18 granted during the year 1893. Nine orphans were thrown upon the community for support.

New Zealand is the most socialistic country in the world. A large part of the land is owned by the colony and little of it is being sold. All public improvements are in the hands of the State, including the railroads and irrigation-plants. The factory-laws, female-labor laws, and child-labor laws are the most favorable to labor. All conspiracy-laws have been abolished and compulsory arbitration substituted. The contract-system on public works has been abolished, and in its place the cooperative system of construction substituted The land-tax (single tax of Henry George) and the graduated income tax discriminate against the large capitalist in favor of the laborer, and still with all these opportunities for easy living and certain employment the birth-rate is almost the lowest in the world. The prophecy of the Malthusian is denied by this new country, under these circumstances so favorable to the support of large families. This gives a new confirmation of the adage that all prophecies in which man is a factor are very hazardous.

An International Conference of Railroad and Steamship Surgeons.—An important international conference of persons interested in the sanitary service of railroads and navigation was held in Amsterdam on September 20th and 21st. The gathering was participated in by medical men in the service of a number of transportation-companies. Among the communications presented was a preliminary report containing the laws and regulations in force in Holland. From this report we learn that both in Belgium and Holland stringent laws exist relating to the safety of employés and passengers of railroads and steamships.

Owing to the good work of Professor Donders, all employés of railroads are obliged to undergo an examination of the eyes, not only on admission into the service, but also every five years thereafter, or after any disease or accident; and although this examination is conducted by the ophthalmologist of the company, yet the supervision of a governmental commission acts as a check in preventing any serious infringement of the act. The companies and the employés also cheerfully cooperate in its enforcement.

A commission appointed by the government regularly inspects each passenger-boat before it sails for a foreign port. The food is tested, both as to quantity and quality; the accommodation and necessary supplies are looked after, as well as the machinery and the general condition of the vessel; and the medical and surgical supplies necessary are prescribed by law. The ship-surgeon and the shore-doctor of the company examine the emigrants as they embark, and reject those who are unfit for the voyage, or whose admission into the foreign port would not be allowed.

To afford first aid to the injured on railways, it has been suggested that signal-stations and block-houses be supplied with surgical-emergency cases, and the employés of the road be given instructions in their use. Depots and railway-trains should likewise be provided with such medical supplies as are necessary in cases of accident. No doubt many a life is lost in railway-accidents because of lack of early attention.

There is as much, if not more, reason for the equipment of a train with emergency-cases as with axes and Bibles. The long-distance trains may even find it an advantage to carry with them a medical officer, whose services shall be at the disposal of passengers and employés.

In all seriousness, we venture to say that a well-equipped hospital and medical service may be one of the conveniences offered to end-of-the-century tourists by some of the transcontinental lines.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held in Detroit, September 3, 4, 5, and 6, 1895.

(Concluded from page 360.)

Dr. C. B. Burr, of Flint, Mich., read a paper on

THE PARANOIAC—A MENACE TO SOCIETY.

He made reference to the numerous recent murders of prominent persons by so-called "cranks." What to do with these persons is one of the problems confronting modern civilization, and is one demanding an answer from students of the subject. There is room enough in our asylums. The trouble is that harmless lunatics are kept in confinement, while dangerous paranoiacs are allowed their liberty. These murders disturb the public but a day, and do not scare us into further provision for a safeguard. The public does not sincerely seek advice from professional sources in the matter. No one who has been threatened by a paranoiac would be willing to have his commitment settled by a jury without medical testimony as to the danger involved in granting freedom to such an individual. The paranoiac is a menace to society, and should be sequestrated; but doubtless the public will continue to view with indifference, or approval now and then, the execution of a criminally insane person as "sane enough to hang," and vainly hope for a deterrent effect of this example upon other deluded minds.

Dr. I. N. Love, of St. Louis, related the case of a man who murdered his wife and child, having become a paranoiac through excesses and debauchery. The local medical profession agreed the deed was that of a paranoiac, yet a country jury declared that the man was sane enough to hang. The fact was emphasized that often these persons are stimulated to crime by the notoriety the newspapers give them, and consequently the papers should be encouraged to suppress such items.

Dr. Hugh T. Patrick, of Chicago, called attention to the fact that fixed delusions began as early in life as five or eight years, and that in such cases measures of restraint should be instituted early. These delusions are not always discovered, even by the family-physician.

Dr. A. E. Sterne, of Indianapolis, read a paper entitled

TOXICITY IN HYSTERIA, EPILEPSY, AND NEURASTHENIA.

He maintained that a toxic state is one of the most frequent and important etiologic factors in the diseases

named, and one that has received the least attention. The term toxicity should mean functional cellular perversion, causing or being caused by abnormal chemic reactions. The ordinary forms of hysteria are functional. There are, however, no pathologic alterations in the central nervous system itself. We have in many cases a condition of cellular intoxication. It is not necessary that there be any structural change. Many drugs induce a condition similar to hysteria; shock or injury does the same thing. In almost every case there will be some form of cellular malnutrition, and by failing to seek for this possibly the physician will miss the cause and cure. The female generative organs have no doubt been too often blamed as an etiologic factor in hysteria. When actual disease exists in these organs it should be properly attended to; but the organs are not to be blamed any more frequently than other organs. Again, some severe cases of hysteria occur in males. Epilepsy, like hysteria, is a diathesis, though of a more profound nature; but epilepsy presents true pathologic changes in the walls of the vessels, produced by some toxic agent acting at the same time on the ganglionic cells of the cortex. The attacks of epilepsy may resemble severe hysteria, but there is a fundamental difference. The attacks of the latter are never dangerous, while those of the former may frequently be so. Neurasthenia is not often complicated by either epilepsy or hysteria. There are three grades of neurasthenia—weakness, prostration, and exhaustion. Sexual neurasthenia is essentially a masculine affection, though not always or necessarily resulting from a vicious life. In the treatment of all of these cases the toxic element should always be kept in mind. In certain cases surgical interference is demanded. Change of scene and environment is the best treatment for hysteria and neurasthenia. The energies should be diverted into other channels, the remaining vital forces conserved, and suggestive therapy added as largely as possible, but hypnotism is to be omitted. The wakeful state is much better for suggestion. Electricity and the "rest-cure" play an important part in the treatment of all of these conditions; but every atom of nerve-force in every case should always be conserved.

DR. HUGH T. PATRICK, of Chicago, held that traumatic cases must be excluded from this consideration. They come under another class, such as adhesions, etc. He is quite sure that very many of these cases are due to a direct toxemia. Indeed, all conditions that may cause any functional derangement are in a measure toxic.

DR. STERNE, in closing, said he was convinced that the knife was being used too much in these cases. If one can be sure of the lesion, then operation should be undertaken if advisable. In many cases of hysteria, particularly in females, the thyroid gland is enlarged.

DR. HUGH T. PATRICK, of Chicago, read a paper on

SOME OF THE MORE RECENT METHODS OF STAINING NERVE-TISSUE,

illustrated by water-color drawings and presenting a most thorough and practical *résumé* of the subject, with its applications and technic. He considered the method of Nissl to be the method *par excellence* for nerve-cells. With it minute changes in the cell-structure could be detected which would elude any other method. The method of Bevan Lewis, while marking an advance in technic, was thought to be less perfect than it was claimed to be by its originator. It is, however, excellent for hypertrophied neuroglia-cells. There beautiful results obtained by the Golgi method, as modified by Ramon y Cajal, were illustrated, and the importance of the discoveries due to it were emphasized. Rosin's stain, which is practically the Ehrlich-Biondi blood-stain, gives in some cases almost ideal results. The method of Platner—ferric chlorid and dinitrosoresorcin—was illustrated as applied to normal and degenerated nerve-fibers; the method was thought to have an important future. The method of Marchi was said to excel any other for degeneration of from three weeks' to three months' duration. Allusion was also made to the developmental method of Flechsig, and to an unusual but valuable result of the Weigert-Pal stain.

DR. STERNE said that the carmin stain has a particular adaptability for double staining. In bringing out the anatomic details it is practically a necessity. The Nissl stain is the most exact, and for giving an idea of the ganglionic structure cannot be excelled. For all purposes the Marchi method is perhaps the most reliable.

DR. A. P. BUCHMAN, of Fort Wayne, Ind., read a paper entitled

PSYCHOLOGY IN MEDICINE.

He discussed the subjective and objective relations of mind and pathologic conditions. The unit, force, acting properly is health; abnormal action of this unit is disease. The structure of man is governed by a connected train of associated movements called ether, of the existence of which we can have no anatomic proof, but to which the growth of the body must bear definite relation. Fear, grief, anger, or joy modifies the functions of the vital centers. The sympathetic nervous system is the center of the emotions, the cerebro-spinal system that of abstraction. Thus we come to psycho-physiology and bio-chemistry. Thence we step to the subject of hypnotism. The different methods used in producing hypnotism were minutely described, then the possible uses and dangers of hypnotism in medicine were discussed, showing that while good might be done there was also much danger in its use.

DR. STERNE said that the hypnotizer possesses a dangerous power. Any one can hypnotize, as only a certain mental concentration is necessary. The interest in the subject is not so much medical as scientific. There is frequently, if not always, an element of fraud in hypnotism. There is a chance of murderers claiming that they were hypnotized.

DR. PATRICK emphasized the fact that the hypnotizer has no hypnotic power. It seems almost a farce to discourage this idea, as it was exploded a century ago. The influence is purely subjective.

DR. BURR remarked that the insane could not frequently be hypnotized. This would not be so if the hypnotizer had any power in reality. It is possible to accomplish some good in epilepsy with hypnotism; also in hypochondriasis and melancholia it might be valuable.

DR. C. J. HELM, of Peru, Ind., then presented a paper on

THE NERVOUS SYSTEM AS A FACTOR IN DISEASE.

He gave an excellent *résumé* of this subject, pointing out that slight functional disturbances, if constant and

continued, may produce actual organic lesions. Change is the great remedy for these troubles, not necessarily of surroundings, but of the waste places in the nervous system; the forces should be given some new direction. The patients are to be studied in every phase and gotten out of the ruts they have fallen into.

Dr. Robert H. Babcock, of Chicago, read a paper entitled

SOME CONSIDERATIONS WITH REGARD TO THE SENILE HEART.

He pointed out that the condition named is not always due to or necessarily found in the aged. Importance should always be given to the myocardial changes. Dyspnea is a most frequent symptom of senile heart, although it occurs in other conditions as well. It finally becomes the almost surely fatal symptom—Cheyne-Stokes respiration. Among the remedies advised was the hypodermic use of morphin in a single dose.

Dr. Fuetterer, of Chicago, said that some cases present a more or less intermittent pulse.

Dr. J. B. Herrick, of Chicago, stated that he considered arrythmia a frequent and most important symptom of the senile heart.

Dr. Babcock said that intermittence is not necessarily a dangerous symptom, but at the same time the senile heart is liable to stop during one of these diastolic irregularities of sudden onset. When Cheyne-Stokes respiration was present morphin seemed to act best in conjunction with small doses of atropin.

Dr. Frank Billings, of Chicago, presented a paper on

INTERCOSTAL NEURALGIA.

He took the ground that the affection is always secondary and, consequently, in reality, only a symptom. It may be due to toxic forms of functional nerve-disturbance, or to pressure by tumors. The functional form is most common and is usually due to a toxemia, or to defective excretion, or to malassimilation. Indigestion is a most frequent factor, whether due to the character of the food ingested or to nervous conditions. Insufficient food and lack of outdoor exercise are frequent causes. Intercostal neuralgia occurs oftener in females, usually on the left side. Palpitation is usually present, and gas in the stomach with eructation always. In diagnosis search must be made for the cause. The disorder may be confounded with pleurisy or muscular rheumatism of the heart. In treatment the cause is to be removed and any simple restorative tonic given.

Dr. W. H. Porter, of New York, read a very exhaustive paper entitled

NEW LIGHT ON THE ROLE WHICH IRON PLAYS IN THE PHYSIOLOGIC ECONOMY—HOW AND WHERE DOES THE HEMOGLOBIN COME FROM?

He maintained that hemoglobin is not the product of synthesis. Iron when employed medicinally is not excreted by the salivary, gastric, or sudoriferous glands. The hair takes up some, the urine a slight amount. The bile uses most, but the total in both hair and bile is only one-tenth grain daily. Some writers say that the iron is stored up in the liver, but this is not practical. The intake and output both being very small, we must conclude that iron in the body is very stable. There is then a question whether iron should be so frequently and indiscriminately used in anemia.

Dr. John North, of Toledo, said that he had almost given up the administration of iron in cases of anemia. In most cases the trouble in the alimentary canal should be corrected, the destruction of the nucleo-albumins avoided, and no iron will be needed.

The paper of Dr. John Aulde, of Philadelphia, on

THE ABORTIVE TREATMENT OF TYPHOID FEVER,

was read by the Secretary. The advantages of guaiacol, carbolic acid, salol, betanaphthol, and other drugs were reviewed, and the results of experience with copper arsenite related, the statement being made that the disease could be aborted at almost any stage by the use of copper arsenite, in conjunction with appropriate constitutional remedies. As a rule, gr. $\frac{1}{100}$ of copper arsenite should be given every four or six hours. The remedy may be given hypodermically if the disease has advanced to the second or third week.

Dr. Gustav Blech, of Detroit, read a paper on

MEDICINAL TREATMENT OF TYPHOID FEVER.

Dr. J. E. Woodbridge, of Youngtown, O., read a paper on

TYPHOID FEVER AND ITS ABORTIVE TREATMENT.

Dr. E. L. Shurley, of Detroit, presented a paper entitled

TREATMENT OF PULMONARY CONSUMPTION IN HOSPITALS.

He contended that for many reasons the treatment of this disease in general hospitals is not practicable. Other patients and dangers of contagion, whether real or imaginary, are important considerations. Homesickness and poverty are also against it. Foreign hospitals for tuberculosis are successful, but the conditions are different in this country. The Harper Hospital of Detroit has been more nearly successful than any other American institution. Americans are too restless and have not patience enough to test the system. The hospital must not only be thoroughly equipped, but located in an equable climate.

Dr. Gustav Fuetterer, of Chicago, presented a paper on

THE DIRECT CAUSE OF TUBERCULOSIS.

Inhalation, food, drink, direct injection of tubercle-bacilli into wounds, and heredity were considered the chief means of infection. What can be done to arrest its spread? (1) Early diagnosis. (2) Disinfection by every possible means. (3) Care by the patient. (4) Care by friends and attendants. (5) Personal cleanliness—bathing. (6) Avoidance of kissing at all times. (7) Cleanliness of teeth and mouth. (8) Sleeping alone. (9) Non-attendance upon public and private gatherings. (10) Care of expectoration. (11) Treatment in special hospitals. Scrofulosis and chlorosis were considered in their relation to tuberculosis, and treatment and diet for each dwelt upon at length.

The curability of pulmonary tuberculosis depends greatly on whether or not the patient comes early for treatment. A preference was expressed for treatment with oil of cloves. (1) A No. 1 gelatin capsule is filled

with pure oil of cloves, and taken with a glass of milk every two hours, from 8 A.M. to 10 P.M. (2) If the oil is tolerated, one capsule should be given every hour. (3) Oil of cloves and cold-pressed olive-oil are mixed in equal parts and injected hypodermically, a syringeful once or twice daily. This treatment is continued for four weeks, stopped for two weeks, and then resumed.

Dr. E. B. Dench, of New York, read a paper on

THE TREATMENT OF ACUTE INFLAMMATIONS OF THE MIDDLE EAR AND MASTOID PROCESS.

For convenience he divided the middle ear anatomically into two parts by a line drawn through the styloid process. Inflammations in the middle ear produce the ordinary results of the same process elsewhere within a cavity lined with a mucous membrane, but the tissue-necrosis is not so extensive; yet there is enough matter retained to cause an outward bulging of the tympanic membrane. If seen early, free bloodletting should be practised and a single dose of an opiate given—not more. Dry heat should also be applied locally. Wet heat is to be avoided. If the case is not seen until later, free opening is the only thing to be advised. The technic of the operation was minutely and carefully described. The more acute and severe the case the more prompt should be the measures for relief. An incision should be made often, even when it is known that the cavity contains no fluid. The incision does not end the danger; the entire cavity must be thoroughly washed out and made antiseptic by irrigation.

Dr. F. C. Heath, of Indianapolis, read a paper entitled

SEQUELÆ OF LA GRIPPE.

He reported several cases of ocular complications, and the more common ear-complications were noted and their treatment considered.

Dr. J. M. Ball, of St. Louis, read a paper entitled

ARTIFICIAL RIPENING OF CATARACT.

The history of the various operations was given and the several methods were explained. Before undertaking any of them, the surgeon should be sure the zonula is intact, the tension normal, and the pupil dilatable. Division of the anterior capsule in these cases is always more or less dangerous and may be serious. Bettman's operation, or direct massage or trituration, is, of all, the most desirable. It is the least dangerous, most certain, and speedy. It has stood the test of experience and is worthy of confidence. If prolapse of the iris occurs, the extended portion is to be snipped off at once, contrary to most authorities; but this course has been found satisfactory and beyond expectation.

Dr. J. O. Stillson, of Indianapolis, read a paper entitled

COMPLICATIONS IN CATARACT ARISING FROM DIABETES, ALBUMINURIA, ETC.

He admitted that diabetic cataract is as yet a puzzle. A serous retinitis is often a symptom of nephritis. Albuminuria is a frequent complement of cataract. It is not only desirable but necessary to treat these conditions, if they exist, before operating for senile cataract.

Dr. K. K. Wheelock, of Fort Wayne, Ind., read a paper entitled

RHEUMATISM AND GOUT IN THEIR RELATION TO THE EYE.

Dr. G. W. McCaskey, of Fort Wayne, Ind., followed with a contribution on

BIO-CHEMISTRY IN ITS RELATION TO NERVOUS DISEASES.

An endeavor was made to establish the general theory of the causation of nervous diseases by chemic poisons circulating in the blood and acting by a process of selective affinity upon different parts of the nervous system. These poisons were considered in the following groups, the classification being entirely tentative and based upon the source of origin instead of the ultimate chemic analysis or physiologic action. (1) Bacteriologic products—ptomains. (2) Products of perverted tissue-metabolism. (3) Defective elimination or excretion. (4) Perverted secretion of glandular organs. (5) Products of imperfect digestion. (6) Chemic compounds probably present in independent blood-states and of unknown origin.

Dr. J. H. Taylor, of Indianapolis, read a paper entitled

HOW SHALL WE REAR OUR BABIES?

Dr. Fenton B. Turck, of Chicago, read a paper entitled

DISEASES OF THE MOUTH, NOSE, AND THROAT AS ETIOLOGIC FACTORS IN CHRONIC GLANDULAR GASTRITIS, WITH BACTERIOLOGIC STUDIES OF THE PHARYNGEAL VAULT.

He said that bacteriologic study has developed the fact that upon the mucous membrane of the mouth, nose, and pharynx groups of micro-organisms may form which may also be found growing on the mucous membrane of the stomach, and certain germs that are found in the inflamed mouth may also be found growing on the walls of the stomach in gastritis. Under normal conditions the mucous membrane of the stomach does not favor colonization upon its walls; but let some etiologic factor come into play and micro-organisms will develop. The mouth, nose, and throat, when in a diseased state, become incubators ready to infect when the conditions of the stomach permit the development of micro-organisms upon its walls. The micro-organisms of the mouth are carried with the food into the stomach; many of them are again to be recognized in the stomach, and in cases of gastritis are found in colonies growing upon the walls of the mucous membrane. Dr. Turck, in his clinical and experimental work, has obtained similar groups of micro-organisms from the gums and from cavities in the teeth, as well as from the material removed by the gyromele (revolving sound) from the walls of the stomach. He has been able to cultivate upon the prepared mucous membrane of the pig some of the micro-organisms and to find them also developing in the stomach; but in the control-animal he has not yet found micro-organisms growing in colonies in the stomach. The conclusion was expressed that clinical observation indicates a marked relation between diseases of the mouth and post-nasal cavity and chronic inflammation of the stomach and intestines; that the invasion of the stomach from the infected mouth and pharynx is

supported by the fact that many of the non-pathogenic micro-organisms present the same biologic and physical forms in cases of gastritis as those found in diseases of the mouth and post-nasal cavities of the same patients.

Dr. H. W. Loeb, of St. Louis, read a paper entitled

EXPERIENCES WITH PAQUIN'S ANTITUBERCLE-SERUM IN THE TREATMENT OF LARYNGEAL TUBERCULOSIS,

in which he gave the history of nine cases of this disease, seven of which had been treated with the serum. The patients all improved greatly. One case in particular lost all dysphagia, pain in the larynx, cough, and night-sweats. Other patients showed a much greater improvement than under any other plan of treatment yet tried.

Dr. Paul Paquin, of St. Louis, explained in detail the treatment that he had instituted. He said that it was just in its beginning. It will have to be improved, and it will take years to do so. The best results have been obtained in the acute forms of the disease, and not in the chronic. The law underlying serum-therapy is a natural one. It is trying to fight bacteria by using Nature's remedy. He had had failures with serum, but he could mention some forty or more cases of recovery. He thought that in some cases other treatment would be required in addition to the serum. He had not had good results within periods of two or three months, and five or six months, or even longer, were frequently required. He had made over ten-thousand injections with the serum in tuberculous cases, but did not recall one that was attended with fatal results. He counselled study of the climate, as well as the patient, before sending a patient away.

Dr. Victor C. Vaughan, of Ann Arbor, Mich., read a paper on

YEAST-NUCLEIN AND ITS THERAPEUTIC USES.

He said that physiologically nucleins form the chief chemic constituents of the living parts of cells; that constituent of the cell by which this histologic unit grows, develops, and reproduces. This nuclein of various cells differs, and its variety is limited only by the variety of cells. Chemically the nuclein contains a large amount of phosphorus. Some is combined with albumin, forming so-called nucleo-albumin. The nuclein-molecule has a remarkable power of recuperation after partial decomposition. Some nucleins have germicidal properties. Experiments upon animals apparently proved that previous treatment with nuclein conferred immunity to the pneumococcus.

Dr. Hugh T. Patrick, of Chicago, read a paper on the

DIAGNOSIS OF HYSTERIA.

He dwelt particularly upon the peculiarities of hysterical anesthesia, hyperesthia, and paralysis. The principal peculiarities of the first are its distribution in the form of a glove, sleeve, or stocking, with a sharply cut border, and in disseminated and irregular patches. Attention was called to a distinguishing trait not yet described, namely, almost instantaneous shifting of the line of demarcation between the anesthetic and normal areas. This peculiar feature applies equally well to hyperesthesia. Among the hyperesthesias were described hysterical joint-disease and hysterical angina pectoris, with the differential points of diagnosis between these affections and organic disease. The peculiarities of the hysterical gait were described at some length and their relation shown to astasia-abasia. A protest was uttered against the last-named affection being considered a nosologic entity, as it is simply an exaggeration of a common feature in hysterical paralyses. The peculiarities that distinguish an hysterical from an organic paralysis of the upper extremity were also described, and hysterical affections of the special senses were briefly alluded to.

Dr. B. M. Ricketts, of Cincinnati, read a paper entitled

HEMORRHOIDS; PROLAPSED RECTUM; A NEW OPERATION.

In the treatment of hemorrhoids it was recommended that after widely dilating the sphincter with the fingers under surgical anesthesia, a large semicircular needle should be passed subcutaneously from the muco-cutaneous line to the upper border of the pile-bearing area, and then returned so as to make its exit at the point of entrance. The needle is then removed and the silk ligature made tight about the venous plexus, and the ends left hanging out. These ligatures may be from one-half to an inch apart as the case may require. It is not necessary to tie all the varices in this way, as the atrophic changes will necessarily obliterate the remaining ones No tissue is sacrificed; the mucous membrane remains intact; there is no hemorrhage, no infection, no pain of consequence, and there is practically no loss of time. The sutures are allowed to come away of their own accord. The operations performed in this way have resulted in an absolute cure, and the patients have experienced but little pain during the life of the ligature.

Prolapsed rectum is treated in the same manner, except that a greater number of ligatures are required. If they are properly and evenly adjusted, the atrophy of the tissues is symmetric and the pathologic condition is relieved without stenosis.

Dr. Wm. Pepper, of Philadelphia, delivered the Address on Medicine. His subject was

DANIEL DRAKE, OR THEN AND NOW.

Daniel Drake died in Cincinnati in 1852. He was universally recognized as the leading medical man of the West. He graduated at the University of Pennsylvania in 1816; the exceptional honor of a special commencement held for this purpose being granted to him. He had already practised medicine for twelve years without a diploma, and had won a high reputation by his scientific and literary work. Dr. Drake received no fewer than thirteen separate calls to medical professorships and actually held at different times nine chairs in five separate institutions, in Cincinnati, Lexington, Louisville, and the Jefferson Medical College in Philadelphia. Dr. Gross, who was a colleague in two institutions, pronounced him the most forceful and eloquent teacher he had ever known.

Dr. J. Homer Coulter, of Chicago, read a paper entitled

THE DEFLECTED SEPTUM AND ITS REPAIR.

He first dwelt upon the etiology of the condition. In stenosis of any degree there is with each inspiration created within the nasal cavity a more or less complete

vacuum. Thus the atmospheric pressure is to that degree increased and is a constant force of no inconsiderable gravity. It was further contended that such a force would be more efficient in producing structural changes in the cartilaginous septum than would a more violent force suddenly applied, because the natural cartilaginous resiliency would more easily recover and throw off the effect of the latter. Some points in the operation were dwelt upon, because in the observance of these lies the success of the operator. When the deviation is well anterior or involving merely the alæ, it is very much simplified because of convenience in operating and after-treatment as well. Until recent years but little attention was paid to the preservation of the mucous membrane when operating on a deflected septum. A new form of punch was suggested for removing the cartilage and leaving the membrane intact.

DR. W. F. BREAKEY, of Ann Arbor, Mich., read a paper entitled

A CASE OF COMMINUTED FRACTURE OF THE ILIUM, WITH SPECIMEN AND PHOTOGRAPHS.

(See page 375.)

DR. HAL C. WYMAN, of Detroit, read a paper entitled

THE TREATMENT OF CARCINOMA.

He urged early removal, while the disease is local.

DR. LEWIS C. CLINE, of Indianapolis, read a paper entitled

LARYNGITIS FROM A RHINOLOGIC STANDPOINT.

He applies the affix *itis* only to inflammations of a purely catarrhal character, which excludes at once syphilis, tuberculosis, and other constitutional diseases, as they are more properly described by their specific designations. The cases that are least amenable to treatment are the atrophic, but much can be done to comfort and palliate these cases by attention to dress and by stimulant and lubricant applications. As a stimulant and astringent, he finds nothing equal to silver nitrate, from 10 to 40 grains to the ounce, according to indications. When the condition is due to overwork, the first law is rest, with occasional mild, stimulating applications with an atomizer. The great majority of cases that had come under his observation had had atrophic or hypertrophic rhinitis to a greater or less degree. Spurs and deflected septa are often associated with these conditions. The lesions most frequently observed are hypertrophies of the posterior ends of the inferior turbinate body, and a thickened, lumpy condition of the posterior end of the septum. The drill, saw, snare, and galvano-cautery are aids in removing these conditions in the more aggravated forms, while the application of silver and various astringents by means of sprays had served well in the mild form.

DR. J. A. WESSINGER, of Ann Arbor, Mich., contributed a paper on

THE THERAPEUTICS OF OLEO-CREOSOTE AND CREOSOTE CARBONATE.

He summed up his experience with these remedies in the following conclusions: 1. The dosage is practically unlimited as far as toxicity is concerned, but it is preferable to begin with a small dosage, from two to three drops after eating, and increase until the desired result is obtained. 2. To be of value in tuberculosis, a clinical diagnosis must be made early. 3. While these agents are distinctly germicidal, they also serve as tissue-builders. 4. Creosote carbonate and oleate have the power of increasing the number of red blood-corpuscles, and they also increase the percentage of hemoglobin in the blood.

DR. I. N. LOVE, of St. Louis, read a paper entitled

THE BICYCLE FROM A MEDICAL STANDPOINT.

He contended that bicyclists should understand the importance of going reasonably slow. The wheel brings into play all the muscles, and the maintaining of equipoise has beneficial results. The matter of position is important. The rider should maintain an erect posture and not assume an unsightly stoop in imitation of the hoop-snake, which takes its tail in its mouth and sails through the country. A study of the question of the wheel for women had resulted in an opinion favorable to its moderate use in cases of acute diseases. Specialists had agreed to this. Numerous cases of long-standing pelvic disease had been benefited by a judicious use of the bicycle. Women maintain a better position than men. An hour's wheeling three times a day is ample. The costume is important from the standpoints of health and art.

The discussion was participated in by Dr. C. B. Parker, of Cleveland; Dr. W. M. Wishard, of Indianapolis; Dr. Sterne, of Indianapolis; Dr. Walker, of Evansville, Ind., who all advocated and advised a moderate use of the wheel for both men and women.

DR. T. O. SUMMERS, of St. Louis, read a paper entitled

THE PHYSIOLOGIC ASPECTS OF LEUKOCYTOSIS.

DR. A. GOLDSPOHN, of Chicago, read a paper entitled

THE PROPER INDICATIONS FOR REPAIR OF PATHOLOGIC LACERATIONS OF THE CERVIX UTERI, AND FOR THE RELIEF OF PATHOLOGIC ANTEFLEXIONS AND THE PROPER OPERATIONS TO MEET THEM.

The Nominating Committee reported as follows, and the report was adopted:

President, Dr. H. O. Walker, Detroit. *First Vice-President*, Dr. B. M. Ricketts, Cincinnati. *Second Vice-President*, Dr. F. C. Woodburn, Indianapolis. *Secretary*, Dr. H. W. Loeb, St. Louis. *Treasurer*, Dr. H. N. Moyer, Chicago. *Judicial Council*, Drs. W. M. Wishard, T. E. Holland, and A. P. Buchman.

The Nominating Committee also submitted the following resolutions:

Resolved, That it is the sense of this Committee that the best interests of the Association will be subserved by the appointment of a permanent Executive Committee, composed of the titulary officers of the Association and the ex-presidents, and that this Committee shall conduct all the business of the Association; be it further

Resolved, That we recommend the creation of the office of Assistant Secretary, to be appointed by the Chairman of the Committee of Arrangements from the place in which the meeting is held.

On motion, the Association adjourned to meet in St. Paul, Minn., on the third Tuesday of October, 1896. Dr. C. A. Wheaton, of St. Paul, was selected Chairman of the Committee of Arrangements.

AMERICAN ORTHOPEDIC ASSOCIATION.

Ninth Annual Meeting, Held in Chicago, September 17, 18, and 19, 1895.

(Concluded from page 363.)

Dr. James Kerr, of Washington, D. C., followed with a paper entitled

JOINT-DISABILITY FOLLOWING FRACTURES.

Dr. R. W. Lovett, of Boston, read a paper entitled

AMBULATORY TREATMENT OF POTT'S DISEASE.

He considers this disease a very grave one, which ought to be treated largely by recumbency during the active stage, for the reason that existing apparatus is intrinsically imperfect on account of the nature of the problem. Apparatus is to be used in a small way to vary the monotony of recumbency. Used in any way it should be remembered that the position of the superincumbent weight is a most important matter, and that the chest and head should be thrown as far back as possible. Indeed, nature is continually trying to throw the chin into this position. It should also be remembered that the higher up the body or the more nearly backward the pull is made, the less force is required, and that when this limitation in the use of apparatus is accepted, its field will be more limited than it is now. The use of traction during recumbency seems an advantage, inasmuch as it adds but little to the discomfort of the child and manifestly increases the length, which it can only do by diminishing the curvature of the vertebral column.

Dr. A. E. Hoadley, of Chicago, exhibited and described a new

SPINE-BRACE,

designed and adapted for the mechanical support of the middle region of the spine. The range of its greatest utility is the support that it affords to the spinal column between the middle of the lumbar and the middle of the dorsal region, although its usefulness is not strictly confined to these limits. Inasmuch as the greater number of diseases of the spinal column requiring mechanical fixation occur within this region, the usefulness of the brace will be comparatively very great, if it is found to be efficient. In its simplest form the brace consists of a steel frame, a rigid chest-pad, and two aprons. The chest-pad is so adjusted in contour as to fit the upper anterior portion of the chest. The pad is in length about three times its width and is adjusted transversely, resting immediately below the sterno-clavicular articulations. Its real length transversely should be as great as is practicable without being interfered with by the action of the pectoralis major muscles in the movement of the shoulder. It should be made of sheet-metal, hammered to give shape and rigidity, covered and lightly padded.

Dr. Reginald H. Sayre, of New York, read a

REPORT OF FOUR CASES OF SPONDYLITIS OF THE SECOND CERVICAL VERTEBRA.

Three years ago he brought before the Association some cases of spondylitis of the second cervical vertebra, coming under observation within a few months and presenting almost identical lesions, accompanied by similar deformities. These cases had now been without apparatus to support the head for a number of months. In all there was noted a small swelling at the back of the neck, at the level of the first or second cervical vertebra, which in each instance happened to be on the right side of the neck. In each case the chin was directed toward the right side of the body; the right sterno-mastoid muscle was rigid; the face looked downward; while the left ear was brought much nearer the corresponding shoulder than its fellow. In one instance the face was deflected so far from the perpendicular as to be almost parallel with the floor, and pressed so closely against the clavicle as to cause an excoriation. The position of the head was in marked contrast with that assumed by patients with torticollis due to contraction of the right sterno-mastoid muscle. Motions of the head in any direction were excessively painful, and the patients supported their heads with their hands almost incessantly. In turning to view any object, the entire body moved as a solid mass, without any rotation of the head. The jaw was opened with great difficulty in all of the cases. At the present time in all but one of the cases the patients can open their mouths freely, and this one has much more control of the mouth than formerly, and is enabled to swallow with much more ease. In all the cases the chin was so much depressed as to make swallowing difficult. These cases were treated by means of a support consisting of a pelvic belt, with two upright back bars passing upward over the shoulders, and held in position by shoulder-straps and an apron. From this an extension-rod passed from between the shoulders to the base of the skull, where it joined a rolled metal band passing around the head and secured in position by a forehead-strap and a strap passing under the jaw from ear to ear. Universal joints at the back of the neck and between the shoulder-blades allowed the adjustment of this apparatus to any position of the head, while the distance between the head-piece and the body-piece was regulated by a ratchet-and-key extension. Three cases at the present time seem practically well, and since the removal of the support the range of motion of the neck has increased in all directions, and there has been no return of pain.

Dr. A. M. Phelps, of New York, followed with some remarks on a

STUDY OF THE ANTERIOR FORMS AND BURROWINGS OF LUMBAR ABSCESSES.

Dr. S. L. McCurdy, of Pittsburg, described and exhibited a

COMBINATION TRACTION AND IMMOBILIZATION HIP-JOINT BRACE.

He said that protection is afforded a diseased joint by confining the patient either in bed or in some portable appliance or brace that serves the same purpose. Immobilization is afforded by the use of plaster-of-Paris, the cuirass of Bauer, the portable bed of Phelps, or of Bradford and Lovett, or a Thomas hip-splint. Traction is of the utmost importance during the early stage to overcome muscular spasm, and secondly interarticular pressure, and ultimately to relieve pain, and during the stage of dissolution of bone to prevent shortening and angular deformity. In order then to apply traction, as well as immobilization, to the hip-joint in disease, Dr. McCurdy has devised a combination of the long traction hip-splint and the Thomas splint.

DR. JOHN D. SKEER, of Chicago, exhibited by invitation a

NEW SURGICAL SAW,

and made some remarks relative to its use. He said that when there is non-union of the bones after excision of the knee-joint we have conditions that may give rise to any degree of deformity. Any procedure that will prevent the rotation and backward displacement of the tibia, without the interposition of any foreign body between the cut surfaces of the bones, will contribute to the success of the operation. If the tibia were cut off slightly concave and the femur correspondingly convex, the bones would lock together in such a way as to prevent rotation and the backward displacement of the tibia. This method of joining the bones together was first practised by Dr. Fenwick, of Montreal, in 1868, and published in the *International Encyclopedia of Surgery*. The doctor used a fretwork saw adapted to a butcher's frame, and states that the "bones should be accurately adjusted, and if they do not fit nicely saw off a thin slice from either or both of the bones, and if necessary remove thin slices with the cartilage-knife."

Objection has been urged against Fenwick's operation, for the reason that pockets have been found between the ends of the bones, in which matter accumulated and prevented union. Dr. Skeer apprehends that the pockets and irregular open spaces were made with the narrow saw and the cartilage-knife at the time of the operation. He proposes to improve the technic of this operation by making the sections with a concavo-convex saw which he has devised for that purpose, and which cuts a true circle, so that when the cut surfaces of the bones are brought together they will coaptate with mathematic accuracy. The saw-blade is nine inches long and two inches broad, curved on the flat, with a concavity of one-fourth of an inch.

DR. W. O. PLIMPTON, of New York, read a paper entitled

EXCISION OF THE KNEE AS AN ORTHOPEDIC PROCEDURE.

He said that the success of the operation is no longer an experiment when performed under right conditions and by a skilful operator, and should save not only limbs but also lives. Too much cannot be said in favor of early treatment by mechanical and fixation methods in disease of the knee-joint. If the profession at large recognized disease of this joint in its incipiency and employed extension and fixation methods of treatment, comparatively few cases would advance so far as to necessitate excision. It is the duty of the teacher of orthopedic surgery to lay special stress upon the early recognition, as well as the early mechanical treatment, of these diseases. When the fixation-and-extension plan of treatment has been conscientiously tried and has not arrested the disease, the surgeon should explore the joint and do whatever the conditions demand, whether to wash out or to excise. When the articular surfaces are destroyed, the bone and the soft parts extensively involved, the joints should be excised.

In the series of excisions reported there were several examples of great destruction from osteomyelitis and tuberculous disease, in which amputation was avoided and several inches saved in the length of the limb by allowing the cavity to fill and the clot to organize. In one case of osteomyelitis seven inches of bone were reproduced. In determining what operation for excision of the knee best subserves the requirements, it may be said that that method which allows of the most complete removal of all diseased tissue and affords perfect drainage retains the parts in best apposition and fixes the bones without the use of pins or wire, and last but not least the one that can be performed with the greatest ease and rapidity is to be preferred. Fenwick's operation fulfils all requirements with a few exceptions. When the head of the femur is destroyed, precluding the section according to Fenwick, Phelps has devised a method to meet this condition by sawing a wedge at the end of the femur and a V in the tibia for its reception. The length of time taken for excision of the knee is an important element with regard to the mortality of the operation, as the shock of the operation in excision of the knee must of necessity be profound. It was said that Dr. Phelps did not consume on an average more than fifteen minutes in excisions of the knee, except in exceptionally bad cases. He has, in fact, effected an excision in ten minutes from the time the first incision was made until the last plaster bandage was in place.

DR. A. J. STEELE, of St. Louis, exhibited

AN APPARATUS FOR THE TREATMENT OF CLUB-FOOT, AND TWO CONTRIVANCES TO BE USED IN HEAD-TRACTION AND IN HIP-TRACTION.

DR. LOUIS A. WEIGEL, of Rochester, N. Y., read a paper entitled

MECHANICAL SUPPORT IN THE TREATMENT OF SCOLIOSIS.

He said that when a bony distortion has taken place of slight degree it can be easily understood that the superincumbent weight falling upon an inclined plane must of necessity increase the deformity, and any plan of treatment that will endeavor to relieve the spine of this adverse factor is certainly a rational one. It was contended that mechanical support may be worn for an indefinite length of time without producing atrophy, and that in spite of an appliance exceedingly good muscular development may be secured. If this can be shown, the principal objections against appliances will be done away with. The belief was expressed that a mechanical appliance can be used with as much benefit and be made to do its work and be worn as comfortably on the back as on the legs.

The following officers were elected:

President—Dr. Royal Whitman, of New York. *First Vice-President*—Dr. George W. Ryan, of Cincinnati. *Second Vice-President*—Dr. Joel E. Goldthwait, of Boston. *Secretary*—Dr. John Ridlon, of Chicago. *Treasurer*—Dr. E. G. Brackett, of Boston.

The next meeting will be held at Buffalo in the third week of May, 1896.

Louis Pasteur, the distinguished scientist, died at Paris on September 28th, at the age of seventy-two years. Among his most noteworthy work was an investigation into the morphology of bodies having a crystalline structure, his studies in fermentation, the discovery of the silkworm-parasite, of the parasite of chicken-cholera and a means for eradicating the disease by inoculation, and the treatment of hydrophobia by inoculation.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eighth Annual Meeting, Held in Chicago, September 24, 25, and 26, 1895.

The Association was called to order by the President, Dr. J. Henry Carstens, of Detroit, Mich.

After an Address of Welcome by Dr. William E. Quine, of Chicago, and a response by the President, the reading of papers was proceeded with.

Dr. James F. W. Ross, of Toronto, read a paper entitled

BILATERAL SUPPURATIVE PAROTIDITIS.

He narrated a case in which, on the tenth day after vaginal hysterectomy, the temperature rose to 103°, and a swelling in each parotid gland presented itself. The swelling gradually increased. The sides of the face became enormously swollen, the eyelids were puffed, and the patient could scarcely separate them. Double parotiditis is seen occasionally as one of the sequelæ of the infectious diseases, a distinctly septic affection. It is difficult to believe that the removal of the ovaries can produce a parotiditis. If parotiditis has a peculiar tendency to follow the removal of the uterus, we should have sufficient data upon the subject to make us well aware of this fact also.

Dr. Edwin Ricketts, of Cincinnati, related a similar case in which, two days after the removal of diseased appendages, double parotiditis made its appearance.

Dr. C. C. Frederick, of Buffalo, saw a case in the practice of a prominent practitioner in Buffalo a few years ago in which a double parotiditis followed ovariectomy. The woman made a good recovery. There was no suppuration in the case.

Dr. James F. Baldwin, of Columbus, narrated an instance in which the parotiditis was limited to the left side, having followed a vaginal hysterectomy about the third day, and being accompanied by elevation of temperature, pain, and swelling.

Dr. W. G. MacDonald, of Albany, said that parotiditis associated with the removal of the uterine appendages is not a new thing. Among the earlier operators it was not an unusual or uncommon complication. The patients, however, usually died. He saw one case following a supravaginal hysterectomy. He had also seen the complication after amputations of the thigh.

Dr. John M. Auld, of Chicago, had seen one case of non-suppurative parotiditis of one side, following perineorrhaphy and operation for hemorrhoids.

Dr. H. W. Longyear, of Detroit, had seen parotiditis associated with typhoid fever.

Dr. A. H. Cordier, of Kansas City, Mo., said that parotiditis occurs with greater frequency than is supposed in connection with operations involving the ovaries and tubes. He is inclined to believe that there is a sympathetic relationship between the ovaries and the parotid gland.

Dr. A. H. Ferguson, of Chicago, asked as to the condition of the patient's mouth at the time of the parotiditis. In scarlet fever, diphtheria, and a number of diseases associated with disease of the uterine appendages, extension takes place to the parotid gland. In such cases the mouth is foul, and if it can be kept clean parotiditis is not so likely to occur.

Dr. Ross said it is well known that the parotid gland, the thyroid gland, and the submaxillary gland frequently become inflamed in association with inflammatory disease of the testicles; but as to inflammation of the ovaries we are not so sure. He could not say as to the condition of his patient's mouth at the time of operation.

Dr. A. B. Miller, of Syracuse, N. Y., read a paper entitled

INTERMEDIATE TREATMENT OF PUERPERAL SEPSIS.

He summarized his views as follows: (1) Suspected infection of the birth-canal should be confirmed when possible by a bacteriologic examination of the vaginal secretions, and every means of differentiating it from other affections should be resorted to, that it may be treated rationally either by medicine or surgery. (2) Irrigation and antiseptics destroy the nutrition of the parts when continued, and, furnishing increased moisture, improve the field for the development of micro-organisms, aside from the danger of death resulting from the antiseptic used. (3) The birth-canal can be kept comparatively dry by absorbent dressing, removing the culture-media, and arresting the development of germs and infection until the abraded parts have been repaired.

Dr. L. S. McMurtry, of Louisville, Ky., followed with a paper on

THE INDICATIONS FOR OPERATION IN PUERPERAL SEPSIS.

He said that since operative surgery a few years ago disclosed the various lesions of pelvic disease, it has been known that pregnancy and the puerperal state may be complicated by pre-existing inflammatory diseases of the uterine appendages, tumors, and septic accumulations inside the pelvis. Chronic and circumscribed disease of this character may be converted into acute and diffuse inflammatory conditions by the trauma of labor. Puerperal sepsis may in this way be the result of pre-existing disease. This class of cases must necessarily be small, as women thus diseased are, as a rule, sterile. That such cases necessarily come within the scope of operative treatment will be generally conceded. The indications and guides for operative interference in this class of cases were then considered. In all cases of puerperal sepsis the most careful examination of the pelvic organs should be made.

In conclusion, allusion was made to the class of puerperal cases wherein the local symptoms are those of diffuse peritonitis without localization of lesions, but in which the uterus is presumably the focus of infection. This class of cases has recently been discussed extensively in relation to treatment by hysterectomy. Empiric operations in surgery are likely to prove more disastrous than similar methods of treatment in medicine. The gravity of such cases may often justify exploration and drainage, but the more extensive operation of hysterectomy will almost invariably prove disastrous.

Dr. W. E. B. Davis, of Birmingham, said with reference to cases of puerperal sepsis, in which the temperature runs high, that they usually die in from a week to ten days, and he believes surgery offers very little hope.

Dr. Herman E. Hayd, of Buffalo, said that when a septic condition arises in the endometrium, or when there remains a portion of the placenta which breaks down, he is satisfied that a sharp curet should be used.

With such an instrument the surgeon can scrape away a good piece of tissue and yet do very little harm.

DR. WM. WARREN POTTER, of Buffalo, said there is no puerperal fever except that due to infection; that if the history of these cases was carefully traced, the gynecologist would find underlying somewhere infection, which may be carried into the genital tract either by the obstetrician himself or by the environment of the puerperal woman; hence the great collateral interest lying closely alongside this subject is the one of preventive medicine. The important question is aseptic midwifery. If aseptic midwifery were practised in every case, there would be no puerperal sepsis and no ophthalmia neonatorum.

DR. W. P. MANTON, of Detroit, had never had in his private practice a case of puerperal sepsis. The curet is an instrument that, if properly used, is absolutely devoid of harm.

DR H. W. LONGYEAR believed that when the uterus is packed full of gauze the flow of mucus, blood, and serum is prevented. While more or less serum may possibly come away, fragments of placenta or bloodclots will certainly be retained. Rise of temperature, etc., should not be an indication for surgical interference in puerperal sepsis.

DR. WM. H. MYERS, of Fort Wayne, emphasized the importance of differentiating between septicemia and pyemia.

DR. C. C. FREDERICK said that out of forty cases of puerperal septicemia that he had seen in consultation in the last eight years, only two had died. Nothing could be found in the uterus, and there were hardly any localized symptoms.

DR. JAMES F. W. ROSS, of Toronto, dwelt upon the importance of the subject, inasmuch as a new craze at the present time has seized the profession—that of taking out the uterus in cases in which it is unnecessary, in his opinion, to remove that organ. The pendulum has swung too far, as it did when the removal of the ovaries was undertaken for vague symptoms, and the Association should take some means of swinging it back again to its normal position.

DR. W. G. MACDONALD, of Albany, related a case in which he favored the use of the sharp curet.

DR. SHERWOOD DUNN, late of Paris, France, said that in the Broca Hospital, Paris, there are 184 beds, 48 of which are devoted to obstetric cases. In his three-years' connection with the hospital-service there no case of confinement had ever been followed by any septic condition.

DR. A. J. BURGESS, of Milwaukee, said that in cases of uterine traumatism, especially in abortions, when there are retained septic tampons within the uterus, it is absolutely impossible to curet them away with a dull instrument. He has seen the dull curet used for half an hour at a time, and yet two days afterward pieces of membranes or clots had come away the size of a hen's egg. With a sharp curet everything can be removed.

DR. A. H. CORDIER, of Kansas City, Mo., emphasized the importance of treating every case of puerperal sepsis as an individual one. When surgical interference is called for, it must be resorted to early if we expect to save lives.

DR. G. E. KRIEGER, of Chicago, predicted that in time we would treat puerperal sepsis very much in the same manner as we treat diphtheria with serum.

DR. J. HENRY CARSTENS, of Detroit, emphasized the importance of differentiating between the different forms of infection. While the obstetrician may in some cases infect his patient, he believes in auto-infection. He thinks a sharp curet is not necessary for removing the shreds of membrane or other débris that may be left.

DR. FREDERICK BLUME, of Pittsburg, said that it had been proved years ago that in 50 per cent. of healthy women there were found streptococci or other pathogenic micro-organisms in the vagina. He uses a sharp curet for curetting the uterus.

DR. MARCUS ROSENWASSER, of Cleveland, O., read a paper entitled

EXCEPTIONAL LOCATION OF THE BLOODCLOT IN A CASE OF RUPTURED ECTOPIC PREGNANCY.

The case reported was presented with the hope that the knowledge of such possibility might prevent future confusion of an otherwise clear diagnosis.

DR. H. W. LONGYEAR, of Detroit, reported a case in which a woman bled for several months. On opening the abdomen the cavity was found filled with blood and clots, and after a tedious operation he was compelled to leave some of the clots in the abdomen. The patient died of shock some three or four hours after the operation.

DR. JAMES F. W. ROSS, of Toronto, reported a case of acute general peritonitis produced by the rupture of a suppurating clot. After an ectopic gestation this clot was found lying in the neighborhood of the broad ligament, and was not at all connected with the tube.

DR. EDWIN RICKETTS, of Cincinnati, said that the cases reported showed the importance of the earliest possible diagnosis. The subjective symptoms should be more carefully considered.

DR. W. E. B. DAVIS, of Birmingham, related a case, in the wife of a physician, who was delivered at full term of a uterine pregnancy. Then a mass was detected in the right lumbar region, which continued to grow larger. The patient was losing blood. Operation revealed a second ectopic gestation. The bleeding was easily controlled, and a rapid operation was undertaken, but the patient died from shock.

DR. RUFUS B. HALL, of Cincinnati, emphasized the necessity of early operation, or, at least, an early exploration in all instances of obscure abdominal disease. After an experience of fifteen operations for ectopic pregnancy, he is more and more convinced of the necessity of early operative interference.

DR. THOMAS J. MAXWELL, of Keokuk, Ia., called attention to transfusion with common salt-solution to tide over severe cases of hemorrhage.

DR. L. H. DUNNING, of Indianapolis, followed with a paper entitled

RUPTURED INTESTINAL PREGNANCY.

After describing a case in detail, he presented the following conclusions: 1. Ruptured tubo-uterine pregnancy is more frequently fatal than ruptured tubal pregnancy, for the reason that in the latter case the rupture frequently takes place through the abdominal end of the tube, in which case but slightly vascular adventitious tissue is torn, while in the former case vascular uterine tissue is torn. Again, in tubal pregnancy not infrequently the rupture takes place through the inferior surface of the tube into the folds of the broad ligaments,

and thus the amount of hemorrhage is limited, while in tubo-uterine pregnancy such a rupture is rare. 2. In ruptured tubo-uterine pregnancy before the fifth month, unless the abdominal section is made early, the anemia will be profound, so that the patient will be unable to withstand any operation involving prolonged anesthesia and manipulation. The operation should be as free from shock as possible. 3. There is no pedicle to tie. 4. All actively bleeding-points must be secured by ligature. 5. Mr. Tait proposes hysterectomy as a proper procedure in such a case. Unquestionably, if the patient is not too greatly shocked or anemic, such a procedure would be clearly indicated. 6. As a measure attended with less risk of shock, Dr. Dunning proposes the tying of bleeding arteries, clearing the gestation-cavity of the ovum, establishing free communication between the gestation-cavity and the uterine cavity, and free drainage by means of tube and gauze, and finally closing the rent in the uterine wall by deep and half-deep sutures, or by Czerny and Lembert stitches; or, instead of this method of closure, the stitching of the walls of the gestation-cavity to the lower angle of the incision, with drainage from above and through the uterine cavity, and finally closure of the upper opening by tying deep sutures placed and left untied at the time of the operation. This latter method will probably be found applicable only in a limited number of cases, namely, in those in which the uterus is freely movable and can be brought to the abdominal wall without tension. Whether the methods proposed have ever been employed is not known, and whether they will prove of value a trial must demonstrate.

Dr. T. J. Watkins, of Chicago, had met with a number of cases of extrauterine pregnancy, but none of interstitial pregnancy with rupture. He had one case in which the tube had ruptured and the placenta had grown fast to the cornu of the uterus, and in which it was impossible to form a pedicle, the condition in the case being similar to that of an interstitial pregnancy.

Dr. Byron Robinson, of Chicago, said that so far as operating on these cases is concerned it seems to him that anything other than hysterectomy means death to the woman.

Dr. Henry T. Byford, of Chicago, said that while he had never encountered a case of interstitial pregnancy, it was very essential to know how to proceed in such cases by surgical interference.

Dr. A. H. Cordier, of Kansas City, Mo., had seen one case of interstitial pregnancy in the practice of Dr. Lanphear, the uterus containing in addition several fibroids. Abdominal hysterectomy was performed.

Dr. E. T. Tappey, of Detroit, read a paper entitled

INTRAPERITONEAL ADHESIONS.

He said that abdominal surgery in the last few years had established, among other things, that many of the pains, vague, uncomfortable feelings, and so-called dyspepsias are caused by adhesions of various organs in the abdominal and pelvic cavities. The question of diagnosis is often perplexing, and in many instances impossible without abdominal section. Whenever there is pain, and palpation does not reveal any tumor or other enlargement, adhesions are one of the possible causes. The belief was expressed that it would be proper to subject cases of chronic dyspepsia, chronic and obstinate constipation, and cases of persistent pain caused by the accumulation of flatus, to exploratory incision to determine whether there be adhesions and for the purpose of severing them.

Dr. W. G. MacDonald, of Albany, read a paper entitled

INTESTINAL OBSTRUCTIONS—CLINICAL OBSERVATIONS.

He said that in no other branch of abdominal surgery is precise diagnosis so difficult or operative procedure more taxing to the ingenuity of the surgeon. At the present time surgeons of experience are quite unwilling to give a definite opinion until the abdomen is opened and closed. There is a large group of cases of ileus which may be regarded as purely symptomatic, a condition in which the continuity of the intestinal tube is interrupted, but the obstruction is due to conditions of paralysis in the intestinal wall.

The treatment cannot always be preventive, from conditions that arise during operations. The enucleation of pus-tubes or an extra-uterine pregnancy involves the leaving of extensive denuded surfaces to which intestines readily attach themselves, and those who have made secondary section can readily testify to the number of innocent adhesions found as a result of primary operations.

Dr. Edward J. Ill, of Newark, read a paper entitled

A CLINICAL CONTRIBUTION TO THE STUDY OF THE LATERAL DISPLACEMENTS OF THE UTERUS.

After reviewing the literature, reference was made to the importance of this abnormal condition, which it was thought had been generally overlooked, the patient's symptoms being attributed to other ailments. He had collected from his last year's office case-book all cases of lateral displacement except such as come with tumors. In 14.2 per cent. there was lateral displacement. Especial attention was directed to those cases that were considered congenital and in which the pain is referred to the elongated broad ligament. The symptoms begin early in the patient's sexual life, in severer cases progressing gradually to complete invalidism. Several histories were read and a typical case described. The non-operative treatment consists in endeavoring to elongate the shortened ligament by the use of dry-wool or oakum tampons pushed between the cervix and the ilium on the side of the shortened ligament, keeping the tampon in place by a second and a third one. All this is to be retained for forty-eight hours. A hot douche, with the patient on her knees and elbows, twice daily, when the tampons are *in situ*, is also ordered. Two cases were related of extreme suffering in which total extirpation of the uterus, tubes, ovaries, and broad ligament was deemed advisable after years of unsuccessful treatment, and both of which are much relieved of their suffering.

Dr. X. O. Werder, of Pittsburg, read a paper on

SOME OF THE INDICATIONS AND ADVANTAGES OF VAGINAL HYSTERO-SALPINGO-OÖPHORECTOMY.

He said that the operative results in suppurative disease of the pelvis in the hands of the abdominal surgeon form one of the proudest chapters in modern surgery.

While a more careful technic and a more thorough operation had lessened the number of fatal cases, they had not been entirely eliminated. Hysterectomy with salpingo-oöphorectomy in suppurative disease of the pelvis not only allows us to remove the nidus of infection more completely, but it gives the patient the very best chance for complete recovery, without adding any additional risk to the operation. The mortality compares favorably with that of salpingo-oöphorectomy alone. The opinion was expressed that hystero-salpingo-oöphorectomy is unquestionably the operation of the future; but whether vaginal or abdominal, still remains *sub judice*. The vaginal method has many features to recommend it. It precludes the possibility of ventral hernia and of intestinal and omental adhesions in the line of incision; and is followed by less shock because of the minimum exposure of the peritoneum during the operation, and absence of manipulation of the abdominal viscera. Convalescence is more rapid, and recovery more complete. Two cases of vaginal hysterectomy were then reported.

(To be concluded.)

The Canadian Medical Association has elected the following officers for 1895–96: *President*, James Thorburn, Toronto. *Vice-Presidents*, for Prince Edward Island, James Warburton, Charlottetown; for Nova Scotia, William Tobin, Halifax; for New Brunswick, W. W. White, St. John; for Quebec, Hon. D. Marcil, Quebec; for Ontario, Fife Fowler, Kingston; for Manitoba, H. H. Chown, Winnipeg; for Northwest Territory, G. Brett, Banff; for British Columbia, R. E. McKechnie, Nanaimo. *General Secretary*, F. N. G. Starr, Toronto. *Local Secretaries*, for Prince Edward Island, H. D. Johnson, Charlottetown; for Nova Scotia, G. C. Jones, Halifax; for New Brunswick, William Christie, St. John; for Quebec, J. G. McCarthy, Montreal; for Ontario, John H. Mathieson, St. Mary's; for Manitoba, W. J. Neilson, Winnipeg; for Northwest Territory, George Macdonald, Calgary; for British Columbia, W. A. Richardson, Victoria. *Treasurer*, H. B. Small, Ottawa. The place of meeting in 1896 is Montreal.

Medical Students at Philadelphia.—The following estimate has been made of the number of medical students attending the several schools of Philadelphia, together with the number in attendance during the last session:

	1895–96.	1894–95.
University of Pennsylvania	900	865
Jefferson Medical College	725	700
Medico-Chirurgical College	350	225
Hahnemann Medical College	285	260
Women's Medical College	200	175
Philadelphia Polyclinic	150	120
	2610	2345

The Riverside Baths.—Since the opening of the Riverside Baths in New York City in last February over 15,000 baths have been taken, including 1250 Turkish baths, and over 1230 hydriatric treatments. The baths are open daily throughout the year, and have attached a free library and reading-room, a kindergarten, and a playground for little children. The success of the institution is in no small measure due to the energy and personal interest of the Chairman of the Bath Committee, Dr. Simon Baruch. The fees are nominal, ranging from three to twenty-five cents, and provision is made for those unable to pay.

Dr. John R. Angney, a retired physician of Philadelphia and an ex-member of the Board of Guardians of the Poor, of the Board of Education, and of the Fifth Sectional School Board, died on September 29th, aged seventy-six years.

FIVE YEARS' EXPERIENCE WITH THE COLD-BATH TREATMENT OF TYPHOID FEVER.[1]

BY WILLIAM OSLER, M.D.,

OF BALTIMORE, MD.;

PROFESSOR OF MEDICINE IN JOHNS HOPKINS UNIVERSITY.

DURING the first year of the hospital-service typhoid fever was treated symptomatically. The number of severe cases admitted was unusually large, and there were eight deaths among thirty-three patients—a percentage of 24.2. For the past five years ending May 15, 1895, systematic hydrotherapy has been used—the method of Brand, with certain minor modifications. In the first report (vol. iv) the plan was given, but I may repeat here that each patient receives a tub-bath of twenty minutes at 70° F. every third hour, when the rectal temperature is at or above 102 5° F. Frictions are applied in the bath, and a warm drink or a stimulant is given afterward. In a large proportion of the cases no other treatment is employed. If the pulse is feeble, whisky is given, and strychnin. The diet is either wholly milk or in part broths and egg-albumin. It may be noted that all the cases come under my immediate care or, in my absence, that of Dr. Thayer, the Associate in Medicine.

In estimating the value of any plan of treatment it is important that all circumstances should be taken into account. In the previous report I dealt with the statistics as so many patients admitted, of whom so many died; and this, I think, should be done in all institutions—give the total number of cases of each disease treated to a conclusion, and the number of deaths, irrespective altogether of the length of stay in the hospital or the condition on admission. General hospitals are everywhere liable to be repositories of the more severe or troublesome cases, and in typhoid fever more particularly of protracted cases, in which serious symptoms have developed late in the disease. A high rate of mortality in any given acute disease may be an indication of a special usefulness of the institution. As already given, the general statistics of the hospital in typhoid fever are:

Cases admitted during the six years ending May 15, 1895	389
Number of deaths	34
Percentage of mortality	8.7
Cases admitted before the introduction of hydrotherapy	33
Number of deaths	8
Percentage of mortality	24.2
Cases admitted since the introduction of hydrotherapy	356
Number of deaths	26
Percentage of mortality	7.3
Number of cases bathed	299
Number of deaths among the bathed cases	20
Percentage of mortality in the bathed cases	6.6

The percentage 7.3 represents the total mortality during the past five years; but as it does not represent the mortality of the cases treated by hydrotherapy, the figures must undergo a further analysis. Many circumstances interfere with the systematic carrying out of the plan, among which the following are the most important:

In the first place, a number of cases are admitted in the second week, and even in the third week, with a falling temperature, and the fever constantly below 102.5° F. Cases, too, are admitted early, which have low temperatures and mild symptoms throughout. Brand and others urge that these should also be bathed; but in a large proportion of all such cases this appears superfluous. There are exceptions, however—cases in which the fever is low on admission, and even remains low for a week or ten days, to be followed by active and threatening symptoms. Nos. XXII and XXIX of the fatal cases were of this kind, and in both one could not but regret that the baths had not been used from the outset. In the very mild cases, seen more frequently in private than in hospital service, the baths are unnecessary. Last year we admitted an unusually large number of such mild cases.

In the second place, some patients are admitted late in the disease, and are too ill to bathe. A patient brought in at the end of the third week, with high fever, rapid, feeble pulse, meteorism, and diarrhea, stands, I believe, a much better chance with careful sponging, to reduce the fever, than he does with tubbing every fourth or fifth hour and the disturbance unavoidable in the lifting out of bed. There were five patients admitted in too feeble a condition to bathe, not one of whom died.

Thirdly, there is a group of cases which on admission present serious complications—hemorrhage, signs of perforation, very intense bronchitis, pneumonia, pleurisy or intense meteorism, with severe diarrhea. On account of hemorrhage the baths were postponed on several occasions. There was

[1] From forthcoming "Studies in Typhoid Fever," No. ii, Johns Hopkins Hospital Reports, vol. v.

no instance in which on admission the pulmonary symptoms seemed to contraindicate the treatment.

Fourthly, there are cases which were not bathed at first because the diagnosis seemed doubtful. Two of the fatal cases, to which reference will be made shortly, were not recognized clinically as typhoid fever. Each autumn we have a certain number of cases of malaria that present features closely resembling typhoid fever—so much so that baths have been given. These are instances of the so-called estivo-autumnal fever in which the organisms may at first be difficult to find. In other instances, with a strong suspicion of malaria for a day or two, the symptoms of typhoid fever have developed subsequently, but the temperature meanwhile has fallen below the bathing-point. In several cases the condition at first resembled tuberculosis.

And, lastly, the baths have been frequently changed to cold sponges, on account of hemorrhage, profound weakness, tenderness, and swelling of the abdomen, signs of perforation, and in a few cases because of the active protestations of the patient. The sponging, when thoroughly done, is almost as formidable a procedure as the cold bath; indeed, we have had patients ask to have the baths resumed.

The following are among the most important reasons which caused transient suspension of the method: Hemorrhage, 13 cases; perforation, in which condition even the sponging is rarely allowable, but in which the extremities may be bathed without disturbing the patient; great weakness and prostration, 11 cases; active mental symptoms, for one day in one case, for two days in another; extreme tenderness of the abdomen, for one day, one case; severe bronchitis, intense laryngitis, after operation on abscess of parotid, severe phlebitis, pleurisy, each one case. In many of the fatal cases the baths were suspended for 24, sometimes 48 hours before death.

There were several instances in which the symptoms of relapse were so slight that the treatment was not rigidly enforced.

Of the 356 cases treated during the five years, 299 were bathed; of these, 20 died, a mortality of 6.6 per cent.

Of the 57 cases that were not bathed for various reasons, usually because of the mildness of the disease, 6 died, a percentage of 10.3. This high ratio of mortality in the unbathed cases is, of course, due entirely to the circumstance that conditions, mentioned later, interfered with the use of the baths in a group of cases of unusual severity. In the 6 fatal cases, the histories of which are given in full in another place, in two, Cases XI and XVIII, the diagnosis was wrong; in the one, in an old man of 70, with consolidation of the lower lobe, the disease was thought to be lobar pneumonia, and in the other the patient had been in the hospital the year before with entero-colitis, and on readmission with severe diarrhea typhoid fever was not suspected.

In Case XXVII the disease was at first thought to be tuberculous cerebro-spinal meningitis; the temperature was low, the nervous symptoms marked, and it was not until parotiditis developed that our suspicions were aroused about typhoid fever.

In Case XXVIII, after twelve days of moderate fever, severe symptoms developed, with tympany and abdominal tenderness and diarrhea. It was thought best to use the cold sponges; death was probably due to perforation.

In Case XXXII the patient was admitted bleeding profusely from the bowels.

In Case XXXIII the fever was low, only touching 104° at entrance, and subsequently not rising to the bathing-point. Death occurred from thrombosis of the middle cerebral arteries.

Two advantages are claimed for hydrotherapy in typhoid fever—a mitigation of the general symptoms of the disease and a reduction in the mortality. Our experience during the past 5 years bears out these claims.

In general hospitals, to which cases rarely are admitted before the end of the first week, the full benefits of the cold bath, as described by Brand, cannot be expected; nevertheless, in any large series, the severer manifestations appear to be less common. As has been urged so often and so ably by many writers, the beneficial action is not so much special and antipyretic as general, tonic, and roborant. The typhoid picture is not so frequently seen, and we may have 20 or more cases under treatment without an instance of dry tongue or of delirium among them. It is a mistake to claim, as do the too-ardent advocates of the plan, that severe nervous symptoms are never seen. I have taken the pains to go carefully over our records on this point. There were in the first 3 years 13 cases, in the past 2 years 9 cases with delirium. Most of these were protracted cases which had from 75 to 120 baths.

A far more important claim is that the use of the cold bath reduces the mortality from the disease. The comparison from death-rates as a measure of the efficacy of any plans of treatment is notoriously uncertain unless *all* the circumstances are taken into account. Our own figures for the past 5 years, for example, illustrate this—6.2 per cent. in the bathed cases, 10 in the unbathed cases—as the latter group is made up entirely of cases too mild to bathe and 6 patients in whom either the disease was not recognized or who were too ill on admission to treat.

Statistics have a value in this connection only when the figures on which they are based are numerous enough to neutralize in some measure

their notorious mobility. Small groups of cases are useless; 24 per cent. of mortality in our first year in 33 cases, and a series of nearly 50 bathed cases without a death illustrate the liability to error in discussing a few cases. Unfortunately, typhoid fever is a disease in which the cases may be reckoned by hundreds and thousands, and the average mortality in general and special hospitals throughout Europe and America is easily gathered. The rate may be placed between 15 and 20 in each 100 cases. In the Metropolitan Fever Hospitals, London, the death-rate, as given in the report for 1893, was 17 per cent.

The cold-bath treatment, rigidly enforced, appears to save from 6 to 8 in each hundred of typhoid patients admitted to the care of the hospital physician.

While I enforce the method for its results I am not enamored of the practice. I have been criticised rather sharply for saying harsh words about the Brand system. To-day, when I hear a young girl say that she enjoys the baths, I accept the criticism and feel it just; but to-morrow, when I hear a poor fellow (who has been dumped, like Falstaff, "hissing hot" into a cold tub), chattering out malediction upon nurses and doctors, I am inclined to resent it, and to pray for a method which may be, while equally life-saving, to pu it mildly, less disagreeable.

SOME VAGARIES IN RECTAL PRACTICE.[1]

By JOSEPH M. MATHEWS, M.D.,
OF LOUISVILLE, KY.;
PROFESSOR OF SURGERY AND CLINICAL LECTURER ON DISEASES OF THE RECTUM IN THE KENTUCKY SCHOOL OF MEDICINE; RECTAL SURGEON TO THE KENTUCKY SCHOOL OF MEDICINE HOSPITAL AND THE LOUISVILLE CITY HOSPITAL; PRESIDENT OF THE LOUISVILLE SURGICAL SOCIETY, ETC., ETC.

We are all cognizant of the fact that even the text-books, or so-called authorities, do sometimes err. This was never so forcibly impressed upon my mind as in reading all the literature I could obtain upon rectal diseases when I wrote my own work on this theme, and in the remarks I shall make to-night I shall take up a few of the diseases that are incident to the rectum, and try to show what, in my opinion, are vagaries in regard to those that I shall mention.

In the first place, I beg to consider the subject of *hemorrhoids*, mentioning first *external* hemorrhoids. As regards the diagnosis of this condition, it is nearly universal with authorities to divide external hemorrhoids into two different kinds—one is a tag of skin that may become inflamed under certain conditions, and the other a thrombus, or rupture of a bloodvessel and the running of blood out into the tissues. The literature of the subject will show that the majority of those who have written upon it believe that external hemorrhoids of the second variety, a bloodclot, may be caused by pressure of the child's head in parturition, for instance, and that it amounts to only a dilatation of the bloodvessel, with a contained clot. My experience certainly has taught me that this is not true; but that there is necessarily *rupture* of a bloodvessel, and the flowing out of blood into the tissues, in which it coagulates. Therefore I have been led to believe that such pressure as a cause as laid down is a mistake, and that this variety of external pile is not often caused by pressure of the child's head, tumors, or what not, but by force; a strain, a blow, a kick, or anything of that nature that would rupture the bloodvessel, often constitutes the cause of the second variety. That the other variety—inflammation of a tag of skin—does occur is very true, as far as the diagnosis is concerned.

As regards treatment, I wish to say that authorities, as far as I have ever read, advise that external hemorrhoids should be lanced; that a bistoury should be run through them and the clots turned out. There never was a greater vagary in my opinion than this. When it is considered that a person suffering from this variety of hemorrhoids is an invalid for two or three weeks from excessive pain, caused by the inflammation, the procedure is not a very small affair. If we follow the universal practice, to which I have never found an exception, of lancing an external hemorrhoid to let the clot out, anyone who has ever practised this method has seen that he causes a condition which will last longer than it would take Nature to reabsorb the clot. In other words, by letting out this clot one necessarily excites an inflammatory condition, and in twenty-four hours the part itself is larger; there is more exudation of plastic material, more inflammation, more irritation than would exist if it were let alone and Nature were allowed to reabsorb the clot. Therefore, in lieu of accepting this doctrine, as far as the treatment of external hemorrhoids is concerned, I remove the *entire* pile by pinching it up with a pair of forceps and extirpating it, leaving simply an open wound, and in from twelve to twenty-four hours the patient is able to resume his business, only a small wound remaining to heal by granulation. I consider any other method, therefore, a vagary.

It has become the common impression, as far as the treatment of hemorrhoids is concerned, especially the external variety, and among very many surgeons, the internal variety also—and I can quote from so good an authority as Manley, of New York, who has written elaborately upon the subject lately—that all operations for hemorrhoids can be done under the effect of cocain. I want to say very positively that this practice should be condemned by every physician and surgeon, not only on scientific but also on practical

[1] Delivered before the Louisville Clinical Society.

grounds. It can be demonstrated that cocain is more dangerous than any general anesthetic. There have been more deaths reported from injecting the tissues around the rectum with cocain than have been reported from both ether and chloroform combined. Cocain is going forth to the profession in the writings of its advocates as a very simple anesthetic in dealing with hemorrhoids and it is said to be devoid of danger; while it is an incontrovertible fact that death is much more common following operations upon the rectum since cocain has been used. If I accomplish nothing more by this paper, I would warn the profession against the use of cocain, as far as its injection into the tissues around the rectum is concerned, in performing any minor surgical operation upon these parts. It is a dangerous agent; especially is this true with regard to its use in operations for piles; the patient should always have general anesthesia for rectal operations, no matter what the nature of the procedure may be.

Internal hemorrhoids. I shall not take time to discuss the pathology of internal hemorrhoids; it is a mooted question as to exactly how this tumor is formed. More especially do I want to speak of the fact that all conditions around the rectum, at least nearly all, are generally called hemorrhoidal, when in truth this is a great vagary, a great mistake.

As regards the *symptoms of hemorrhoids*, I may say that those laid down by authorities, some at least, are vagaries. Internal hemorrhoids, without complications, really have no symptoms. If the pile is a small one that does not bleed, it cannot be noticed by any symptom; if it is a well-formed tumor, an internal hemorrhoid, it has no symptom except protrusion. Whenever there is pain, whenever there is simple itching or any of the other so-called symptoms of hemorrhoids, this is simply a complication.

Another point I wish to make is, that it seems to be the common opinion, as far as I can gather by having a personal talk with most of the medical men in the country who do work in this line, that internal hemorrhoids are easily diagnosticated, not only by prominent symptoms, but by touch, by making an examination of the rectum with the finger. I want to make the point very positive that it is the only condition or disease of the rectum that *cannot* be diagnosticated by touch. Hemorrhoids may be ever so large and yet not be detectable by touch. There is no way of diagnosticating internal hemorrhoids except by visual inspection if they have protruded, or by a specular examination.

Another vagary is that small piles, of the *capillary* variety, amount to but little, when in truth they are the only dangerous variety of hemorrhoids, either external or internal. Many persons have lost their lives through a small internal capillary pile. I have seen and recorded five cases in which the patients lost half a gallon of blood at one sitting. I am satisfied that people have bled to death from these very insignificant little tumors that authorities state amount to almost nothing. I refer to the bleeding pile, one in which an artery has ruptured, constituting the so-called hemorrhage from the rectum, which originates in a capillary pile, the blood being bright red in color, and coming in jets from the rectum, just as it would from an artery in another situation.

Another mistake, I believe, is the *classification* of internal hemorrhoids. Authorities universally classify them as *arterial*, *venous*, and *capillary*. I do not believe there is any internal pile that does not partake of both the arterial and the venous variety—whether one predominates over the other no one is able to say. One is as much venous as it is arterial, and *vice versa*. It is misleading and entirely a mistake to say that an arterial pile is a much more serious condition than a venous pile; they are both very nearly the same.

As *to the treatment of hemorrhoids*. If I were to follow my own inclination in the treatment of internal hemorrhoids, I would be too dogmatic, because I would say, use carbolic acid injection *never*. I would be inclined to say, use the Paquelin cautery *rarely*, when there is so simple an operation, one so devoid of danger, and so easy of execution, as throwing a ligature around the hemorrhoid, transfixing, and removing it. By this method the blood-supply of the part is effectually shut off; there is very little danger of septic infection, and I do not believe as much can be said of any other method. I regard this treatment as superior as far as this affection is concerned.

Fistula in ano. I suppose mistakes are made every day in the diagnosis of fistula in ano from one standpoint—that is, the character of the fistula with which we have to deal. Authors are not sufficiently explicit; they do not go into the details with a minuteness commensurate with the gravity of the condition. It is not enough to say that fistula in ano is a sinus, with an *external* and an *internal* opening, constituting a *complete fistula;* if with an external opening, being an *external incomplete fistula;* or if with an internal opening, constituting an *internal incomplete fistula;* when we remember that it is one of the most destructive conditions from which the human body can suffer. When we realize that a man or woman may become a physical wreck from fistula in ano, it seems strange that writers on general surgery, for instance, do not deal more minutely with the subject. Therefore I have seen fit to make a different division than other authors make in this disease. My division has been *progressive fistula* and *non progressive fistula*. There are many conditions about the rectum in which we can advise a patient against operative in-

terference. If there is no physical defect, we might in some cases say that the fistula would not injure the patient at all. We have seen men who could go through life with such a condition without apparent harm. But if one applies this rule to all fistulæ he will wreck his patient, and perhaps cause death from sepsis in the course of a few weeks, certainly in a few months, if the fistula is of the *progressive* variety; I mean by this a condition attended with an acute inflammatory action and rapid burrowing of pus. We know that pus will burrow by continuity into the vagina from the rectum; it will burrow to, and even into, the bladder, from the rectum; it may destroy the perineum, especially in the female; it will often extend into the buttocks, undermine the sphincter muscle, etc., and do these very quickly. Under these conditions I say that every surgeon having the welfare of his patient at heart should advise an *immediate* operation for the fistula.

If I had the time, I would like to detail some cases I have witnessed within the last few months, being ably assisted in the operations by Dr. Laws, in which, if the fistulæ had been allowed to remain three months, no surgeon on earth could have cured them. Therefore I say it should be recognized that some fistulæ are very progressive, and some are not progressive at all. There is thrown out by plastic exudation a material that narrows the fistula down to a very small tract, which will scarcely admit a probe; that can be very readily left alone, not operated upon at all. But if the other condition is met with, the point I make is, that there is not only a rapid destruction locally, but also risk of sepsis.

Another thing I think should be done is to contrast the condition of fistula in women with that of fistula in men. Fistula in ano in the female is a very serious condition. I have now under observation a young married woman who had an abscess in the left side of the rectum and extending to the labia, which was allowed to go for two months without being opened, and at last was lanced. I have been three months trying to cure the fistula. I doubt if I shall succeed, because the process has by its destructive course branched through the perineum, involving the vagina and the sphincter muscle, with different channels running in many directions. Any surgical attempt at cure must of course destroy the septum, and also the sphincter muscle. I do not think enough attention is given to the respective difference occurring in the male and the female.

Another vagary is placing the greatest stress upon finding the *internal opening of a fistula*. I have spoken of this before, and have had my views criticised. Every surgical work gives general directions for finding the internal opening of a fistula when there is an external opening. Of what importance this is to the surgeon I have never been able to understand. Why a surgeon should abandon an operation for fistula because he could not find an internal opening I certainly cannot comprehend; yet I have seen very good surgeons refuse to operate upon patients because this opening could not be found. I have had several patients come to me to be operated upon for fistula who had been refused by other surgeons because the latter could not find an internal opening. That a person has a fistula is proved by the fact of the existence of the external opening; it is not necessary to use a probe at all; the condition calls for an operation. The fact of there being an external opening is enough to decide in favor of an operation; the fistula should be freely slit up, following the channel to the bottom, and, of course, the internal opening will then be found. That a surgeon should refuse to operate simply because an internal opening cannot be found before the operation is to me a vagary.

Ulceration of the rectum. Before I speak of what I wish to consider a vagary in this connection, I wish to relate one case out of many:

A lady was sent to me from a Southern city three months ago, with a note from two surgeons who had treated her for a year. They agreed that she had carcinoma of the rectum, and wanted me to do the best I could under the circumstances. In an examination of this woman I found, situated on the septum half an inch above the internal sphincter muscle, an ulceration larger than a silver dollar. The ulceration was well defined, having raised edges and an indurated base, and from its surface was discharging pus. The septum was thickened by an inflammatory exudation, not being as thin as normal, and I believe the surgeon who refused to operate was afraid of destroying the septum. The question with me at the time was, What was the cause of this ulceration? I did not believe, with the doctor who wrote me the note, that it was malignant. The patient had been under treatment a year, and was in perfect health as far as physical appearance would indicate, weighing one-hundred-and sixty pounds, presenting rosy cheeks, and being in good flesh. Therefore, I looked about for another cause. I asked the patient if she was married, and she replied that she was a widow; I then inquired as to the cause of her husband's death, and she said that he was not dead, but that they had separated. I then asked her if she would tell me of her past life. She said she separated from her husband because he had a bad "trouble." When questioned as to what she meant, she said he had sores on his body, and gave a very good description of syphilis. Therefore, I was led to believe that syphilis was the cause of this ulcerated condition of the rectum, but it did not have the appearance of a syphilitic ulceration; nor did it have the characteristic feel of a syphilitic ulcer. The woman did not look like a syphilitic subject; so I was constrained to believe that the trouble was not syphilis; nor did I believe it was carcinomatous.

In this connection I want to say that I differ with some authorities on the subject. Ulcerations of the

rectum from benign causes are usually simply erosions and are very small affairs. In an experience of eighteen years, my record-book will not show a dozen cases of benign ulceration of the rectum. In the case just reported I do not believe that the process was benign.

Upon further questioning, the woman told me that she had suffered from slight hemorrhages from the lungs two years before, but not recently. From the appearance of the ulceration of the rectum, from its feel to the touch, and from that portion of the patient's history just given, I concluded that the trouble was tuberculous.

In dealing with ulceration of the rectum, I believe there is only one mode of treatment for tuberculous ulceration, and that is through curettement. Notwithstanding that this lady had been treated for a year by two most excellent physicians and had all the local remedies applied that could be suggested, the ulcer would not heal.

The patient was placed under the influence of chloroform, and I thoroughly curetted the ulcerated portion of the rectum, going down to what I believed to be healthy tissue. She remained here three weeks, then returned to her home, with the ulcer entirely healed, with the exception of one edge, which showed some induration. I also informed her physician and her family that I did not think she could live many years, at least unless she removed to another climate.

My experience has been that when ulceration exists in the rectum in any degree, it is due to a special diathesis, malignant, syphilitic, or tuberculous. Benign ulceration occurs very seldom.

As regards *carcinoma of the rectum*. I do not desire to speak of its diagnosis, but rather of its treatment. Perhaps my views are sufficiently well known in regard to colotomy for carcinoma of the rectum not to require any further mention, and all I shall say is that I am nearly convinced that any operative procedure upon the rectum for carcinoma is unwarrantable in the larger percentage of cases. Kraske has done the profession good service by telling us of his method of extirpating the rectum. It may be said of his operation that by it more of the rectum may be removed than by any other method; but I think the surgeon should consider a little more than that, and that is, whether he is justified in performing any severe operation upon a patient when he recognizes that very little if any good will be thereby accomplished. I do not believe, therefore, that when carcinoma exists in the rectum, involving as much of the rectum as would warrant Kraske's operation, one case in ten would justify the operation.

I read once from the pen of a distinguished gynecologist an article in which he said he doubted very much whether hysterectomy should ever be performed for carcinoma of the uterus. I am very much inclined to adopt the views of this gentleman as far as carcinoma of the rectum is concerned.

I saw this afternoon a lady, thirty years of age, who has carcinoma of the rectum. She has not lost five pounds in flesh, and weighs one-hundred-and-forty-five pounds. She has rosy cheeks, and is healthy and robust in appearance. I cannot get my own consent to excise this rectum by Kraske's or any other method. The carcinoma extends as far as my finger can reach. The rectum is almost completely blocked with the carcinomatous mass, although she does not present the characteristic carcinomatous cachexia. Kraske's is a difficult operation, and the man who undertakes to extirpate the rectum by this method, with the idea that it is an easy procedure, will find himself very much mistaken. Of all operations that I have ever undertaken, complete extirpation of the rectum is one of the bloodiest and most difficult that I have ever witnessed or tried to perform. Are we warranted in doing so fearful an operation when we can promise so little? Mayhap there is some little relief, perhaps none.

I shall not take time to speak of the vagaries of *orificial surgery*, except to denounce it. There is not a day that passes but I find some new evidence against this fearful criminal practice. Men in every city of the Union are given to cutting out the rectums of men, young girls, boys, and infants for the relief of diseases outside the rectum. They are running wild with the idea of reflexes from the rectum, and healthy rectums are extirpated for so-called heart-disease, dyspepsia, neurasthenia, etc. I think the profession at large should be outspoken in this regard; not that we have anything personally against the operators, but to save human life and human wretchedness. If medical men were aware of the number of people in the city of Louisville who have submitted to this outrageous practice—it is more than a vagary—they would agree with me that it should be denounced by every medical journal and every medical man in the United States.

Another vagary, I take it to be, is the frequency with which *prolapse of the rectum* is supposed to exist. In my experience, extending over eighteen years, I have had but six cases of prolapse of the rectum. I have had several hundred cases of prolapse—so diagnosticated. It is true that a great many physicians call large protruding hemorrhoids prolapse of the gut. This is a mistake. When I say that I have seen only six cases, I mean in the adult. Young children often have prolapse of the gut which will take care of itself under simple treatment. The number of cases of prolapse in the adult is very insignificant, and it is a mistake to have it stated in books and periodicals that the condition is often met with.

From the literature of the subject one would be forced to believe that the simple affection of *pruritus ani* was the symptom of some other trouble. Some very eminent authorities say that it is. I must differ positively from that position. I do not believe that pruritus ani is a symptom of anything except *pruritus*. It is a distinct affection, not dependent upon nor a symptom of any other trouble. I saw to-day a case in which there was excessive pruritus extending not only aronnd the anus, but also upon the scrotum. The patient has as perfect a rectum as I ever examined, and there was no discharge from it. Pruritus that comes from a discharge from the rectum—that is, the itching—is not pruritus *per se*. Therefore, I believe that pruritus is a distinct disease.

Fissure of the rectum. I only want to speak of a vagary in this connection so far as the treatment is concerned. In my work on *Diseases of the Rectum*, in commenting upon the different methods advocated by various authorities, I referred especially to the writings of Dr. Adler, of Philadelphia, and stated that I was sorry to see so learned an authority contending for local treatment of fissure of the rectum that occupied weeks and months to effect a cure, when relief could be afforded so quickly and so effectually by slight divulsion of the sphincter muscle. In the last few months a number of articles have been written on the subject of treatment of fissure of the rectum by local measures. Dr. Adler saw fit to reply to my criticism, saying that he believed that I was mistaken, that I was not borne out in my statement by facts as regards dilatation, when he had demonstrated that the condition could be cured by local applications.

A number of months ago a gentleman stepped into my office with a bad fissure of the rectum, and said that he wanted me to treat him for it. I made an examination and told him that he had a fissure, and he then asked how long it would take to effect a cure. I told him that it would take but a few minutes, and he would be detained in the house only a day or two. He was inclined to doubt my statement, and said that he had been treated by a physician every other day for three or four months without much improvement. Therefore, I contend that there should be but one method of treatment, and that dilatation. A word as to the method of dilating. Nearly everyone who has written on this subject has explained that they mean forcible dilatation; breaking the sphincter muscle if necessary. This certainly is a vagary. The more I treat fissure, the more I am satisfied it can be cured by slight dilatation, often by means of a small speculum, dilating until slight pain is evinced, and in the majority of instances the fissure disappears. Then, I say, what is the use of taking three weeks, three months, or a year to cure a condition that can be relieved permanently in a few minutes?

Fissures of the anus are often found in children, and can be cured by the mother, as I have tried to demonstrate in several articles on the subject. An elaborate article was written not long ago by an eminent surgeon, in which he questioned whether fissure ever existed in the child; even so good an authority as Kelsey has said that he had never seen an anal fissure in the child. I saw numbers of them while I was a practitioner in general medicine; and will say that they can be cured by the mother simply anointing her finger and slipping it into the child's anus, practising a little massage for five minutes at a time, and repeating this if necessary. If this plan is followed, a complete cure will almost invariably result.

WHAT IS THE CAUSE OF THE SHADOW IN SKIASCOPY?

A Criticism of the Current Theory.

By CARL WEILAND, M.D.,
OF PHILADELPHIA;
CHIEF CLINICAL ASSISTANT IN THE EYE DEPARTMENT OF JEFFERSON MEDICAL COLLEGE HOSPITAL.

Although much has been written of late about skiascopy, and although the test has become widely known and accepted, nevertheless, from the statements concerning it that I have heard, there can be no doubt that the optic principles involved are not always completely understood, not even by the recognized authorities on the subject. Especially do the ideas upon the cause of the shadow and its movements seem to be very erroneous. So far as my reading goes, only one author, Dr. Rüppell, gives a mathematically correct, but incomplete, explanation of this phenomenon.[1] All other writers attribute it to a real dark area or shadow, and its movement on the retina of the patient. The crescentic shape of the shadow is also explained wrongly, and is referred to the round light-area on the patient's retina. Thus Nettleship[2] says: "In both cases, high M. and high H., the border of the shadow is crescentic, because the diffused image forms a nearly round area on the retina." Swanzy[3] states: "When we speak of the motion of the shadow we mean that the margin of the illuminated area, or the boundary-line between illuminated and non-illuminated area[of the retina], moves along with the illuminated area in response to the motion of the mirror." Noyes[4] distinctly asserts that "we may see in the pupil a portion both of the luminous and the non-luminous surface" [of the retina]. Hartridge[5] says: "It may, therefore, be stated that the illumination and the shadows which we see are an enlarged

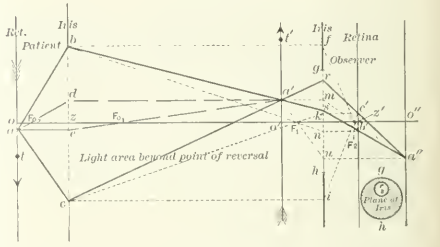
[5] Refraction of the Eye, p. 84.

image of the lamp, with the surrounding shadow brought more or less to a focus on the retina, according to the refraction of the eye." Jackson, in his recent monograph, also clings to this idea of the shadow having its cause in a corresponding shadow of the patient's retina—for example, when he says: "But when the point of reversal is approached, so that the magnification of the retina prevents all of the retinal light-area from being seen at one time, only a portion of its outline is visible as an arc of the greatly enlarged circle." At another place he says: "Since in skiascopy one has to observe the movement of an area of light across the shaded retina, the size, brightness, and sharpness of the contrast between the margin of this light area and the shadow immediately adjoining it are very important factors in determining the definiteness and accuracy of the test." Finally, we even find Parent[1] holding the same opinion, as shown by the following passage: "Mais à quoi est due cette ombre quit apparait dans le champ pupillaire quand nous faisons pivoter le miroir de gauche à droite ou réciproquement? C'est tout simplement une partie de la rétine qui faisant partie de notre champ d'examen (lequel correspond à l'image de notre pupille sur la rétine de l'observé, Helmholtz) était éclairée d'abord, mais ne l'est plus, quand, par un mouvement du miroir, nous déplacons l'image nette ou diffuse de la lampe sur la rétine de l'observé. Ainsi, cette ombre n'est autre chose que la partie non éclairée ou ob-cure de la rétine, incrite dans notre champ d'examen."

I shall endeavor forthwith to indicate briefly that these ideas are erroneous, and that the iris and accommodation of the observer have a great deal to do with the phenomenon under consideration. First of all, it must be understood that the observer must accommodate his eyes for the pupil of the patient if he wishes to obtain accurate results, as otherwise not only the shadow but also the whole light-area of the pupil moves more or less according to the ametropia of the observer. This can be easily proved geometrically by anyone who has mastered the principles of the following geometric construction, and the importance of this is also well understood by Chibret[2] when he states: "L'observateur, s'il est amétrope, doit corriger sa réfraction afin de voir avec netteté le bord de la pupille pendant l'examen." But, strange to say, no allusion is made to this very important condition of accuracy in the recent monograph by Jackson, though he is otherwise very careful in calling attention to all the nice points of the test.

In the following description and diagrams the human eye is represented by the retina, the two principal foci, and the iris, the last being taken as the principal plane. This conception is sufficiently accurate, as the iris lies only 1.5 mm. behind the second principal plane of the schematic eye. We shall assume, for the sake of simplicity, that the plane mirror is employed and that the patient is naturally or artificially myopic. The mirror is supposed to be rotated downward, so that the light-area in the patient's eye wanders down on his retina. This light-area is at the present assumed to be reduced to a mathematic point, the point *a* in Fig. 1. The point *a* has its image in the air at *a'*, and this point is found by means of the principal plane and the two principal foci by drawing first the ray *aa* through Fo_2 and then *da'* parallel to the axis *oz*, and by further drawing *ae* parallel to the axis and then *e* Fo_1. The point of intersection is *a'*, the image of *a*. Line *a'o'*, perpendicular to the axis, contains all the images of the patient's retina, so that if *t* were the illuminated point of the retina, *t'* would be its image. Fig. 1 shows the observer's eye beyond this point *a'*.

Fig. 1.

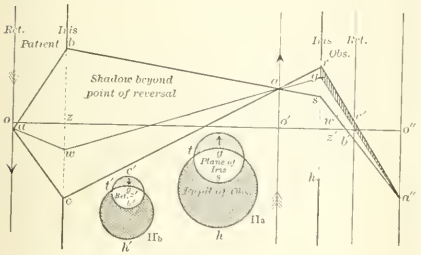


Let us now inquire how the bundle of rays, *abc*, which comes to a focus at *a'*, is affected by the eye of the observer, if this person is supposed to have his eyes accommodated for the pupil, *bc*, of the patient so that an exact image of this pupil is formed on his retina. We can construct this image of the patient's pupil by drawing *ci* parallel to the axis and then *i* F_2; the latter ray cuts the observer's retina at *c'*, the image of *c*. In the same way we find point *b'*, and thus obtain a clear inverted image *c'b'* of the pupil *bc*. It is evident that ray *ba's* must after refraction pass to point *b'*, because *b'* is the image of *b*, toward which, therefore, all the rays emanating from *b* must converge. It is further clear that ray *ca'r* must finally pass to *c'*, as *c'* is the image of *c*. Now, as all the rays from *a* emerging from the patient's eye are contained between these two marginal rays, it is evident that they must all meet the retina of the observer between the two points *c'b'*; so that in reality the observer obtains a circular image *c'b'* on his retina wholly filled with light. This circle of light is but the diffusion-

[1] Festschrift für Herm. von Helmholtz, 1891.
[2] Archives d'Ophthalmologie, 1890.

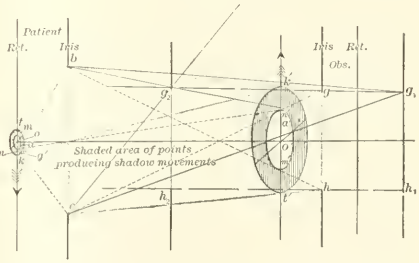
image of point a' produced by the observer's eye, the real image of which, point a'', we find by our old construction to lie at a'' beyond the retina and below the axis. If, now, our mirror is rotated downward, point a will go down, too; point a', however, will go up in line $o'a'$, and a'' will go down on line $o''a''$. Nevertheless, the ray ra'' will always go through c', because it comes from c, and the eye of the observer is supposed to be so adjusted that all rays from c will meet at c'; and, furthermore, the ray sa'' will always pass through b' for the same reason. Therefore, no matter where the point a lies, whether on the axis or above or below it, as long as *all* the rays bca' can enter the hole in the mirror and the pupil, gh, of the observer, so long will they always form a stationary diffusion-circle, $c'b'$. There can be no shadow and no movement of light. But the moment the point a goes down so far that ray ca' falls beyond g, the margin of the pupil, the phenomenon is changed at once.[1] This is explained by Fig. 2. Here the mirror is supposed to have been rotated so far down that from the bundle of rays bca' not all can enter the eye of the observer. That part of the bundle between $a'r$ and $a'g$ or the bundle wca' is cut off by his iris. If the piece gr of the iris were absent, ray $a'r$ would pass to c' as it comes from c, but now all the rays up to $a'g$ are prevented from entering the eye. Ray $a'g$ will pass through w' if w' is the image of w. Therefore, the former circular diffusion-image of point a' has now changed its shape. We can find this shape by remembering that at the pupil of the observer we have (IIa) the pupil, gh, partially filled with light. This light-area has the form of a circle, the upper part of which is cut off by the iris, together with its circular pupillary border tg. If we want to know what form this light-area has on the retina, we simply have to draw lines from tgs to the point a'', the image of a', because all rays filling the area tgs come to a focus at a''. The figure that these rays form on the retina (which is parallel to the iris) must necessarily have the same shape as the light-area in the pupil, although a little smaller, as is represented in IIb, where $t'g'b'$ is the light-area. Therefore, if point a goes down so far that ray $ca'r$ just passes beyond g, the circular light-area on the retina of the observer will begin to show a slight dark crescent in its upper part. But, of course, if a crescentic shadow appears in the upper part of the retinal image of the patient's pupil, the observer projects it out as belonging to the lower part of the observed pupil, and so it happens that he sees a shadow, crescentic in shape, and moving upward in the stationary light-area in proportion as the shadow moves downward on the retina from c' to b'. In short, we may say that the shadow moves *against* the mirror. As soon as point a goes down so far that even ray $ba's$ reaches g, all the light disappears from the eye of the observer, though the same amount of light as before may fall on the patient's pupil if the mirror be large enough.

Fig. 2.



Attention must be called to the fact that the light-area is quite stationary on the observer's retina as long as he sees the pupil distinctly, and that, therefore, the physician can see no movement until the light-point, a, on the patient's retina (Fig. 3) has gone to n; that is, so far down that ray ca', in our diagram ray cn', reaches g, the margin of the observer's pupil. This movement of the shadow lasts until a has gone as far down as k; that is, so far down that even ray bk' touches g, when all the light disappears. We have, therefore, around the point of fixation, o, of the patient an area of points that give only a stationary light-circle, as indicated in Fig. 3, by the inner circle mn, and outside of

Fig. 3.



[1] Here it must be mentioned that in the diagrams the mirror has been omitted for clearness' sake. For the same reason the rays are supposed to be intercepted only by the iris of the observer, which indeed corresponds with the actual condition of affairs, if the hole of the mirror is larger than the observer's pupil. Should, however, the pupil be larger than the hole of the mirror the rays from bc would be intercepted by the circular opening in the mirror first. But in reality the mirror is so near to the iris of the observer that practically this mirror may be supposed to be in the plane of the iris. We have, then, only to substitute for the observer's pupil the smaller sigbt-hole of the mirror. Everything else remains unchanged.

this another ring-shaped area that produces movements of shadow, the shaded area *tm kn;* but as we judge the refraction by the movement of the shadow, and as the point of fixation *o*, lying on the optic axis, does not give rise to such shadows, we see that in reality we do not measure the refraction of the point of fixation (if the patient looks at us), but only that of a point or series of points a little distance away from it. This distance, however, for a myopia of 1 D. does not amount to more than seven seconds angular deviation, so that for our purposes this little inaccuracy may be neglected. We further see by reference to Fig. 3 that the area, *n'm'*, of the light-producing points is the smaller and the area of the shadow-producing points the greater, and therefore the accuracy of the test is the greater the smaller *gh* the pupil of the observer, and the greater the pupil, *bc*, of the patient, the other conditions remaining the same.

If we now look more closely at Fig. 3, we shall find that the circle *tk* is but the diffusion-image of the pupil *gh* of the observer on the patient's retina, and we shall see further that the shadow-producing ring of light-points *tkmn* consists of but the diffusion-circles of all the points of the margin of the observer's pupil if this were luminous. For the ray *gc* from *g* goes to *n*, and the ray *bg* from *g* goes to *k*, while both rays intersect at *g'* in front of the patient's retina. Line *nk* represents, therefore, the diameter of the diffusion-circle of point *g'*, the image of point *g*. This knowledge allows us at once to foresee what happens if the light on the patient's retina is not reduced to a mathematic point, but has a definite extent. For it will be seen that as long as this extended light-area lies wholly within the area of the light-producing points *mn*, so long will the observer see only a stationary circle of light; but as soon as a small part of the light-area enters the ring of shadow-producing points a crescentic shadow will appear at once.

It is evident, therefore, that the shadow we see in skiascopy has nothing at all to do with the dark area around the light on the patient's retina, but is caused by some rays emerging from the patient's pupil being intercepted by the iris of the observer, so that this iris throws its shadow on the light-area that the observer's retina receives from the luminous pupil of the patient. How this same reasoning also applies to the case in which the observer is at a', the point of reversal, when no shadow can appear gradually, but in which the stationary light-area of the pupil is darkened all at once by point a' of Fig. 2 coming to *g;* and how, further, the same construction applies to the observer within the point of reversal and also to a case of astigmatism, to spherical aberration, and to emmetropia and hypermetropia, all this can be well shown by similar diagrams; but to reproduce them all here would be too costly, and would require too much space. Besides, to give a complete description of all the phenomena is not the object of this communication. It will have fulfilled its purpose if it has attracted attention to some important points usually overlooked or even entirely misunderstood not only by the practising skiascopist, but also by authoritative writers. These points are the following:

1. The observer must keep his eyes accommodated for the pupil of the patient.

2. The light-area has then exactly the shape of the patient's pupil, round or otherwise, as the case may be, and remains perfectly stationary throughout the test. The shadow alone moves.

3. The shadow is produced by the iris of the observer.

4. The usual crescentic shape of the shadow has its cause in the usual circular form of the pupil of both patient and observer.

5. Skiascopy is the more accurate the larger the pupil of the patient (provided there is not much aberration in the peripheral zone) and the smaller the pupil of the observer.

315 NORTH SIXTH ST.

CLINICAL MEMORANDA.

A CASE OF ILEOCOLOSTOMY BY THE MURPHY METHOD; EXCISION OF THE CECUM; TOTAL EXCLUSION OF A PORTION OF THE ILEUM (ENTERO-APOKLEISIS).

BY CLAYTON PARKHILL, M.D.,
OF DENVER, COL.;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; VISITING SURGEON TO ST. LUKE'S AND ARAPAHOE COUNTY HOSPITALS, ETC.

AT the beginning of my last term of service in the Arapahoe County Hospital I found in the wards a patient, E. B., twenty years old, who had been admitted August 4, 1894, to the service of one of my colleagues. He was suffering at that time with an appendicitis, with a perityphlitic abscess. He was operated upon for the removal of the appendix and the evacuation of the pus. Within a few days the walls of the cecum gave way in several places, and a fecal fistula was formed. My colleague operated upon him subsequently, with a view to closing the cecal openings by sutures, but was unsuccessful.

When the man came under my care, on September 1, 1894, he was greatly emaciated, and suffered much pain. There were four large fistulæ in the outer wall of the cecum, through which all the fecal matter was discharged. The opening in the abdominal wall had a length of about five inches and a width of two-and-half, and was suppurating profusely. I was convinced that any further attempt to close the fistulæ by sutures would fail, so I decided to effect an anastomosis between the ileum and the colon, in order to shut off the cecum from the fecal circulation.

I operated on September 14, 1894. My incision began about an inch below the cartilage of the ninth rib, extending downward and slightly inward for six inches, in a line midway between the margin of the fistulous opening and the linea alba. When the section of the abdominal wall had been made, exploration disclosed the fact that the suppurating focus about the head of the cecum had been very perfectly circumscribed by loops of intestine matted together by adhesions.

With comparatively little difficulty I discovered, as I thought, the terminal portion of the ileum. This I cut across at a point about three fourths of an inch from what I believed to be the valve. Leaving a clamp on the short portion of the gut, I caried the other end upward, and by means of the largest size Murphy button made an end-to-side anastomosis with the beginning of the hepatic flexure of the colon. I then closed the end of the ileum left attached to the cecum below. I used first a continuous suture and then invaginated the line of union by a row of Lembert sutures. After a careful toilet of the peritoneum the abdominal wound was closed, the cecum was plugged with gauze, and the usual dressing applied.

In the patient's weak condition it was out of the question to think of excising the cecum at that time. In fact I was very doubtful when the patient was put on the table if he would survive an intestinal anastomosis. He rallied from the operation, however, very satisfactorily, showing almost no evidence of shock. His progress toward recovery was uninterrupted and exceedingly rapid. As it was impossible to weigh him before the operation I have no means of judging with accuracy as to his gain in weight, but my impression is that it was not less than a pound each day for a month.

On the eleventh day after the operation the sutures were removed from the abdominal wound, and this was found to be perfectly united. The cecum was kept plugged with gauze, notwithstanding which there was some discharge of fecal matter, although the main portion of the feces was passed naturally. The button was passed from the rectum on the thirteenth day. I was determined to see if nature would close the defect in the cecum and in the abdominal wall, and so had the patient discharged from the hospital on October 31st. At the end of a month he was readmitted, begging for a second operation. The fistula had contracted to about two-thirds of its original size, and there was still some regurgitation of fecal matter. The man's general health was excellent. On December 8th I operated a second time. Before beginning the second operation I passed my finger into the colon and examined the site of the anastomosis. I had used the largest size Murphy button in the set. I found that the opening was barely large enough to admit the end of my index-finger as far as the base of the nail. On measuring my finger at that point I find that it has a circumference of exactly two inches, while the button used had a circumference of three-and-a-quarter inches.

Entering at the fistulous opening I dissected the large bowel loose from its attachments, and cut it across somewhat above the junction of the cecum with the ascending colon. I then closed the colon by a continuous suture, reinforced by a series of Lembert sutures. Then taking up the cecum, I dissected it downward to the ileo-cecal valve. On passing my finger through the valve I discovered that in my first operation I had not cut the ileum at its junction with the cecum as I had believed. It was impossible to reach the end of the segment. It at once became evident to me that nature in her attempt to circumscribe the original infected area about the head of the cecum had matted together the small intestines in such a way that what I believed to be the external portion of the ileum was only the point where it had entered into the formation of this wall. How much of it was involved I had no means of determining. On observing this condition I excised the cecum at the valve. I then proceeded to close the ileum by the same method that I had used for its other end, thus excluding that portion of the gut that lay between the point where I had cut it in the original operation and the ileo-cecal valve. I did not attempt to bring together the edges of the abdominal wound, but packed it with gauze and left nature to fill it up. The patient made an excellent recovery, and at the present time (January 20, 1895) is perfectly well.

This case presents several points of interest. It adds another to the list of end-to-side anastomoses by the Murphy method. I cannot speak too highly of the mechanical ingenuity of this button, and the facility with which an anastomosis can be made with it. In fact, I believe that it is the only possible method that I could have used in this case, owing to the patient's extremely weak and depressed condition at the time of the first operation. Any prolonged procedure would unquestionably have terminated his life on the table. By this method, however, the anastomosis was effected in a very few minutes, and the operation speedily finished.

So far as I know, this is the first opportunity in which the amount of contraction at the point of anastomosis has ever been observed in the living subject. Forty-two days had intervened between the time that the button was passed and the time of the second operation, and as the opening was found to have a circumference of but two inches instead of three-and-a-quarter, which it necessarily must have had at the time that the button was passed, this brings up a very interesting question as to whether this contraction will continue and where it will end.

The case also furnishes an addition to the 104 cases of excision of the cecum tabulated by Magill.[1] The article of Dr. Magill is a most exhaustive and admirable one, but I am at a loss to understand why he should apply the term "resection" to an "excision of the cecum." It is certainly a misnomer to speak of a primary removal of the cecum as "resection."

The second operation, I believe, furnishes the first example of a total exclusion of the portion of the intestine which has been performed in America.

In the *Centralblatt für Chirurgie*, 1894, No. 49, Obalinski discusses the case of total exclusion operated on by von Baracz, and reports two cases of his own. One of his patients suffered from a fecal fistula. The operation disclosed the fact that it communicated with a tuberculous appendix and cecum. Both of these structures were excised. The surgeon was not able to approximate the ileum to the ascending colon on account of the shortness of its mesentery; so he cut the colon at the junction of the hepatic flexure with the transverse

[1] William S. Magill: "Resection of the Ileocecal Coil of the Intestine, its Indications, Results, and Modus Operandi, with a Review of 102 Cases and Two Yet Unpublished." Annals of Surgery, December, 1894.

portion and made an end-to-end anastomosis between the transverse colon and the ileum. He then sutured both ends of the ascending colon, totally excluding it. In the other case he first effected a partial exclusion by fastening both ends of the excluded gut in the abdominal wound. This gave rise to so much inconvenience from the discharge of mucus from the fistula that he operated a second time, making a total exclusion. Both of the patients made good recoveries. Obalinski contends that to Polish surgeons is due the credit for the first two cases of total exclusion of a portion of the intestinal tract, and points out the fact that this operation has been confused with that of partial exclusion and simple excision. He cites Dr. Carmalt, of New Haven, as claiming in his article published in the *International Clinics* for October, 1891, to have made a total exclusion. Dr. Carmalt's case was simply an excision of the cecum, with an end-to-end anastomosis between the ileum and the ascending colon. He made no claim to having done an exclusion.

Obalinski further objects to the term exclusion as applied to this operation, and proposes in its stead "elimination." There can be no doubt that some confusion has arisen regarding the exact character of this operation through the indefinite term "exclusion," but to my mind "elimination" is no more definite. There is need of a term that will signify a shutting up of both ends of a portion of the intestine, thereby cutting it off from the fecal circulation and yet leaving it in place. I would propose for this operation the name "entero-apokleisis." This word in the Greek defines exactly the operation that is done, and if used the operation could be mistaken for nothing else.

The invariably good results that have followed this operation of entero-apokleisis show that it has a distinct and important position in modern abdominal surgery. It makes it possible to operate successfully on cases that without it would either be left with an artificial anus and its attendant horrors, or to die of the original disease. While on first thought it seems rather a rash procedure, its results show that it is not only justifiable but also to be commended.

PERFORATION OF THE RECTUM AND PERITONEUM BY IMPALEMENT UPON A PITCHFORK-HANDLE.

By WELLER VAN HOOK, A.B., M.D.,
OF CHICAGO.

A SHORT time ago a case of rupture of the rectal wall and perforation of the pelvic peritoneum by impalement came under my observation. It seemed at first to be a case of great rarity, but medical literature I find contains several instances of such penetrating injuries, and conversation with medical and lay acquaintances leads me to believe that only a small proportion of such cases are reported. The case to which I refer was as follows:

CASE I.—Leo M., aged thirteen years, in the enjoyment of perfect health, slid down from the top of a load of hay. Having had a common four-tined pitchfork in his hand, he had allowed it to slip to the ground, tines downward. The fork, instead of falling over, stood upright, leaning against the hay, with the tines sticking in the ground, and as the boy slid downward the handle of the fork perforated the clothing and entered the rectum. The boy fell over on the ground, and the handle became disengaged from the bowel. The boy made his way to the farmhouse near by and lay down upon a bed. The pain at this time was astonishingly slight, and the boy, whose parents were absent, did not send for a physician until the next day. Dr. Frederick Doepp, of Homewood, Ill., then saw the patient, and at once telephoned for me, but on account of the distance I did not see the patient until several hours afterward, when twenty hours had elapsed since the injury.

The instrument of penetration was first examined, and found to be a common cylindrical wooden fork-handle, three-and-three quarters inches in circumference, upon which blood and fecal matter were smeared for a distance of seven-and-three-quarters inches from its rounded extremity.

The patient's pulse was 110 and his temperature 101°; but the character of the pulse-beats was ominous, the vessel being hard and small. There was some tenderness over the hypogastric region. As I believed peritonitis had begun celiotomy was performed. In Trendelenburg's posture the abdomen was opened, and sero-purulent fluid with a fecal odor at once escaped. This was wiped out carefully, and the rent in the bowel sought for. The peritoneum was lacerated between the rectum and the bladder, in a transverse direction, to such an extent that the tips of four fingers could easily be introduced. The wound in the rectum was located in a line between the anus and the peritoneal laceration; *i. e.*, at a point about two inches above the anus. The wound in the peritoneum was closed with several interrupted sutures, and the inflamed intestines were gently cleansed by pressure with sterilized gauze, a great number of flakes of plastic lymph being removed. A large strip of iodoform-gauze was carried up by an assistant through the rectal wound into the space between the bladder and the rectum beneath the sutured peritoneum. Another strip of gauze enclosing a glass drainage-tube was carried down to the rectovesical space from the lower angle of the abdominal wound.

During the next two days the peritonitis spread rapidly. On the third the patient's condition improved somewhat, but on the fourth day the inflammation proved fatal.

Dr. Vinnedge, of Lafayette, Ind., has kindly placed at my disposal the notes of a similar case in which the outcome was favorable. It is probable, however, that the peritoneum was not injured in this case.

CASE II.—While engaged shaking out sheaves of wheat and pushing them into a moving thrashing-machine, near Lafayette, a man, about thirty years of age, strong and well, lost his balance, and fell backward off the feeding-table on which he stood, striking on a pitchfork-handle, which penetrated his rectum for a distance apparently between six and eight inches. The pitchfork-handle had been cut or sawed off so that it was only about one-third the usual length of a three-tined fork-handle, and was standing in a vertical position when the man fell on it, the tines having been thrust into the ground. The blunt handle entered the injured man's person one inch in advance and one inch to the right of the anus, external to the sphincters, and passed into the rectum low down, apparently following its course upward to the extent stated, if not a little further.

The injured man fell over with the fork in his person, and his associates who pulled it out of his body insisted that it was buried ten inches, and in proof of this they showed the forkhandle, one-and-a-half inches thick, which was bloody that distance from its extremity.

When first seen by Dr. Vinnedge the injured man was lying on a sofa, under a shade-tree in the yard of the farmhouse, apparently suffering only a moderate amount of pain. As to treatment, he was simply placed in the recumbent position, and advised to remain so until further notice. During the night his companions placed him in an improvised ambulance, and removed him to a point seven miles distant. On the following day Dr. Vinnedge, in company with Dr. W. C. C. Brown, of Lafayette, found his pulse and temperature each one-hundred, with but little pain. On the following day his condition was unchanged. From this time forward the man made a good recovery, leaving his bed at the end of a week. He defecated for the first time five days after the reception of the injury. There was never any suppuration or sloughing, and three weeks after his fall, when for the first time he presented himself for inspection, he said that he felt as well as he ever did, and that he was going to return to his work.

A hasty search through the *Index Medicus* and the *Catalogue of the Surgeon-General's Library* shows that cases of impalement upon sticks have been reported by Osberghaus, W. C. Jones, Watson, Chatterjee (bamboo-stick), Forget, and P. G. Hewett (leg of chair). Three cases of rupture with bougies, and one each with a colpeurynter, a coin, a wineglass, a gunbarrel, and a candle are reported. Two cases of laceration by a bull's horn are recorded, while in eighteen cases the nature of the instrument is not stated in the title.

Dr. Joseph B. Bacon reports a case of rupture of the rectum by impalement upon a tool-handle, the small intestine protruding through the wound into the rectum. The attending physician pushed back the prolapsed bowel and introduced a strip of iodoform-gauze to act as a drain. The patient recovered.

The original cases here reported are published in order to place them on record, but especially in order to request members of the profession who have made similar observations to communicate with me. All reports received will be fully credited to those gentlemen sending them. Upon the basis of such a collective investigation an attempt will be made to determine a number of important points in connection with these grave accidents; *e. g.*, the anatomic injuries sustained, the success of the different methods of treatment, and the general mortality.

MEDICAL PROGRESS.

Auscultation of Joints.—Richardson (*Asclepiad*, vol. xi, No. 43, p. 270) recommends auscultation of joints as a diagnostic procedure. He prefers the double stethoscope, though sometimes he uses the simple differential stethoscope, composed of two single-mouthed tubes quite separate, the ear-pieces of which can be adapted one in each ear. The mouthpiece should not be large (¾ in. in diameter is sufficient), and it is advisable to have the mouthpiece covered at its edge with India rubber, so as to avoid friction. If the double stethoscope is not at hand, the ordinary wooden instrument will suffice, but the double instrument enables the operator to manipulate the joint without the aid of an assistant. Auscultation of the healthy joint of a young person yields no sound or movement whatever. If movement be made in such a manner as to bring the end of the movable bone with some force into collision with the joint or bone that opposes it in the socket, no sound will be heard except a very gentle soft percussion-sound. When the sound is produced it may be called a cushioned sound. It ceases the moment the action that produced it is slowly carried out without pressure. A very slight derangement within the joint itself—less than a friction that produces impediment of motion, much less than an impediment that gives rise to pain—leads, however, to sounds that are distinguishable, the abnormal sound increasing in degree as the impediment within the joint is intensified or modified. Five modifications of joint-sounds are described: Simple dry friction-sound, dry grating sound, coarse grating sound, moist crepitant sound, and coarse crepitant sound.

Hysterectomy for Carcinoma of the Uterus.—Clarke (*Johns Hopkins Hospital Bulletin*, vol. vi, Nos. 52, 53, p. 120) recommends the following radical method of performing hysterectomy in the treatment of carcinoma of the uterus: He first introduces bougies into the cavity of the uterus under the local influence of cocain, thus saving time and conserving the patient's vital powers. The abdominal incision is made of sufficient length to insure freedom of manual movements. The upper portion of the broad ligament, together with the ovarian artery, is ligated; the vesico-uterine peritoneum divided around to the opposite side; the bladder pushed off and the layers of the ligaments spread apart, exposing the uterine artery. The uterine artery is dissected out for 2½ cm. from the uterus beyond the vaginal branch, and tied. The ureter is dissected free in the base of the broad ligament. The remainder of the broad ligament is ligated close to the iliac vessels, and cut away from its pelvic attachment. The dissection is carried well down below the carcinomatous area, even though the cervix alone seems to be involved. The same steps are followed on the opposite side. The vagina is perforated with sharp-pointed scissors, making strong traction on the uterus with small volsellum-forceps, so as to pull the vagina up and make its walls tense. The affected parts are then ligated in small segments (1 cm.), and each segment is cut as it is tied. Iodoform-gauze is next inserted from above into the raw space left by the hysterectomy; and the vesical and rectal peritoneum is drawn over this with a continuous fine silk suture.

Dermoid Cyst of the Tongue.—Dumstrey (*Deutsche medicinische Wochenschrift*, 1895, No. 35, p. 573) has reported the case of a man, twenty-four years of age, who presented himself on account of difficulty of speech and deglutition of three-years' standing, caused by a swelling in and under the tongue, at first increasing in size slowly but latterly more rapidly. Mastication and deglutition could only be performed slowly and with difficulty and effort. Speech was markedly nasal, and for a short time there had been distressing though transient attacks of intense dyspnea, especially in the morning on arising. On examination a tumor was found beneath the tip of the tongue presenting a doughy feeling and

fluctuation. The mass was almost as large as a fist, and displaced the tongue upward and backward. The formation was believed to be a ranula, and an operation was undertaken for its removal. After the induction of cocain-anesthesia, the mucous membrane covering the tumor was carefully divided in the median line, when it was found that the mass was covered also by a thin layer of muscular tissue, on the removal of which the growth was with some little difficulty extirpated. The tumor was reniform in shape, 7 cm. (2.75 in.) long, 3½ cm. (1.38 in.) wide, and 4.75 cm. (1.87 in.) thick. It weighed 68.6 gm. (2.42 oz.), and on microscopic examination proved to be a dermoid cyst. The further course of the case was uneventful, recovery ultimately ensuing, the patient after the lapse of twelve days being relieved of all difficulty of speech and deglutition.

Gastric Carcinoma in a Young Man.—At a recent meeting of the Société médicale des Hôpitaux of Paris, MATHIEU (*Wiener klinische Rundschau*, 1895, No. 35, p. 552) reported a case of fatal carcinoma of the stomach in a man twenty-five years old. The first symptoms of gastric derangement appeared three years before death, and were characterized by features of hyperchlorhydria. The administration of alkalies being unattended with improvement, the gastric juice was examined and anachlorhydria found. The patient subsequently became cachectic; a tumor appeared in the epigastrium, and an exploratory celiotomy disclosed the existence of carcinoma of the stomach and peritoneum. In the discussion Catrin and Ferrans each reported a case of carcinoma in a young person, pursuing a protracted course and terminating fatally.

THERAPEUTIC NOTES.

The Treatment of Hemophilia with Calcium Chlorid.—At a recent meeting of the Medical Society of Victoria, BRYANT (*Australian Medical Journal*, vol. xvii, No. 8, p. 340) reported the case of a boy, four-and-a-half years old, who, at the age of twelve months, had received a slight scratch upon the mucous membrane of the lower lip, as a result of which there was a constant oozing of blood for eleven days. The bleeding was controlled by gentle pressure between fingers and the application of collodion on cotton-wool. At the age of two-and-one-half years the child fell and injured the knee-joint. The neighboring parts became black, and the joint swelled and became tense and was apparently filled with blood-clot. Treatment by rest and evaporating lotions was followed by complete recovery. The parents stated that the slightest touch resulted in a black skin-mark, and the child always presented bruises. The boy was rather anemic in appearance, but had grown stout and appeared quite healthy. At the age of four-and-one-half years a punctured wound in the right supraorbital region, resulting from a fall, was followed by obstinate bleeding that failed to yield to the usual hemostatics. The child became almost pulseless, blanched, and transparent. The hemorrhage was partially controlled for a time by applications of hot water, followed by lint soaked in collodion, together with compression. Slight oozing persisted, and on the fourth day a large clot was found protruding from the wound, the edges of which were sloughing and bleeding. Matters continued thus alarmingly for ten days, when a solution of calcium chlorid was administered at intervals of two hours. Thereafter the hemorrhage gradually ceased, and did not recur. In addition to the administration of a soluble salt of calcium in large doses, the local application of pads soaked in a recent infusion of thymus gland is recommended for the control of obstinate hemorrhage.

The Treatment of Diphtheria with the Antitoxin.—In support of the utility of the antitoxin in the treatment of diphtheria, BEHRING (*Deutsche medicinische Wochenschrift*, 1895, No. 38, p. 623) has collected from official sources the following statistics, showing that the proportion of cases of diphtheria admitted to the hospitals of Berlin has not increased since the introduction of the antitoxin:

	1891	1892	1893	1894	1895 to July 28
Number of cases of diphtheria treated in the city of Berlin	3502	3772	4296	5240	3111
Number of cases of diphtheria treated in Berlin hospitals	1727	2120	2403	2900	1666
Per cent.	(49.3)	(56.2)	(55.9)	(55.3)	(53.5)

The increased number of cases is to be attributed to increase in population.

The following figures show the reduction in the mortality from diphtheria in Berlin, both in and out of hospitals, since the introduction of the antitoxin:

	1891	1892	1893	1894	1895 7 mos.
Number of cases of diphtheria treated in the city of Berlin	3502	3772	4296	5240	3111
Number of deaths	1144	1376	1577	1496	495
Per cent.	(32.6)	(36.5)	(36.7)	(28.5)	(15.9)
Number of cases of diphtheria treated in Berlin hospitals	1727	2120	2403	2900	1666
Number of deaths	613	867	931	611	250
Per cent.	(35.3)	(40.9)	(38.7)	(21.1)	(15.5)

Extended investigation shows that the mortality from diphtheria in Berlin in the year 1895 was two-thirds less than in the previous seventeen years, during which careful official statistics have been collected.

The following figures show the results obtained in the surgical clinic of Prof. Bose at Giessen in the treatment of 112 cases of diphtheria with the antitoxin:

	All cases.		Tracheotomized.		Not tracheotomized.	
		Died.		Died.		Died.
Jan. 1, 1890, to Jan. 1, 1893	93	48	84	45	9	3
Per cent.		(51.6)		(53.5)		(33.3)
Jan. 1, 1893, to Jan. 1, 1894	186	82	148	78	38	4
Per cent.		(44.0)		(52.7)		(10.5)
Jan. 1, 1894, to Oct. 26, 1894	144	54	91	49	53	5
Per cent.		(37.5)		(53.8)		(9.4)
Oct. 27, 1894, to July 31, 1895	112	9	52	8	61	1
Per cent.		(8.03)		(15.2)		(1.6)

Philadelphia.

SATURDAY, OCTOBER 12, 1895.

THE EMPLOYMENT OF PRISONERS.

We do not know of any example of popular legislation that equals in folly and wickedness the amendment to the New York State Constitution, recently offered to the people for ratification, which prohibits the employment of prisoners at productive labor. We learn from a New York contemporary that this brutal amendment was included with a number of others, and that all had to be voted on together. As some of these amendments were intended to secure much-needed reforms, the people were confronted with the disagreeable alternative of accepting the evil with the good, or rejecting the good entirely. We presume, or at least hope, that it was for this reason alone that this particular amendment was adopted.

It is to be noted that this is not a statute-law, which can be altered at any time by the Legislature, but that it is a part of the constitutional law of the State. Therefore, under our cumbersome system of national and State Constitutions, it is somewhat like the ancient laws of the Medes and Persians. There is no getting rid of it easily. Originally the intention of the fathers was that the Constitution should contain only fundamental law; but the opportunities for demagogues and labor-agitators not to keep their hands off were too good to be missed, and so now we witness these politicians securing "labor-" legislation and foisting it into the State Constitution, whence nobody, it is presumed, will ever be able to get it out again. The true nature and tendency of this piece of lawmaking can be illustrated in a few propositions.

First, let us consider the policy of it. It is evidently intended to placate the "labor-" element. It is inspired by "socialism"—which is the most truly unsocial cult that was ever preached, and is, or would be, the worst tyrant that ever held sway. In this instance the monster disregards the rights of all other persons, not only the unhappy prisoners, but all taxpayers, and frames a law in favor of a few special classes. It protects those only whose labor is in competition with that of the convicts, and embodies this grossly discriminating law in the State Constitution, which is designed to be only the repository of fundamental law for all. The whole scheme shows a lack both of intelligence and of conscience; of intelligence to grasp the higher principles of statecraft, and of conscience to regard the rights of all.

Second, let us consider the effects of the amendment. We learn that under it convicts are to be limited to such labor as is necessary for supplying the public institutions of the State with such articles as they need. This sounds well; but it is specious and tricky. All labor for the State of New York must, by this very Constitution, be given out on contract to the lowest bidder. Convicts are therefore excluded from all this productive labor. Mr. Eugene Smith, an authority, says that all the available work under this amendment will not give employment to *one per cent.* of the prisoners. The Superintendent of State Prisons estimates that *fifty* prisoners could do it all. The effect, therefore, is obvious. This amendment will condemn the whole convict-population practically to idleness. Under the Yates law, which secured by legislation what this amendment forces into the Constitution, this very experiment was tried a few years ago. As a consequence the prison-workshops were closed and the wretched prisoners were shut up in their cells. Almost immediately the death-rate in the prisons rose to the highest figure ever known; insanity increased. The prisoners sent forth a wail of protest and begged for any work, however menial. The finances suffered also. The first year there was a deficit of $150,000, and the second year one of

$370,000, in contrast with the old system, which had been self-supporting. This deficit, of course, had to be made good by the taxpayers, many of whom can ill afford to bear the burden; and no person's wages were increased a penny so far as any one knows.

In the third place, let us consider the injustice of the amendment. It assumes that one class of men may forbid another class of men to work. This is a common and vicious kind of tyranny seen in trades-unions. When, however, it is exercised against a class who, like the State prisoners, are unable to defend themselves or to exercise their natural rights, it is conspicuously base and cowardly. We speak of the *rights* of these prisoners advisedly. Men do not lose all their natural rights and their claims upon society when they enter a prison's walls. Some of these claims, in fact, are immensely increased and strengthened as soon as the condemned are incarcerated; and among these claims are the reformation of character, the preservation of health, and the exercise of an inalienable right to do honest and productive work. By what principle of law or equity is a State to be denied the right to give work to a class of citizens that she has taken to be her wards? It is to be noted in this connection that no cruelty equals the cruelty of which an ignorant proletariat can be capable toward the weak and the defenceless.

Finally, let us consider the inhumanity of the amendment. The men who framed this constitutional amendment were absolutely indifferent to the fate of several thousands of their fellow-citizens. They were either too ignorant to know or too callous to care to reflect that this amendment was primarily a blow at the prisoners and only secondarily a favor to the artisans. In other words, the good that it could do the artisans was infinitesimal in proportion to the evil that it would do the convicts. For the former it provided a possible benefit; for the latter an inevitable disaster. The proof of this is to be found in the facts and figures already stated; and is abundant in all the literature of penology. This proof is so patent and above argument that it is probably well known even to lobbyists and walking delegates. Prisoners cannot be immured in solitary cells without labor without also undergoing physical, mental, and moral deterioration. The sufferings attendant upon such a confinement are worse than what any civilized government has a right to inflict, and can only be compared with those that fell to the lot of political prisoners who rotted in the Bastile under a régime which it was supposed that modern democracy had abolished forever. Such sufferings, in fact, could only be inflicted by an irresponsible despotism on the one hand or an irresponsible populism on the other; so near in effect are the extremes in politics.

We do not care, of course, to venture a prediction as to what will be the force and effect of this evil example set by the great State of New York. We do not know at this writing whether there is a similar law or amendment in actual operation in any other of our States. It is not likely, however, that such jurisprudence will stop where it began. If it is about to inaugurate an era of proscription against the productive labor of prisoners, it sounds the knell to some of the most enlightened philanthropy of the day. We remember to have heard of an incident that occurred in one of our interior States, where a gang of convicts was set to work to carry a pile of bricks from one side of the jail-yard to the other, and then back again, and so on indefinitely. This was done by the authorities on the humane pretence of supplying work that would not compete with honest labor. It is needless to say that such work proved at first a farce and finally a torture to the prisoners and a menace to the discipline of the jail; but such as it is we commend the example to the political penologists of the Empire State as peculiarly appropriate both to the situation and to their intelligence.

BOVINE TUBERCULOSIS AT THE NORRISTOWN HOSPITAL FOR THE INSANE.

In our issue of March 30, 1895, we called attention to the very high death-rate from tuberculosis existing at the Norristown Insane Hospital, a death-rate that compares unfavorably with that of other hospitals, and that we thought needed investigation in order to discover the causes at work.

A special report by the pathologist of the institution, Dr. Florence Hull Watson, giving the results of experiments with tuberculin on a herd of cattle in part supplying the institution with milk and meat, has recently been issued, and, though no attempt is made to show the connection existing between the high mortality from tuberculosis among the inmates of the hospital and a milk-supply from animals suffering with bovine tuberculosis, the report is a very valuable one, not only adding much to the knowledge of animal pathology, but demonstrating

the diagnostic value of tuberculin in a most conclusive manner.

Probably never before in the history of medicine have so many valuable animals been given over at one time for the purpose of experiment, and the results of this investigation have an interest therefore not only because of the care taken in their collection, but also because of the amount of material placed at the disposition of the investigator.

From Table XXVI of the report we learn that the whole number of animals examined was 206; of this number, 170, or 82.5 per cent., were found infected with tuberculosis, the disease being general in 53 and thoracic only in 114. In only three cases was the udder found diseased.

From other tables in the report it is to be seen that tuberculin was used in 183 animals, 117 of which were condemned as tuberculous after the first injection. The rise in temperature took place in from twelve to fourteen hours, and reached on the average 106.1°F., the normal temperature before the injection being on the average 102.3° F. No relation could be discovered between the degree of reaction and the amount of disease; nor did sex or breed have any influence. Young animals are not well suited for experiment, as in them the temperature in the normal state often varies several degrees. Dr. Watson believes that tuberculosis can develop very rapidly, and in this way she explains the failure of tuberculin to call out a reaction in seventeen animals that at autopsy, two months after the injections, were found slightly tuberculous. The question might be raised here, and it is a very vital one, What effect, if any, has the injection of tuberculin in lighting up tuberculosis present only to a slight degree before the injection? Or are the products of dead bacilli capable of producing tubercles in healthy tissue, as Prudden has claimed?

Every animal reacting to tuberculin was found tuberculous at the autopsy. Dr. Watson, as the result of her experience, states that while infallibility cannot be claimed for tuberculin as a diagnostic agent, yet in proper hands, combined with physical examination, will lead to the discovery of the disease in the majority of affected animals in a given herd, and if these are removed the danger of contamination will be lessened and the infectiousness of the dairy-products reduced to a minimum.

When we consider that 70 per cent. of the cows furnishing milk for the inmates of the institution were markedly affected with tuberculosis, and that for many of the patients this milk was the principal article of food (about 1000 quarts are used in the hospital daily), and that according to the recent investigations of Ernst, referred to in The News of August 31, 1895, page 244, tubercle-bacilli are found in milk from tuberculous cows, irrespective of the existence of disease of the udder, we are warranted in assuming that the milk-supply stood in a causal relation to the prevalence of tuberculosis among the inmates of the hospital.

In stating this we are well aware of the position many alienists take in regard to the connection supposed to exist between insanity and pulmonary tuberculosis. Yet, Clouston, who originated the term "phthisical insanity," and who is responsible for much that has been written on the subject, in an article contributed to Tuke's *Dictionary of Psychological Medicine*, refers to the fact that under better hygienic conditions the percentage of deaths per 1000 from pulmonary tuberculosis, in insane-hospitals, has been greatly reduced, and whereas in 1862, when he first described this particular form of insanity, he considered it incurable, he now finds that under proper treatment and better conditions recoveries are frequent.

That tuberculosis is more common in insane-asylums than in the community at large no one will deny, but we doubt that it need necessarily be so. It is most frequent when nutrition is interfered with, as in the dementias and melancholias, and in such forms of insanity the tubercle-bacillus, if present in the surroundings, finds a ready soil for development; overcrowding, close confinement, and infected food accelerating its growth.

The result of the investigation at Norristown shows how important it is to be able to control the sources from which food is obtained, and how necessary it is to have the supply of milk carefully and regularly tested, in order that its wholesomeness may be beyond doubt.

Although the trustees of the hospital have so far found dairy-keeping an expensive affair, the advantages to be derived from it far outweigh its costliness. With a little care in the selection of animals and with inspection of the herd at frequent intervals, the need of a repetition of the experiment just ended may never arise, while, on the other hand, a wholesome supply of milk is obtained for the inmates, and one of the sources of infection eliminated.

EDITORIAL COMMENTS.

The Growth of United States Naval Cadets.—Dr. Henry G. Beyer, a surgeon of the United States Navy, has made a very interesting study based upon a series of measurements of students at the Naval Academy, extending over a period of thirty years. Such examinations are made at intervals of a year, so that each cadet who remains for the full term of four years leaves a record of at least five measurements.

The growth of school-children has formed the subject of a number of investigations by such men as Bowditch, Boas, Porter, Pagliani, Axel Key, and Schmidt, and approximately similar conclusions have been arrived at by these separate observers. Beyer has been very careful to avoid error in drawing his conclusions, and it seems to us that his judgment in the matter is well warranted by the figures he presents. An inconsistency, however, appears in his paper that we would call attention to. Because the cadets are appointed from all parts of the United States, Beyer believes his measurements have a national character—"more national, at least, than the measurements taken from local schools and colleges;" and yet, curiously enough, the great majority of cadets have blue eyes and light-brown hair—a fact that Dr. Beyer himself observes is indicative of an Anglo-Saxon or Teutonic origin. In another place he finds a source of congratulation in the fact that the facial type under investigation is not a mixed one, but "undoubtedly Teutonic in character."

Unfortunately, anthropologists do not recognize a German type, inasmuch as the inhabitants of North Germany are fair and those of South Germany dark; the Irish, too, according to Dr. Wilde, are as often dark-eyed as blue-eyed. Now, although immigration to this country for the last seventy years has been principally from Germany and Ireland (53 per cent.), the representative American can hardly be said to be a North German in type, possessing the elements of as many brunet European types as blond ones, not to speak of admixture with the Negro and Indian races.

From the tables presented we find that the bodily weight increases steadily from the fifteenth to the twenty-third year, declining thereafter as age advances. Height increases mostly between the fifteenth and sixteenth years; for the succeeding two years a rapid decline in the rate of increase occurs, and growth practically ceases. After this a marked increase again occurs, which stops at the twenty-first year; finally, a third upward curve leads to the attainment of full growth.

"Height sitting" (the distance from the perineum to the top of the head) ceases to increase about the nineteenth year, and "height perineal" (the distance from the perineum to the feet) is fully attained at the same age. The circumference of the chest advances rapidly to the nineteenth year, and after that only by small fractions of an inch.

An interesting fact which other observers have also noted is that both the relative and the absolute annual increase in growth is greater for short than for tall boys. If boys of the same age are divided into two groups according as they are above or below the average height or weight, and if these groups are studied for several years, it will be found that the taller will stop growing sooner than the short group, and that the average percentage of increase will not be nearly as great in the former as in the latter. Beyer found that the short boys in the period from sixteen to twenty-two years of age grow 4.2 inches, the middle-sized ones 3.3 inches, and the tall ones only 2 inches. The tall boy is thus, with reference to growth, in reality older than the short boy, his tissues reaching maturity two years sooner.

The measurements of 722 cadets at seventeen years of age gave an average weight of 57.7 kilos (125 pounds); "height standing," 170.3 centimeters; circumference of chest, 82.55 centimeters. At twenty-three years of age the average weight was 65.31 kilos, and the average height 174.29 cm. This is but very slightly in excess of the average attained by Dr. Sargent in his measurements of Harvard students. Gould, in his study of soldiers during the Civil War, gives an average height of 173.6 cm. as that of the true American. According to Topinard, the average stature of the human race, taking the whole population of the globe, is 165 cm., and the tallest race, the Patagonians, average no more than 178.1 cm.

While we must not forget that the measurements of Beyer, Sargent, and Gould are of specially selected groups, and therefore not representative, yet we can safely say that the native-born inhabitants of the United States are to be grouped with the tallest races, being exceeded by few, if any, of the civilized nations.

Occult Compensation.—The following letter, written to a reputable physician, needs no comment or explanation:

A. B. C.,
Physicians' Specialties,
Room —, —— — ——.
————, O., ————, 1895.

— — ———, M.D.

Dear Sir: Owing to the fact that I have been recently unjustly ousted from the responsible confidential position I have held with the Amick Chemical Co. of this city ever since its organization, I think I am fully justified in making the most I can of the knowledge I have of the secrets of that concern; especially in view of the fact that the success of the company is largely, if not wholly, due to my management.

With this end in view, I make the following proposition to a selected list of physicians whom I believe I can trust not to abuse the confidence I place in them, but will keep it to themselves for my protection and their personal profit and interest.

I have in my possession photographic copies of the secret formulæ for Dr. Amick's remedies for consumption, in his own handwriting, which include his chemical constitutional medicine, the tablets, and the inhalant. The well-known merits of these remedies make it useless for me to say anything regarding them; I will say, however, that to my personal knowledge they turned down an offer of $50,000 for these same formulæ, and their reason for doing this was because a single year's dividends amount to more than twice that much, while I who have done the hardest work received of these enormous profits a comparative pittance as my portion.

The actual cost of compounding these remedies is merely nominal, although the best of drugs be used.

I will send you *fac-simile* copies of the original formulæ on receipt of $5; also the names of the manufacturers from whom they buy their drugs.

In order that you may not question my sincerity or

integrity, I respectfully refer you to the enclosed letter to me from Hon. Jno. A. Caldwell, our Mayor; also to a letter written to me by the President of this hoggish corporation while in New York consummating one of my most successful advertising schemes for the concern.

I feel doubly justified in my course, as I am favoring suffering humanity at the expense of a grasping, heartless corporation.

There is no time to be wasted in correspondence. If you are going to accept this offer, you must do so by return mail, for as soon as the Amicks get on to what I am doing they will enjoin me.

Yours respectfully, ——— ——— ———.

P.S.—You may feel it your duty to at once call the Amicks' attention to this, but allow me to call your attention to the fact that by so doing you will be depriving yourself of an invaluable secret and that the Amicks never showed you a favor, or any other interest in a member of the medical fraternity, than to get $10 for a month's supply of medicine.

Tuberculin versus the Microscope in Iowa.—The State Board of Health of Iowa was requested by the health-officer of the city of Ottumwa to make a bacteriologic examination of the milk-supply of that city, with a view of ascertaining whether any tubercle-bacilli could be found in the milk. The bacteriologist of the Board accordingly examined 563 samples, and found the bacilli present in quite a number of the specimens, so that of 196 cows examined 29 were set aside as tuberculous because of the microscopic test. The secretary of the Board was not quite satisfied with the results, and the State veterinarian was called in to apply the tuberculin-test. The animals declared tuberculous by the bacteriologist failed to react to tuberculin, and in a herd of 22 cattle, 21 of which had been pronounced sound, 8 responded to the tuberculin-test, and at the autopsy were found markedly affected, 2 of them having extensive involvement of the udder. The bulletin of the Board states that no conflict exists in its department on account of this difference in opinion; the two tests are on trial, and the wish of the Board is to judge them honestly.

The Iowa Board of Health must know that neither the microscopic examination of the milk nor the tuberculin-injection of the cows can determine the *absence* of tuberculosis. Only when positive results are obtained can an opinion be given; the failure to find the bacillus is no evidence whatever of the non-existence of tuberculosis.

The presence of tubercle-bacilli in milk is not easy to determine, and the frequency with which they were discovered by the Iowa bacteriologist would lead one to suspect the accuracy of his observation; but granting that they were found, the failure of the animals to react to tuberculin is no indication that these animals are sound, as the tuberculin-test is in no manner infallible. The State Board of Health of Iowa should sacrifice the suspected animals and determine beyond a doubt whether tuberculosis is present or not.

Not only in the testing for tuberculosis, but in using other methods of diagnosis, the fact cannot be too often stated that the failure to *find* a symptom or pathologic condition is no indication of the absence of that symptom or condition.

Preventive Inoculations against Cholera.—The evidence is increasing as to the efficacy of the inoculations made according to the method of Haffkine for the prevention of cholera. From a report recently made by Dr. W. J. Simpson, health-officer of the city of Calcutta, it appears that up to July 15, 1895, 4397 persons were inoculated in Calcutta. Of this number 3302 were Hindus, including 363 Brahmins; 1060 Mohammedans; 25 Europeans; and 10 Eurasians.

In some instances it has been observed that cholera ceased in the course of a few days after inoculations had been begun. In some localities noted for recurrences of cholera, and in which large numbers of inoculations were made, the disease did not appear during the year. In a small community in which the people petitioned to be inoculated, because of repeated outbreaks of cholera, not a single case has occurred. In a group of 36 houses, containing 521 inmates, of whom 181 were inoculated and 340 not, there were among the uninoculated 45 cases of cholera, with 39 deaths, while among the inoculated there were only 4 (fatal) cases. Of this last number, one occurred 459 days after the first inoculation in a child not brought back for the second inoculation, and the other three occurred within a few days of the first inoculation, before protection had really been conferred, and thus before a second inoculation could be made.

The following additional noteworthy observations were reported at a later date. When cholera broke out among the troops at Cawnpore thirteen months after the inoculations there were attacked, among 797 uninoculated, 19 cases, with 13 deaths, and among 75 inoculated not a single case. At Dinapore the inoculations were made during an epidemic, after 13 cases and 9 deaths had occurred. Among 729 uninoculated there were 6 cases with 3 deaths, and among 193 inoculated not a case. At Lucknow, where a portion of the soldiers had been inoculated fourteen or fifteen months previously, there were among 640 uninoculated 120 cases with 79 deaths, and among 133 inoculated 18 cases with 13 deaths.

College-attendance and Athletics.—That supremacy in athletics by an institution of learning is the prerequisite and proof of the "success" of that institution has been an assumption that apparently needed no proof. One enthusiastic theorist publicly asserted that the success of his college in football was worth more than a million dollars of endowment. We are very far from believing that the number of students in attendance at a college is any measure of the value of that institution to humanity or to its students. This would be an error of observation and logic akin to that of the football-logicians, but, proceeding upon the assumption of these excellent reasoners, we call attention to the fact that the freshman-class at Yale—Yale supremely victorious over Harvard in athletics—is smaller than that of last year, whilst the freshman-class of Harvard is larger than that of last year. We have frequently prophesied this, but we hardly expected that it would come about so speedily.

"New York as a Medical Center."—After a few weeks' stay in New York our valued contemporary, *The Medical and Surgical Reporter*, returns again to its old home in Philadelphia, where we trust its commercial troubles may end and its customary prosperity long continue.

SELECTION.

"GREAT WITS AND MADNESS."

IF a man in these days has the fatal gift of genius, the best thing he can do is to conceal the fact, and be content to be a "mute inglorious Milton," lest he be sent to a madhouse. With detectives like Lombroso, Max Nordau, and Mr. Nisbet about, the poor child of Apollo would have no chance. As if this trio of "smellers out" were not enough, now we have L. Forbes Winslow, D.C.L. Oxon, LL.M., M.B. Camb., prowling about (marry, tropically, in the best pages of *The Humanitarian*) seeking what man of genius he may devour. For this multiliterate philosopher the line that separates "the babbling drivelling idiot from the man of transcendent genius" is "fine and fragile." We are told that "the development of the brain and nervous system on which the poetical inspiration depends" is nearly allied to "that cerebral condition so frequently associated with insanity." We gather that poets and men of genius generally suffer from "excessive expansion of brain-matter." It is also discomforting to be informed that "in the majority of studious men there already exists a predisposition to cerebral disease which may have actually existed." Further on we read that "Byron had—1784—as a child a temper sullenly passionate." The sentence is a little obscure, but on any construction of the text it would appear that the author of *Childe Harold* must have been the most precocious infant phenomenon of whom there is record if he displayed these unamiable characteristics four years before he was born. Of Scott we are told that although his "early composition" was wonderful, "there was evidence to the psychologist of *that flaccid degeneration of tubular neurine* which probably began with his reverses," etc. Poor Scott! Torquato Tasso may be accounted fortunate that he only suffered from "mania periodique" and "phantasmagoria." The statement that "Jean Jacques Rousseau, the great French poet, suffered from a bane of moral insanity" suggests that the writer had never heard of Jean Baptiste, the rhyming namesake of the Citizen of Geneva. Coleridge's life was not exactly a model of self-restraint, but it is painful to learn that he "became an habitual resorter of drugs." The "premonitory cause" of Charles Lamb's "mental condition becoming unhinged" is alluded to. For the discovery of "Edgar Allen, poet," the printer's devil is probably responsible. Dr. Forbes Winslow sees in the insanity of genius "one of the many awful proofs of immortality," but he does not condescend to explain this mysterious utterance. Rasselas said that his instructor had convinced him that it was impossible to be a poet; had he read Dr. Forbes Winslow's article he would have been thankful for this impossibility. Surely it is far better to plod on along the beaten road of life than to soar into the empyrean and fall a victim to "flaccid degeneration of tubular neurine."—*British Medical Journal*, August 24, 1895.

"GREAT SCOTT!"

AT the last session of the California Legislature a Demosthenean orator, clad in a Bismarckian countenance and a Prince Albert coat, and a former partisan of Carl Brown, Coxey, and other industrial agitators, appeared upon its floor and circulated the following printed handbill or circular-letter to the members of both branches of the Legislature:

SACRAMENTO, CAL., March 9, 1895.

Hon. ———

DEAR SIR: All that LIBERTY means, all that JUSTICE means, and all that PROGRESS means as one united prayer, appeals to you not to hinder the passage of S. B. 830, granting only one favor to the State Therapeutical Society to have a Board of Examiners. Let California make history and throw her protection over the class of healers. We plead for viz.: Those who are liberal in medicine, and those who practice hydropathy (*i. e.*, the water-cure and baths), electricity, massage, mental or scientific healing, providing they have legal diplomas, or evidence of competent instruction and experience. This is our requirement.

PLEASE vote for it and no longer hold this large, intelligent class of practitioners out. They cannot give the death-certificate if one dies, but although over half of the best families employ them. They have to call in an M.D., or "two citizens, or a coroner, or a midwife," often too ignorant to write, to name the disease, and sign that certificate, while we are barred out. Great Scott! To whom CAN we go but YOU? Medical doctors hunt us down with threats and suits. This bill takes no right from them, but it will let justice lie toward merit. This new society has a good college back of it, of able medical men; let the Board simply be granted us as you have to the other school and societies. WHY NOT? Why shall hypnotism and other harmful forces be used by charlatans when we can regulate them and the forces if you give us our Board and let us prove what we claim. This society is a corporation and entirely self-sustaining.

We trust your JUSTICE, KINDNESS, and WISDOM, and ask ONE favor. Will you grant it? If so, you will go home pleased, and millions will rejoice. Come men, we beg it of you in your true justice, and you will do it. We bide in hope, yet in painful suspense. We, the directors, officers, and members of the California State Therapeutic Society; also the directors, officers, and professors of the College of Science, standing in with this Society, authorize the presentation of these interests by

PROF. ———, Ph.D.

[*The National Popular Review.*]

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eighth Annual Meeting, Held in Chicago, September 24, 25, and 26, 1895.

(Concluded from page 392.)

The President, DR. J. HENRY CARSTENS, of Detroit, delivered his address. He selected for his subject

THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

In speaking of specialists, he said: "What we do is not for us, but for the whole profession. We think we can do more by limiting ourselves to a particular branch, and what little mite we add is not for us as

specialists, but is to be the inheritance of the whole profession. We want the whole profession to be elevated, to become accurate, and as nearly scientific as possible in medicine. We want to raise medicine in the estimate of the laity, so that it shall not be laughed at and ridiculed in the pulpit or court-room, but that it shall shine forth as an art and as a science and the noblest vocation."

Dr. F. Blume, of Pittsburg, read a paper entitled

ETIOLOGY OF ECLAMPSIA GRAVIDARUM.

He said that the etiology of this grave complication of labor is still undecided. The theory that has found the most advocates is based upon the investigations of Leber, who first called attention to the relations between albuminuria and puerperal convulsions. Leber's observations were confirmed by various authors, and led to the view that the attacks were the result of blood-poisoning by urea; that they were uremic and identical with those occurring in diseases of the kidney. According to Spiegelberg, all cases of true eclampsia are of uremic origin. The cause is a renal lesion that either pre-existed or developed during pregnancy. In 400 cases of eclampsia observed by Olshausen, Dührssen, and Gusserow, albuminuria was present in 98 per cent. Mackenrodt found that albuminuria developed during the second half of gestation in 46 per cent. in women whose kidneys were normal before conception took place.

Dr. H. W. Longyear, of Detroit, read a paper on

THE PROPHYLACTIC TREATMENT OF ECLAMPSIA GRAVIDARUM.

He recognizes two varieties of convulsions that may occur as a result of the pregnant or puerperal condition—first, those of a purely nervous character, which usually occur in women of neurotic habit and those who are predisposed to epileptic attacks; and, second, convulsions that occur as a result of some change in the blood and tissues of the patient due to renal disease, as especially indicated by the presence of albumin in the urine.

Early diagnosis is of the utmost importance to the success of any preventive treatment, and to insure this the urine of every pregnant woman should be systematically examined by the physician every two weeks after the sixth month. When albumin is found to be present immediate treatment should be commenced and daily examinations of the urine made thereafter. The prophylactic treatment was divided into dietetic, medicinal, and operative, the latter to be adopted as a last resort. In simple cases of albuminuria without scanty secretion, many patients will do well and be tided along to safe confinement on an exclusive milk-diet without medication.

Dr. W. P. Manton, of Detroit, followed with a contribution entitled

SO-CALLED PUERPERAL ECLAMPSIA IN ITS RELATION TO INSANITY.

He had recourse to three sources of information—statistics from private practice; statistics from lying-in hospitals; and the records of hospitals for the insane. Never having had a case of insanity following eclampsia in his own practice, he had collected 8868 cases of delivery reported by eight competent observers, published in current medical literature. In this number he found that eclampsia is noted as having occurred 33 times. In not a single instance is it stated that insanity followed the convulsive attacks. During the four years from 1891 to 1894, inclusive, 282 women were delivered in the wards of the Detroit Woman's Hospital, eclampsia occurring in two cases. Both of these recovered without symptoms of mental alienation. This seems the more remarkable, as of the 282 patients confined, 233 were unmarried. During the same period there were admitted into the three principal asylums of Michigan, with which Dr. Manton is connected, 1271 female patients. In this number the insanity was attributed to puerperal causes in 110 instances, but in only two cases was eclampsia put down as the exciting cause.

Dr. Rufus B. Hall, of Cincinnati, Ohio, read a paper upon

THE PREVENTION OF PELVIC INFLAMMATION IN WOMEN.

He pointed out some of the most frequent causes of this condition, placing septic infection following abortion and gonorrheal infection as the most important. He advocated the dissemination of knowledge among the laity by the family-physician as a potent remedy for the prevention of these troubles. He especially advocated that women should be warned by their physicians of the great danger of abortions in the early months of pregnancy. It is well recognized by the profession that many married women produce abortion in the early weeks of pregnancy, and it is during this time that the membranes are retained and septic endometritis is induced, leading to salpingitis, pyosalpinx, and suppurating ovaries later. It was also advocated that the profession should on every legitimate occasion impart knowledge on the subject of gonorrheal infection in young men and boys. It is well known that men frequently infect their wives years after they themselves believe they are cured of their gonorrhea. The belief was expressed that if the profession imparted this knowledge to the laity, it would only be a short time until many of the abdominal sections now made for the relief of inflammatory diseases will not be called for.

Dr. A. H. Cordier, of Kansas City, Mo., read a paper entitled

DIAGNOSIS OF INTRA-ABDOMINAL TUMORS.

He outlined the methods and procedures that should be followed in examining patients. Tumors through which gases are detected by gurgling indicate either an involvement of the bowel in the tumor, or pressure of the growth on the bowel with adhesions to the same. If this symptom be coupled with a history of a pyloric carcinoma or a cecal growth, it is confirmatory in its indications. Some growths have a disposition to change positions, but all growths have one or more attachments, and it is safe to infer that this attachment is to the site at which the neoplasm had its beginning, and the movements will be only around an arc of a circle with the pedicle-attachment as the center. Adhesions may prevent a growth from moving, or may anchor a tumor in a locality far from its original point of starting. The history of inflammatory attacks and the pain will come to the rescue here. The character of the pain and the amount and area of tenderness are invaluable aids. The

withdrawal of free fluid from the peritoneum will often show the presence of a tumor before undetected. Pus in the pelvis is one of the conditions easiest of diagnosis.

DR. JAMES F. W. ROSS, of Toronto, read a paper entitled

PNEUMO-PERITONEUM.

He reported a very instructive case of this affection, and classified pneumo-peritoneum as follows: First, intraintestinal tympanites; second, extraintestinal tympanites. *a*. Traumatic: 1, from without; 2, from within. *b*. Non-traumatic or spontaneous: 1, without liquid, gas odorless; 2, ascites and gas odorless or fetid; 3, pus and fetid gas. Third, intraintestinal and extra-intestinal tympanites.

With regard to the treatment, exploration by means of a knife and the finger is free from the objection that obtains in the case of a stab in the dark by a trocar. In all of these cases an exploratory celiotomy should be performed. Even after the removal of the pressure on the diaphragm the breathing improves. It has been stated by one operator that it is necessary in puncturing such cases to allow the gas to escape very gradually.

DR. HERMAN E. HAYD, of Buffalo, reported a case of

LARGE HYDRONEPHROTIC CYST SIMULATING OVARIAN TUMOR; ABDOMINAL HYSTERECTOMY, FOLLOWED BY RECOVERY.

The case was interesting on account (1) of the large size of the hydronephrotic cyst, as well as the absence of pain or distress in its formation; (2) of the obscurity of diagnosis, or, at all events, the resemblance of the cyst to an ovarian tumor; (3) of the increased functional activity of the one kidney—in fact, its ability to functionate vicariously for the other organ; and (4) of the ease and facility with which the tumor was removed through the abdomen, and the uninterrupted convalescence for thirteen days. (5) At no time was albumin found in the urine, and quantitatively and qualitatively the secretion of urine was above the average. At one testing the patient passed 287 grains of urea in twenty-four hours. There was no evidence of stone or symptoms of previous ureteritis.

DR. WILLIAM H. MYERS, of Fort Wayne, Ind., read a paper entitled

THE LIMITATION OF CRANIOTOMY.

He said that of late years the happy results following Cesarean section and Porro's operation have done much to remove the necessity of deciding the question whether the life of the mother or that of the child is to have preference, as it is now quite possible to save both. The high death-rate after craniotomy must be referred to the period preceding the introduction of asepsis and antisepsis. The fatality of Cesarean section has radically changed, owing to the modifications in the treatment of the uterine wound, and a perfect technic; these have lowered approximately the death-rate to that which is claimed for difficult embryotomy, a mortality of 10 per cent., with the saving of 95 per cent. of infantile life. It was urged that Cesarean section should be performed as soon as the diagnosis can be assured.

DR. EDWIN RICKETTS, of Cincinnati, reported

THREE CASES OF GALL-BLADDER SURGERY,

and drew the following conclusions: (1) The continual absence of bile from the intestinal discharges does not necessarily signify that there is no operative condition of the gall-bladder existing. (2) The bile may flow periodically, and when this occurs, symptoms demanding surgical interference are generally present. (3) Jaundice, when present, is very satisfactory evidence of biliary obstruction, although it is not always present. (4) Pains in the region of the gall-bladder coming on at intervals and in connection with jaundice, or without jaundice in connection with clay-colored stools, is positive proof of biliary obstruction, and when this exists an operation should be resorted to. (5) Persistent clay-colored stools, whether attended with severe pain or jaundice, are the most reliable symptoms governing operative interference. (6) When a stone is primarily engaged in the gall-bladder, then a pathologic lesion begins. (7) Obstruction of the common duct may be due to external trauma, such as a blow received over the region of the liver. This may produce a catarrhal condition of the common duct leading to entire stoppage of the flow of bile. (8) A solitary calculus may be engaged in the lower end of the gall-bladder, causing thickening of the bladder-wall and also periodic escape of its infected or non-infected contents. (9) Calculi may be formed in the hepatic or common duct. (10) The importance of probing the hepatic duct through the incised bladder in all cases operated upon, whether the condition present be catarrhal alone or associated with the presence of stone.

DR. W. E. B. DAVIS, of Birmingham, Ala., contributed a paper entitled

OPERATIVE PROCEDURES FOR THE RELIEF OF OBSTRUCTION OF THE BILIARY DUCTS.

He alluded to a large number of experiments that he had made on dogs, and in which he had tested the value of gauze in draining bile in injuries of the gall-bladder and ducts. In some cases he had removed the gall-bladder without tying the duct, but by packing with iodoform-gauze, and the animals recovered. In other instances in which the gall-bladder and ducts were incised and the gauze was packed around the openings, no stitches being used, the animals recovered. Complete walling off of the general cavity was noted when the abdomen of the animals was reopened.

Dr. Davis also reported a case of obstruction of the common duct in a human being, in which he had removed the gall-bladder and a portion of the cystic duct, packed the wound with gauze after introducing a glass drainage-tube, and there was also complete walling off of the general cavity. He advised, in cases of obstruction of the common duct, that no attempt should be made to suture the opening after the obstruction has been removed, as the patient's condition is nearly always serious, and a prolonged operation will terminate fatally. The obstruction should always be removed, if possible.

The experiments detailed demonstrate conclusively that the peritoneum is capable of taking care of a small amount of bile, but that large quantities or a constant extravasation will produce a fatal peritonitis usually in from twenty-four to forty-eight hours. It was thought that the field of cholecystenterostomy is a very limited one.

DR. W. B. DORSETT, of St. Louis, read a paper entitled

THE USE AND ABUSE OF THE UTERINE CURET.

He said that the more he had used and seen used the uterine curet, the more he was impressed that the selection as to the shape and form of the instrument in a given case is not always a wise one; that a proper knowledge of its use should be obtained before trying to use it; and that it is not a cure-all. Its use should be practised only in conjunction with other treatment. The blunt curet (as sold in the shops) is to be viewed as a dangerous instrument. The instrument with a sharp cutting-edge, properly constructed, is a most useful one, and in the treatment of intra-uterine inflammatory conditions is the *sine qua non* of success. In order to secure a good scraping-instrument the sharp edge should stand at an angle of 60° with the shaft or handle. If a greater angle be adopted, the instrument will not scrape thoroughly, and a less angle is liable to lead to incision of the uterine wall unless great care be exercised. Cases of perforation of the uterine wall are on record, and it was thought that they are due to want of care in the selection of the proper instrument. The dull or blunt curet should never and under no circumstances be used.

Dr. Thomas J. Maxwell, of Keokuk, Iowa, followed with a paper on

SOME ANOMALIES FOUND IN ABDOMINAL SURGERY.

A case was reported in which an incision in the linea alba disclosed a reddish tumor not unlike a pearl-colored ovarian cyst. The tumor was about seven inches in diameter, and proved to be the uterus containing an interstitial fibroid. An incision about four inches in length through the anterior fundus was made and a white fibrous tumor of the dimensions of a cocoanut was shelled out with the fingers. The incision into the uterus was closed with buried catgut sutures, fortified with one silk suture in the center of the cut. A large ovarian tumor was then brought into view, attached by a very broad pedicle to the right broad ligament. The tumor was emptied of its contents, two-and-one-half gallons, and proved to be a monocyst. The patient recovered. The case is believed to be the first in which an interstitial fibroid, complicating a large ovarian tumor, was enucleated, leaving the uterus intact. The opinion was expressed that many uteri and their adnexa might be preserved by a similar procedure, and the patients left unmutilated.

Dr. B. M. Hypes, of St. Louis, read a paper entitled

SHOULD INTRAUTERINE INJECTIONS OF GLYCEROL BE USED FOR THE INDUCTION OF LABOR?

He maintained that such injections are often inefficient, especially so in doses under 50 c.cm. They are liable to be followed by shock, air-embolism, thrombosis, metritis, and sepsis. They may and sometimes do produce glycerol-poisoning—that is, decomposition of the blood-corpuscles, resulting in diseases of various organs, but more especially in nephritis with hemoglobinuria. The method involves no consideration of the life of the child, and hence results in great mortality. Its use should be abandoned or the dosage reduced, especially in subjects with pre-existing renal affection.

Dr. M. B. Ward, of Topeka, Kan., read a paper entitled

HAS GYNECOLOGY RECEIVED JUST RECOGNITION AS A SPECIALTY?

The purpose of this paper was to call attention to the efforts necessary on the part of the Fellows of the Society and other members of the profession to elevate to a position with the other specialties the standard of gynecology, and at the same time to discuss the best means to educate the profession and laity to the all-important truth that to be a gynecologist one cannot at the same time be a general practitioner. As specialists, the duty of gynecologists is clearly in the line of spreading the gospel of truth regarding the proper methods of examination and treatment of the numerous diseases peculiar to the female sex, in order that every physician shall have a reasonably intelligent understanding of the methods of dealing with the simpler forms of disease. Dr. Ward said the line must be drawn, and, when once fixed, strictly followed before gynecologists can expect to command and receive just recognition as specialists. This advice must naturally mean a great financial sacrifice on the part of those who have been combining the entire field of surgery with gynecology. Such a sacrifice, however, will be as bread cast upon the waters, to return after many days. It may even temporarily almost take the bread from the mouths of the gynecologist's children; nevertheless, it is the only course to pursue if gynecology is ever to be recognized as a specialty whose disciples shall receive the encomiums to which they are justly entitled.

Dr. L. H. Laidley, of St. Louis, Mo., read a paper entitled

SURGICAL TREATMENT OF PERFORATION OF THE BOWEL IN TYPHOID FEVER.

He said that early diagnosis and operation offer the greatest chances for recovery. If perforation of the bowel exists, it is the duty of the surgeon to make an exploratory incision, close up the opening, and cleanse the abdomen. The more rapidly the operation is accomplished in closing the perforation, which is usually single, and because of the danger in prolonging the operation, the better. In selecting a method for the closure of the perforation a Lembert suture should be used for small openings; for the larger openings, when the lumen of the bowel is contracted by the use of the interrupted suture, resection, with the use of the Murphy button, is the most advisable course to pursue. It was urged that greater interest be taken in educating the profession to select the cases, many of which are overlooked, to be placed in the hands of the surgeon and thereby reduce the mortality below 100 per cent., at which it heretofore has prevailed.

Dr. J. B. Murphy, of Chicago, followed with some remarks on

TYPHOID PERITONITIS,

in which he reported some twenty-eight cases that had been operated upon by different surgeons. A case reported by Dr. Van Hook, of Chicago, was the first to recover. Another case was operated upon by Dr. Abbe, and one by Dr. Ill, both of which recovered. Dr. Murphy also reported cases upon which he had himself operated with success. He holds that early diagnosis and prompt operative interference offer the greatest chances for recovery.

DR. H. W. LONGYEAR, of Detroit, read a paper entitled

KRAUROSIS VULVÆ—A CONTRIBUTION TO ITS PATHOLOGY AND THERAPEUTICS.

All the cases of this affection that he had seen had been in women who had passed the fortieth year, and in each case the symptoms were manifested coincidentally with those due to the menopause. In the first case in which the disease was recognized the woman was still menstruating, although irregularly, and the symptoms of the kraurosis had troubled her for about a year, the local appearance of the disease indicating that it was in an early stage of development. In the second case the symptoms had been manifested for six or seven years before the menstrual function had entirely ceased. The patient's ovaries had been removed two years previously. The kraurosis was found to be in the advanced stage of atrophy. In the third case the symptoms of the disease began with the cessation of the menstrual function, and examination four years later showed that the kraurosis had attained what might be called, for comparison, the middle stage. The treatment for this affection is both operative and medicinal.

DR. C. C. FREDERICK, of Buffalo, read a paper entitled

NEURASTHENIA ACCOMPANYING AND SIMULATING PELVIC DISEASE.

He defined neurasthenia as an exhaustion of the nervous system, more particularly the sympathetic nervous system, due to malnutrition. After dealing with the symptoms encountered, he said that there is a class of women in whom neurasthenia simulates pelvic disease. It occurs in those of a nervous temperament. It is a frequent ailment among American women. It is seen alike among the rich and the poor, the fleshy and rotund, as well as the thin and spare of form. With reference to treatment, to correct so far as possible the habits of the patient that lead to nerve-tire, general tonic treatment, and good environment and, above all, the rest-treatment of Mitchell, bid fair to do as much for these women as human skill has thus far devised. Many of them can be nearly or quite cured, and others can only be partially relieved. Removal of tubes and ovaries which are simply tender and not diseased always adds to the suffering.

The following officers were elected: *President*, Dr. Joseph Price, Philadelphia, Pa.; *First Vice-President*, Dr. A. H. Cordier, Kansas City, Mo.; *Second Vice-President*, Dr. George S. Peck, Youngstown, Ohio; *Secretary*, Dr. William Warren Potter, Buffalo, N. Y.; *Treasurer*, Dr. X. O. Werder, Pittsburg, Pa.; *Judicial Council*, Drs. C. A. L. Reed, James F. W. Ross, L. S. McMurtry, A. Vander Veer, and J. Henry Carstens.

On motion, the Association adjourned to meet in the city of Richmond, Va., the second Tuesday in September, 1896.

The Interstate Medical News is the title of "an independent quarterly journal of medicine, surgery, and allied sciences," published at Sioux City, Iowa, by Drs. William Jehson and J. H. Talboy.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-third Annual Meeting, held in Denver, Col., October 1, 2, 3, and 4, 1895.

FIRST DAY—OCTOBER 1ST.

THE Association was called to order by the President, DR. WILLIAM BAILEY, of Louisville, Ky.

DR. HENRY SEWALL, of Denver, Chairman of the Local Committee of Arrangements, made a brief report, in which he called attention to the excursions that would be given to the members and their wives. He also welcomed the Association on behalf of the local medical profession.

The REPORT OF THE EXECUTIVE COMMITTEE was then read by SECRETARY WATSON, of Concord, N. H., and included the presentation of some sixty or seventy applications for membership and their election.

The reading of papers was then proceeded with.

DR. JOSIAH HARTZWELL, of Canton, Ohio, read an exhaustive paper entitled

THE MISSISSIPPI RIVER AS A SEWER.

He spoke of the wonderful extent of the fertile lands of the Mississippi Valley as compared with the valleys of the Rhine, the Nile, and the agricultural lands of the Chinese. Figures were given showing the number of dead animals, tons of sewage, etc., that are thrown annually into the river, and as a consequence typhoid and other fevers resulted from the pollution of the waters. The city of Chicago was severely criticised for using the Chicago River as a sewer. The case of Leeds, England, was cited, in which the city was prohibited by law from polluting the river on complaint of people living below the city. He thought the same course would eventually be adopted in this country. He deplored the action of the Pittsburg garbage-boats, which polluted the Ohio River, and quoted from Pittsburg papers denouncing this action. The government should put a stop to the pollution of its streams; but as a rule the average politician is not a sanitarian. Every other nation has its national board of health, and the time has arrived when the United States should follow this example, and it is only by such a course that the Mississippi can be protected from defilement by these two principal feeders.

DR. PETER H. BRYCE, of Toronto, followed with a paper on

POLLUTION OF WATER-SUPPLIES.

He spoke more particularly of the waters dividing the United States from Canada, and related how, during the past summer, he had assisted, together with government-cutters, in capturing a number of garbage-boats sent down from Detroit with hundreds of tons of garbage, and narrowly avoided an international dispute. He scored the various cities on the American side of the streams for paying little or no attention to the cities below, and suggested that the cities be fined $250 per day until they built sewage-works. International disputes were bound to arise, and the only feasible way to avoid trouble was to make stringent laws and see that they were enforced.

DR. E. WENDE, of Buffalo, said that Buffalo disposed of its garbage by cremation, and that the dispute which arose between the Canadian Government and the

Buffalo garbage-contractors was because the latter dumped earth into the river.

THE REPORT OF THE COMMITTEE ON ANIMAL DISEASES AND ANIMAL FOODS

was next presented by Dr. D. E. Salmon, of Washington, D. C., chairman.

Mr. E. C. Jordan, of Portland, Maine, contributed a paper on

CAR-SANITATION,

in which he described the methods adopted by the Pullman and Wagner companies in maintaining and cleaning sleeping-cars.

Dr. Domingo Orvañanos, of the City of Mexico, forwarded a paper on the general subject of

CAR-SANITATION,

which was read by Dr. C. O. Probst, of Columbus, Ohio. He made the following recommendations :

1. Watchfulness on the part of local sanitary authorities to whom pertains each of the railroad-stations with large traffic, and with the object of preventing the embarkation of individuals who might transmit diseases.

2. The appointment of medical inspectors on the lines or in the places where it is considered necessary.

3. That the railroad-cars should be furnished with cushions and hangings that can be easily taken off and replaced.

4. The disinfection of the cars themselves, either wholly or in part, whenever the medical inspectors should deem it advisable.

5. The prohibition, under severe penalties, of expectorating in any part except in the cuspidors, of which a sufficient number should be provided, and which should contain a solution of mercuric chlorid, 1 : 1000.

Prof. S. H. Woodbridge, of Boston, Mass., transmitted a paper on

THE VENTILATION OF RAILWAY-COACHES,

which, in the absence of the author, was read by Dr. Durgin, of Boston.

It was pointed out that in all ventilating undertakings but one-half of the requirements are fulfilled when the most perfect apparatus conceivable is furnished. The excellence of a tool does not insure the quality of its product. Quite as much depends upon the user as upon the tool, and not infrequently a superior apparatus is made (on its reputation) to bear the burden of the operator's infirmities. It would seem to be of more than doubtful utility to equip coaches with carefully designed means for ventilation unless railroad-employés are systematically trained in their use and they and the travelling public are educated to habits of cleanliness and are free from the trouble-making notions and imaginings that prevail, even among cultivated people, with reference to ventilation. The proper function of ventilation begins only after cleanliness has done its most perfect work. For a long time to come to an innocent and dutiful ventilation is likely to be laid the sin of uncleanliness of person and environment.

Dr. Granville P. Conn, of Concord, N H., Chairman of the Committee on Car-sanitation, presented an elaborate report showing the difficulties of inaugurating a system of car-sanitation that would be satisfactory. Only on one road had the matter been gone into systematically by the officials. The public, however, is becoming more and more critical each year upon matters connected with the hygiene of cars and hotels ; nor is it considered out of place to commend or condemn the sanitary conditions obtaining along the line of public travel. The world moves on, and sanitation that would have been considered fairly good a decade ago will not be tolerated without a protest to-day. The through line that takes the most advanced position in alleviating the discomforts of the traveller ; that shows by the cleanliness of its cars, their heating and ventilation, and, above all, by the uniform courtesy of its employés, the fact that it has a department of hygiene, as well as of surgery, will reap its reward and save thousands of dollars in its advertising department, for no amount of printer's ink will cover want of courtesy on the part of trainmen, or of unnecessary want of sanitation in the car-service ; neither will the public hesitate to proclaim to the world their dissatisfaction. On the other hand, to receive the full and entire approbation of the travelling public is an advertisement that money will not buy, and to obtain which should be the ambition of every railroad-corporation.

Dr. Joseph J. Kinyoun, of Washington, D. C., called renewed attention to the disinfection of sleeping-coaches, a process that should be gone through at the end of every trip lasting over twelve hours. He thought that as the sanitation and ventilation of cars could be carried out cheaply, and as it was certain that tuberculosis and other diseases could be transmitted from State to State, more stringent measures should be enforced. He spoke of a new disinfectant called formalin which he had found to be much more effective than anything he had so far used.

In the evening addresses were delivered by Hon. A. W. McIntire, Governor of Colorado, and Hon. T. S. McMurray, Mayor of Denver.

Then followed the Annual Address of the President, Dr. William Bailey, of Louisville. He said the Association numbered among its members some of the most illustrious sanitarians of the continent. The Association had an object-lesson of the good it had done by a reduction in the death-rate of Denver of 50 per cent. The past year had been a good one from a health standpoint. Cholera threatened the Western border ; but through the efficient corps of health-officers in San Francisco the disease might be prevented from spreading. He spoke of the importance of quarantine-regulations and the value of the report on the purity of water-supplies. A number of college-professors were unable to attend the meeting because of the college-sessions having commenced. He therefore suggested a change as to the time of meeting. The Association should perfect its plans to celebrate the centennial anniversary of the discovery of vaccination. He suggested a memorial report. He said there was some hope that in time they would be able to afford immunity from such diseases as cholera, scarlet fever, diphtheria, and tuberculosis, as we now have immunity from smallpox.

Rev. Chancellor McDowell followed with a plea for those who did not belong to the Association to aid in the efforts of purification and in sustaining the hands of health-officers.

SECOND DAY—OCTOBER 2D.

The Treasurer's report was read and referred to an auditing committee, who subsequently reported that they had found it correct.

Resolutions were then taken up. Dr. Mitchell, of New Jersey, introduced a resolution to this effect, that

WHEREAS, An order of the Postmaster-General has prohibited the use of the mails for the transportation of diseased tissues; therefore be it

Resolved, That the American Public Health Association respectfully requests the Postmaster-General so to modify the order now in force that specimens of diseased tissues, when properly enclosed in approved mailing-packages, may be admitted to the mails for transmission to State and municipal laboratories.

Several samples of tubes and cases for the transmission of bacteriologic specimens were exhibited.

DR. C. N. HEWITT, of Red Wing, Minnesota, introduced the following resolution, which was unanimously adopted by a rising vote:

Resolved, That this Association has heard with profound sorrow of the death of Louis Pasteur. That it offers to his family, to his assistants at the Pasteur Institute, to his country, to the members of the profession, sincere condolence in the loss of a master of science. His work for the alleviation of human suffering is as he would have chosen—his everlasting monument. His example of an humble and attentive servant and student of nature is the precious legacy he has left us.

In addition to this resolution a cablegram was sent, on motion of Dr. Felix Formento, of New Orleans, to Dr. Roux, of Paris, containing the words: "The American Public Health Association mourns the loss of Pasteur."

The reading of papers was then taken up.

DR. H. B. HORLBECK, of Charleston, S. C., read a paper on

MUNICIPAL STEAM-DISINFECTION,

and DR. CHARLES V. CHAPIN, of Providence, R. I., one on

DISINFECTION IN AMERICAN CITIES.

Modern methods of disinfection, as practised in the progressive cities of this country, were considered at considerable length. The statistics of the second paper were gathered from fifty cities in this country and Canada. Only two out of this number disinfect after measles and all the minor contagious diseases. These are Rochester and Toledo, and their systems are very thorough. New York, Brooklyn, and Philadelphia, he said, devote particular attention to the prevention of the spread of tuberculosis. In Detroit, Denver, and Newark the favorite method of fumigation is with sulphur. St. Louis uses steam, and several other cities mercuric chlorid.

DR. H. C. CROUCH, of Denver, Col., read a paper on

THE MICROSCOPIC DIAGNOSIS OF DIPHTHERIA BY A NEW STAINING-METHOD.

He said that diphtheria-bacilli, as seen in preparations from cultures, vary in size, the larger ones particularly presenting characteristic features in the way of club-shaped ends and irregular staining, but all forms showing a tendency to the alteration of deeply and lightly stained portions. In addition to this, and distinct from it, are certain round or oval bodies which may be made apparent by certain methods, the existence of which was brought to our attention by Babes, Neisser, and Ernst. The method pursued by the last was to stain strongly with hot methylene-blue, and follow with bismarck-brown. These bodies would be blue, the rest of the bacillus being brown. Dr. Crouch had been investigating the feasibility of employing this peculiarity of the diphtheria-bacillus to differentiate it from other bacilli found in the mouth, and with a degree of success beyond expectation. He had found, likewise, simpler methods of staining, and peculiarities that he believed to have escaped attention hitherto.

If a fresh serum-culture is stained momentarily with a 1 per cent. solution of methyl-green, it is often possible to bring out these bodies without further treatment. Treated thus they present the appearance of reddish granules in a faintly green bacillus, usually one at each end. By staining with methyl-green more strongly and following with methylene-blue, bacilli with red dots resembling spores will be seen. These bodies have apparently a peculiar affinity for methyl-green, with which they enter into a chemic combination, resulting in change of color from green to red. Dr. Crouch had consequently employed methyl-green for their detection. By adding other colors the penetration of the methyl-green may be increased, and a double stain obtained immediately. Dahlia had been found most useful, employed in the following proportions: One part of 1 per cent. dahlia in water, 5 parts 1 per cent. methyl-green, and 4 parts water. If either color predominates in the stain too decidedly, the other color is cautiously added until the desired result, as tested on the bacilli from a culture, is obtained.

The stain works instantaneously, and if too deep the effect is not obtained. In such a case the cover-glass may be treated quickly with bismarck-brown, which replaces the dahlia in the body of the bacillus, leaving the bodies described standing out in contrast. Dr. Crouch had tested this method in a large number of cases during the last six or eight months, and had never failed to find the result of the culture positive when he found these forms present in the cover-glass examination. In one case in which he had diagnosticated diphtheria the first culture was unsuccessful, but the second culture confirmed the diagnosis, which fact seemed to indicate that the direct examination should always have its place in addition to the culture.

These bodies are not considered to have any connection with spores, in spite of their superficial resemblance. They are found in the greatest numbers in young, freshly growing cultures, and are much less abundant in older cultures. They may be readily detected in cultures only a few hours old, and thus made use of to confirm a diagnosis earlier than the full development of the culture. That they are not degenerative forms is evident from the same considerations. Dr. Crouch inclines to attribute a nuclear nature to them, and proposes the name nucleoid bodies. They are evidently connected with the active growth and are absent in the resting-forms, suggesting thus the resemblance with indirect cell-division. Being particularly abundant during the earlier and more rapid growth, they are readily found in the earlier stages of the disease, and from the ease with which they may be brought out, they acquire a very

great practical importance in the microscopic diagnosis of diphtheria.

Dr. Edward Jackson, of Philadelphia, read a paper entitled

SUGGESTIONS AS TO OCULAR HYGIENE IN SCHOOLS.

He said the child is not taught, in the first place, how to use its eyes; and, secondly, it is not taught how to avoid eyestrain. Much of the work hitherto done in ocular hygiene has been merely in showing the defects existing, without pointing out any remedies. Even if it were customary to have the eyes of children examined, it would not be sufficient. One of the difficulties is that the teachers do not understand the eye so as to teach its proper use, and while it might be thought that the eye itself would be a sufficient monitor, this is not so, as eyes are habitually used after they are tired. The matter of lighting schools was thoroughly discussed, and the following conclusions were drawn:

1. The child should be trained in the use of the eyes.

2. The supervision of the work in the schoolroom, as to the manner in which children use their eyes, should be constant.

3. More care is needed in lighting schoolrooms.

Dr. R. H. Lewis, of Raleigh, N. C., said that one great trouble was that the child was permitted to stoop over in writing. The vertical system of writing makes it impossible for the child to assume a wrong position.

Dr. J. M. Watson, of Elizabeth, N. J., laid stress on the fact that nature must be aided in this matter as in all things. A man walking on the street of a city gradually learns to see many things at once without appearing to see anything. The child should be trained to see many objects at once, but not too many.

Dr. Henry D. Holton, of Brattleboro, Vt., called attention to the danger of the constant change in the focus of the eye of the child in school, looking from the blackboard to the book and back again frequently.

Dr. A. G. Young, of Augusta, Maine, said that it was more trying to read from the blackboard than from a book, because the range of vision was usually less, the figures were not so plain, and the light was often bad. He thought there should be great care exercised in this matter.

Dr. S. H. Durgin, of Boston, thought there should be an inspection of children in all schools to ascertain their ocular powers. Teachers should learn the peculiar characteristics of each child and always consider them.

Dr. H. M. Bracken, of Minneapolis, expressed the belief that teachers should be taught enough to discover faults in the eyes of pupils and know which should be sent to an oculist for further examination.

Dr. James A. Stewart, of Baltimore, suggested the use of a blueboard instead of a black one, to which Dr. Jackson replied that the color was of less importance than the reflection of the board. If a board that was dead black, with no gloss, could be secured it would not, he thought, injure the eyes. The system in use of examining the eyes of railroad-employes might be introduced with good effect into the public schools.

Dr. C. L. Wilbur, of Lansing, Michigan, presented a paper entitled

THE OUTLOOK FOR A GENERAL SYSTEM OF REGISTRATION OF VITAL STATISTICS IN THE UNITED STATES.

He quoted a prophecy made at the first meeting of the Association by Dr. Elisha Harris, who thought at that time that the United States would have a perfect interstate system of vital statistics before the end of the century, and showed why this prophetic vision had not been realized.

Most of the paper was devoted to a consideration of the death-rates according to registration returns, with tables of figures. The State systems of registration of deaths are either fairly perfect or the reverse. The returns in the latter case range from 10 to 80 per cent. of the total number of deaths. A large diagram was exhibited showing the rates per one thousand from the year 1880 to 1893. None of the States having the registration system has abandoned it, and New York, New Hampshire, and Maine have adopted it. Municipal vital statistics are much more complete than those of States. The discouraging features are that the States having defective systems have not improved them. European countries and some New England States, especially Massachusetts and Rhode Island, have very thorough and satisfactory systems. Maine has shown commendable care in compiling her mortality tables, but the United States, as a whole, is far below the density of population at which a perfect and successful registration may be looked for. In most of the cities of over 8000 inhabitants the vital statistics are tolerably reliable. The system put in operation by the United States Bureau will undoubtedly be of great assistance. In case of the establishment of a Bureau of Public Health, the collection of vital statistics would be one of its chief functions.

(To be continued.)

CORRESPONDENCE.

PEDICLE-LIGATION IN ABDOMINAL SURGERY.

To the Editor of The Medical News,

Sir: Mr. Lawson Tait has seen fit to criticise in the *Medical Press and Circular* of July 3, 1895, my article entitled, "A New Method of Pedicle-ligation in Abdominal Surgery," published in The Medical News of January 12th last. I feel constrained to take exception to some of the statements made in this criticism.

Mr. Tait refers to my article as one "in which a series of mistakes likely to be mischievous are perpetrated;" but he fails to point out what these mistakes are. He states that "in giving four sources of danger from intermediary hemorrhage he [I] might have left them all out but the fourth—'a defective method of application.'"

"A defective method," as a source of danger, means absolutely nothing. A practitioner can gain no knowledge from such a statement. It is *detail* that he desires, the *specific points* in "a defective method." The question is, wherein lies the defect?

This point in my contribution was elaborated, and bore upon the weakness of the methods usually employed in this country and abroad, including the "Stafford." It was totally independent of the points which preceded it.

In this connection I wish to add that, as a matter of fact and to my certain knowledge, a young woman lost her life from the non-observance of caution against one of the three sources of danger declared by my criticiser

to be of no moment. But when Mr. Tait says that "if *any* knot slips it is the surgeon's fault, and not that of the knot," he falls short of the truth, for the so-called "granny"-knot will often slip when pressure is brought to bear upon it, no matter how snugly it may have been tied, whereas the reef-knot will grow tighter as the strain comes.

If the "Stafford" method is the one described in the text-books and dictionaries, and the one I have seen applied by operators, it is absurd to state that traction will produce as much compression upon its secondary loops as it will upon the primary loops, as described in the method about which I wrote. Compression produced in direct line with the traction-force must surely be greater than that produced at right-angles to the same.

My criticiser also states that in peripheral fixation I propound an "extraordinary dogma;" but adds a little further on that "peripheral fixation is not alone what is wanted in the broad ligament ligation." In this remark he admits that peripheral fixation is, after all, an important factor in this work, and if he had taken pains to read my paper carefully he would have seen that I recommended as many points of intraperipheral fixation, in addition to the purely peripheral, as the operator may deem necessary.

The idea of peripheral fixation seems to exert a rather peculiar influence upon Mr. Tait's mind, for while admitting it to be possessed of value, he at the same time attempts to ridicule it. According to his humor, this principle may, for centuries past, have effectually put an end to the rogues of Staffordshire; but when employed in connection with as much central support as is necessitated by the width of a pedicle, and applied with the precautions enumerated in my article, it will as effectually avert intermediary pedicle-hemorrhage for centuries to come. Respectfully,

SCHUYLER C. GRAVES.

GRAND RAPIDS, MICH.

ANESTHESIA WITH CHLOROFORM AND OXYGEN.

To the Editor of THE MEDICAL NEWS,

SIR: I wish to ask if any of your readers can give me any information concerning the employment of a combination of chloroform and oxygen for the induction of general anesthesia. I have a recollection of having read somewhere of such a procedure, but am unable to find the reference. Respectfully,

EDMOND SOUCHON.

135 BARONNE ST., NEW ORLEANS, LA.

MENSTRUAL MANIFESTATIONS.

To the Editor of THE MEDICAL NEWS,

SIR: I wish to collect data upon symptoms presenting themselves just before, during, or just after the menstrual period, such as mammary swelling or pain; cutaneous eruptions or markings; enlargement of lymphatic glands; abscesses; mental irritability or perversions of temper; offensive breath; recrudescence of old inflammatory areas; in short, any of the phenomena exhibited near or at the time of menstruation, and which recur with reasonable regularity at that period and seem to be related to it.

Many interesting facts must have been noted by intelligent observers bearing upon this matter, and if those who are so disposed will kindly forward to me a short account of the cases they have seen, I shall be deeply indebted to them, and will duly acknowledge my sense of their courtesy.

HARRIS A. SLOCUM.

1427 WALNUT ST., PHILA.

NEWS ITEMS.

A Pathology Journal-club has been organized by the junior students of the medical department, University of Wooster, at Cleveland. The club is composed of students who have taken a full course of instruction in bacteriology and who are about to enter upon the study of pathology. The chief object of the organization is to familiarize the students with the methods of scientific literary research by bringing them in contact with current literature bearing upon pathology and bacteriology. The first meeting of the club was held on the evening of October 3d. Dr. Ohlmacher exhibited specimens from an autopsy made that day upon an old case of appendicitis, in which the most important lesion was a very extensive thrombophlebitis of the portal vein. The club elected Dr. Ohlmacher as its president and Mr. A. L. Smith secretary. The meetings are to be held biweekly.

Prof. Bardeleben, the distinguished German surgeon, died at Berlin on September 24th, at the age of seventy-six years. He was the author of a *Lehrbuch der Chirurgie und Operationslehre*.

Johns Hopkins University.—Dr. W. W. Russell has been appointed Associate in Gynecology and Dr. Thomas S. Cullen Instructor in Gynecological Pathology in the Johns Hopkins University, Baltimore.

Dr. James Collins, a well-known Philadelphia physician, who served with loyalty during the War of the Rebellion, died on October 7th, at the age of sixty-five years.

ORIGINAL ARTICLES.

SEPTIC PERITONITIS.

BY LOUIS FRANK, M.D.,

OF LOUISVILLE, KY.;

ASSOCIATE PROFESSOR OF OBSTETRICS AND DIRECTOR IN THE BACTERIOLOGICAL LABORATORY IN THE KENTUCKY SCHOOL OF MEDICINE; GYNECOLOGIST TO THE LOUISVILLE CITY HOSPITAL AND THE KENTUCKY SCHOOL OF MEDICINE HOSPITAL, ETC.

ALTHOUGH the gonococcus was not discovered by Neisser until 1879, still in 1872 Noeggerath pointed out upon clinical grounds a close etiologic relation between inflammatory conditions of the female pelvic organs and gonorrhea. In 1886 Westermark, by means of the microscope, first discovered the gonococcus in a case of pyosalpinx. Since then numerous observers have demonstrated the presence of this organism in salpingitis, among them Orthmann, in one of eight cases; Schmitt, in one case; Steman, in one case; Menge, in three of twenty-six cases; Zweifel, in eight of forty-four cases; Reichel, in one case; Döderlein, in one case; Wertheim, in nine of twenty-four cases. In addition, Wertheim has been able to cultivate it in seven cases and Menge in one. In all about one-hundred-and-eight cases have been recorded in the literature that have been examined for the presence of gonococci, either by the microscope or by cultures, and in thirty-four cases, or in 31 per cent., this organism has been found. Sixty-one of the cases were sterile, or free from bacteria, and in but eleven of the one-hundred-and-six were other bacteria than gonococci present.[1]

Wright has by cultures demonstrated the presence of the gonococcus in about 20 per cent. of cases, giving the pathologic condition found and the results of bacteriologic examinations in those cases in which these were positive.

In my own experience of ten cases operated upon for pus-tubes in which bacteriologic examinations were made, I have demonstrated the presence of the gonococcus in only one. Of these ten cases, as ascertained by the clinical history previous to operation, two were undoubtedly due to puerperal infection. In these two no micro-organisms whatsoever were found. Three cases were due to chancroidal infection, the chancroid existing previous to the operation and previous to the occurrence of the pelvic lesion; in two of these cases the development of the pelvic trouble was observed from the beginning. Examination of the tubes in these three cases showed the presence of the streptococcus pyogenes aureus, which was in one found both in cover-slip preparations and by cultivation. One case showed the presence of an organism resembling in morphologic appearance and in staining reaction the diplococcus of pneumonia. Unfortunately, no cultures were made in the second case. One case showed no organisms whatsoever either in cover-slip preparations or by cultivation. In the other five cases, due to gonorrheal infection, as shown by the clinical history, organisms were found in only one. These were demonstrated by microscopic examination, but not by culture-methods. They presented the characteristic appearance and characteristic staining, decolorizing by Gram's method. All of these cases recovered without trouble, although in two there was at the time of enucleation an escape of pus into the peritoneal cavity. As I have said, all the cases recovered. There were no fistulæ, nor was any trouble whatsoever observed during convalesence.

It has been generally believed that the presence of gonococci in pus-tubes meant that the pus was of a low grade of virulence, and that its escape into the peritoneal cavity did not necessarily mean that the patient would not get well. Those operators who have found the gonococcus present, and the gonococcus alone, without mixed infection with the staphylococcus or streptococcus, have regarded the case as free from all danger of infection whatsoever. Even when the pus containing this one organism had escaped into the peritoneal cavity, no drainage has been employed and no extra precautions taken to prevent infection.

In many cases the bacteria that have been present in pus-tubes at the time of infection of these tubes have died out, and it has been the rule that in those cases in which there was much pus there were few or no organisms, and when these were present they were of low vitality; the most virulent, and those that gave the most trouble being found in tubes in which there was very little pus, and in which the infection was more recent. This is no doubt due to the fact that the organisms themselves generate a poison that is inimical to their existence.

In the cases that I have examined microscopically the pus observed has contained a good deal of detritus and many broken-up cells, the cells that

[1] Wright: The American Journal of the Medical Sciences, February, 1895, vol. cix, p. 118, No. 2.

were stained not showing the sharpness of outline that we find in recent suppurative processes. On the contrary, when the pus has been scant in quantity the pus-cells have been well-defined, and in these organisms were found, except in the one case in which the gonococcus was discovered, and in which there was quite a large collection of pus that had existed for some time.

I believe that the gonococcus in its virulent state, before it has been for any length of time in the pus of a pyosalpinx, is perfectly capable of infecting the peritoneum, and will, if opportunity is afforded, produce the most virulent peritonitis—peritonitis that leads to rapid death, with marked symptoms of profound septic infection. I have recently had an opportunity of observing such a case, and while this case was operated upon by another surgeon, it fell to my lot as curator to perform the autopsy and to make the bacteriologic examinaton. In this case gonococci were found free in the peritoneal cavity. It will not be amiss, with all due deference to the surgeon, a most capable and efficient gentleman, one for whom I have the highest regard, to relate the case so far as it came under my observation in the autopsy-room, giving in addition a short history:

The patient was a prostitute, about seventeen years of age, who was admitted to the hospital in April, 1895. She was in the habit of having intercourse during the menstrual period, and to prevent detection by those men with whom she copulated she was in the habit of introducing a tampon into the vagina. Three weeks before her entrance into the hospital she had contracted gonorrhea. About two weeks afterward her menstrual flow came on, and as usual she placed a sponge in the vagina to absorb the bloody discharge, as she had done on previous occasions. The sponge was removed three days later, and she then stated that the odor was exceedingly offensive. She had before removal of the tampon begun to experience some abdominal pain, which increased very much in severity a day or two later, after which time she felt some chilliness, and on the next day distinct chills, headache, constipation, etc. She then came into the hospital, when a diagnosis of double pyosalpinx was made, and six days afterward, that is, on the 23d of April, she submitted to an abdominal section. During this period the temperature had ranged from 100° to 102° F.; at no time was the temperature normal, while the pulse-rate was from 90 to 120.

The right tube was removed without much trouble. A small quantity of pus that was in the left broad ligament escaped into the abdominal cavity. The tissues on the left side were exceedingly friable. The first ligature applied to the stump cut through, as did the second, the third being placed well on the fundus of the uterus. After irrigation a drainage tube was inserted and the abdomen closed. Within twenty-four hours septic peritonitis developed. On the second day the drainage-tube was removed and an enema given, and the bowels moved as a result. On the third day there were nausea, vomiting, and delirium most violent in character, death closing the scene late on the same afternoon, just seventy-two hours after the operation.

The autopsy had to be made rather hurriedly. There was union between the abdominal muscles and the peritoneum at the point of incision. About a pint of pus had collected in the pelvis. The ligatures had held, and the stumps were covered by adherent greater omentum. The entire peritoneum was violently inflamed, the process being most severe in the pelvis. Besides being swollen and softened, the intestinal peritoneum presented numerous small ecchymoses. There was no marked change in any other abdominal organ. The intestines were agglutinated, with some pus between them here and there in the cavity.

After having studied this case carefully from its clinical aspect, I came to the conclusion, as already stated, that the gonococcus, when it directly infects the peritoneal cavity in a virulent form, is capable of producing peritonitis most septic in character. Working upon this line I addressed a letter to a number of prominent surgeons throughout the country embodying the following questions: Had they ever found the gonococcus in septic peritonitis; if so, had it also been found in the genital tract? Had recovery from peritonitis followed? How soon after infection had symptoms first manifested themselves? Were other organisms besides the gonococcus found intraperitoneally? A number of the gentlemen to whom letters were addressed had done no work in this line whatsoever; in fact, had done no pathologic work bearing upon the subjects named. Others stated that while they had found the gonococcous in pus-tubes they never felt any alarm at its presence. One or two of these letters I should like to quote in full as giving the opinions of some of the best men in this country.

Dr. Howard A. Kelly, of Baltimore, wrote that he had made no experimental studies whatever, but his experience had been that the gonococcus is but rarely found either in pus-tubes or in the peritoneum. He further says:

"I have found it in suppurative peritonitis in two cases in which there was a recent rupture. The peritonitis had become general; the intestines were agglutinated in all directions, and there was much free pus. The patients were extremely prostrated, with a rapid pulse. The effect, however, upon the system at large was by no means that of staphylococcous or streptococcous infection. In all my culture-work and cover-slip work with pus-tubes I have not found the gonococcus more than half a dozen times. I look upon these cases as peculiarly favorable, and never think of drainage because of the contamination of the peritoneum with gonococcal pus during an enucleation, as my experience has been that the organism has a very low grade of vitality in the peritoneum."

Dr. Roswell Park, of Buffalo, wrote:

"It has not yet happened to me to find a pure form of gonococcous infection in any case of septic peritonitis. This answer will dispose of your second, third, and fourth questions. In answer to your fifth, I would say that in every instance in which I have found the gonococcus in connection with septic disturbances other organisms have been present.

. . . . . .

"I have not yet seen convincing reason to believe that the gonococcus by itself is anything more than possibly a facultative pyogenic organism, and I certainly am of the opinion that it does not always produce pus."

Dr. Park also kindly referred to the following statements:

"Challan, quoted in the *Gazette di Torini* (1893, No. 40, p. 792), has reported a case of gonorrhea, at first uncomplicated, followed after eight days by fatal suppurative peritonitis, in which only the gonococcus could be found. Mermet (*Annales des Maladies des Organes Genito-Urinaires*, 1893, September, p. 695) has also reported a similar case, which recovered. In this case the disease followed a funiculitis, and seemed to have been the product of a direct extension. Baumgarten claimed that such cases are not rare, and that within two months previously he had seen two similar extensive cases which speedily recovered."

Dr. M. H. Richardson, of Boston, observed some years ago a case of septic fulminating peritonitis following gonorrhea:

"There was enlargement of a lymph-gland in the left side of the pelvis just above Poupart's ligament. The gland was broken down, and contained pus. There was general peritonitis, with all its symptoms. An operation was done, but it did no good, the patient dying in a short time."

Dr. William T. Lusk of New York, has reported two cases dying of peritonitis from rupture of pus-tubes, presumably of gonorrheal origin, at the time of labor, but states that unfortunately no special search was made for gonococci.

Dr. Christian Fenger, of Chicago, wrote that he has never found the gonococcus in peritonitis.

Dr. A. Vander Veer, of Albany, has found the gonococcus in cases of pyosalpinx, with pelvic peritonitis, but, at the same time, has considered these ordinary cases, as recovery has followed, with a very small percentage of mortality.

Dr. Hunter Robb, of Cleveland, has never been fully satisfied that the gonococcus was present in any case of septic peritonitis that he has examined, and has not been able to demonstrate its presence in any culture he has made from septic fluids. In most of the cases he has examined microscopically, and often by cultures, all showed the presence of mixed infection. In those cases of ovarian abscess and pyosalpinx in which pus was found, he seldom, if ever, obtained any organisms that would grow on any media that he had.

Dr. C. B. Penrose, of Philadelphia, believes, as a result of his own experience, that the gonococcus alone in an uninjured peritoneum is probably harmless. He fears only the streptococcus, the bacillus coli communis, and the staphylococcus.

These letters will be sufficient as showing the opinion of the medical profession of to-day. With this my own opinion has been in accord, but from the case just reported, with the result that has been given, we must conclude that the gonococcus is capable of producing the most septic form of peritonitis. In this case, as Dr. Howard A. Kelly, in his letter says of similar cases, there was the greatest prostration. The infection became evident almost from the start. The pulse was very rapid, and there was a most decided impression upon the whole system of the patient. In this case, although most careful search was made by culture and otherwise, no other organisms were found. The organisms found were examined by various methods of staining, and shown positively to be gonococci.

Following out this line of work, I have been making some experiments upon animals to demonstrate if possible more clearly than has heretofore been done the relation that the gonococcus really bears in the production of septic peritonitis. I believe, as stated, that it may, in a virulent condition, when infected directly into the peritoneum when this is not in the best condition for resisting infection, be capable of producing a great deal of trouble; and I believe that when I have concluded my experiments, which will be duly published in full, I shall be able to positively demonstrate this fact. I am not, however, absolutely sure of this, and recognize the fact that a single case is hardly sufficient upon which to base any rule, or to enable us to lay down any definite law with regard to this matter. Still, if the gonococcus is capable, under any conditions whatsoever, of producing a lesion in the peritoneum sufficient to cause death, then we must guard against any possible source of infection by this means. If the organism is present we must not be content to close up the peritoneum without drainage, but we should employ the same means to thoroughly cleanse the abdominal cavity as we would when the streptococcus or the staphylococcus is found. These latter organisms are undoubtedly the cause of the greatest number of cases of septic peritonitis that we see; nevertheless the other as an etiologic factor must not be overlooked.

In conclusion, I desire to express my sincere thanks to Dr. John Cashin, of the Resident Staff of the City Hospital, for his valuable assistance not only in performing the autopsy and bacteriologic research in the case cited, but for his excellent microscopic examinations of several other pus-tubes removed and included in the ten cases mentioned.

419 W. Chestnut Street.

GENERAL ERYSIPELAS OCCURRING DURING THE PUERPERIUM, FOLLOWED BY POPLITEAL THROMBOSIS AND GANGRENE.

BY LLOYD M. BERGEN, M.D.,
OF HIGHLAND PARK, ILL.

THE following case in private practice presents several rare and interesting features. The points that are worthy of special consideration are perhaps not so much the successive individual complications as their association and the determination of etiologic relationship between them:

Mrs. C., aged thirty-four, a tertipara, of Irish parentage, menstruated at fourteen. Her general health had always been considered perfect. She had never been ill in her life, except during her confinements. Her weight was one-hundred-and-eighty pounds, and her temperament phlegmatic. Her first labor occurred in October, 1892, when I saw her in consultation with Drs. Haskin and Haven. After a prolonged and exhausting labor of forty-eight hours she was delivered of a large, dead child. The presentation was normal. The cervix was very rigid, and as the amniotic fluid had escaped twelve hours previously, artificial dilatation was required before forceps could be applied. The third stage was rapid and easy; hemorrhage was moderate. A slight perineal laceration occurred, which was repaired. Recovery was tedious, but I believe uneventful.

On October 17, 1893, I attended the patient in her second labor. Owing to the extreme thickness of the abdominal walls, and the immense amount of amniotic fluid, no presentation could be determined until the end of the first stage, when a very large child presented by the breech. Dr. Haskin, my colleague, was summoned in consultation. Dilatation being complete, we waited an hour, when, as the breech showed no tendency to engage, the patient was anesthetized, and a dead child, weighing twelve pounds, delivered. The death of the infant was undoubtedly due to delay in delivering the after-coming head, which offered the most annoying resistance to all efforts at extraction. The mother's recovery was perfectly normal.

On October 15, 1894, I was again summoned to attend the woman in confinement. The first stage lasted about eleven hours. At its conclusion I determined upon immediate artificial delivery. This decision was based upon the patient's extreme desire to give birth to a living child, and also upon the fact that previous experience with her led me to hope for nothing were the case left to the natural forces.

Dr. Haskin was again summoned, and the patient anesthetized. With moderate difficulty I delivered her of a large living child. The head lay extremely high above and anterior to the symphysis pubis; yet, despite the fact that the child was the largest she had ever borne, the delivery was accomplished with greater ease than in either of her previous labors. I attributed this fact to the early interference while the mother's tissues were still relaxed and moist, and the contractions vigorous.

I may here add that the whole labor was conducted upon strictly surgical principles. Great pains were taken to insure perfect asepsis of the patient, instrument, and operator. The placenta was slightly lacerated in delivery, but came away intact. The uterus contracted firmly.

Convalescence proceeded without interruption until the eighth day, when the nurse called my attention to a small papule at the angle of the nose. The lesion, which had existed for several days, but attracted no attention, now presented about its base an angry appearance, very suggestive of erysipelas. The vulva was immediately sealed with mercuric-chlorid gauze compresses, which were renewed only when absolutely required, and with the utmost care and rapidity.

At the end of forty-eight hours the eruption quite covered the face, and, after a short delay, during which time the cervical and submaxillary glands became enormously enlarged, crept along the post-cervical region, and extended down the spine. The spreading of the eruption was from this time on uninterrupted. The entire surface of the body as far as the thighs became involved. The vulval and anal regions escaped. Various local measures were adopted in succession, but all finally discarded in favor of an ointment containing equal parts of ichthyol, lanolin, and water. Internally quinin, stimulants, and at times iron, with a diet of milk and raw eggs, were principally administered. The patient's temperature ranged irregularly from normal to 104°. The eruption remained about fourteen days.

On November 7th, after the patient's temperature had remained normal for twenty-four hours, and convalescence was apparently established, she was seized with violent pain in the region of the heart, which I attributed to neuralgia, but for the control of which I was forced to resort to a hypodermic injection of morphin. About three hours subsequent to this attack the woman was seized with severe pain of a similar character in the right foot. The most painstaking examination of the foot and leg revealed absolutely nothing abnormal. There was no edema or induration along any of the lines of bloodvessels or lymphatics.

On the following morning the pain was a trifle less severe, but still present. Upon this examination I detected decided coldness of the affected member, and upon further examination found an entire absence of pulsation in both tibial arteries. There was complete anesthesia of the entire foot. During the following hours there developed a marked ecchymosis of the surface, extending over the foot and the lower third of the leg.

From this time on to the date when amputation became necessary the local condition was one of progressive decomposition. The patient's general condition, however, remained good. The temperature ranged from 99° to 100°. Two days prior to the operation it rose to 103.5°, but almost immediately fell again.

On November 20th it was deemed advisable, on

account of the unfavorable surroundings, to remove the patient to St. Luke's Hospital for the operation. The following day Dr. Owens amputated the limb about six inches above the knee. The proximal end of the femoral artery was found to be occluded by a clot for a distance of three inches. This was cleaned out, and the operation completed. Below the line of amputation and surrounding the original point of thrombosis was found a large abscess.

The patient's recovery was tedious, but perfect.

In this case it is manifest that infection could not have occurred through the genital organs, as there was throughout the entire course of the disease no evidence whatever of morbid disturbance in this region. Involution was practically uninterrupted. The lochia were normal in all respects, disappearing entirely on the fifteenth day. There could be elicited no unnatural tenderness of the uterus or any of its appendages throughout the whole puerperal period.

The cutaneous erysipelas must, therefore, be looked upon as entirely independent of the puerperal state, and the fact of its accidental appearance at this particular time renders the case one of more than ordinary interest, both from an obstetric and a pathologic point of view.

Laying aside the question of etiologic relationship, we find a great deal of interest attached to the question as to what modifications of the disease were induced by the puerperal state, and whether the rapid and extensive spreading of the eruption, together with the grave complications following, were not largely favored, at least, by general systemic conditions incidental to the lying-in period.

In puerperal convalescence, even when the transition is perfectly performed, the organs of elimination are taxed almost to their physiologic limit; the restoration of contused and edematous tissues to the normal state, and the awakening to activity of the lacteal glands, all combine to load the eliminating channels with a tremendous amount of waste material, thereby calling upon the excretory organs for a greatly increased activity. Here we must also remember that these same organs have, in a majority of cases, become more or less disturbed during the later months of pregnancy.

When superadded to such a condition we have an invasion of the system at any point by pathogenic micro-organisms, we cannot be surprised that the toxic products of their activities should remain in the lymphatic vessels and spaces, acting detrimentally upon the uninvaded tissues, and diminishing greatly their power of physiologic resistance. Specific germs of any variety find in this effete material an inviting culture-soil in which to thrive and increase in activity.

Again, going beyond the puerperal period, we may possibly look for other factors favoring the complications which followed the erysipelas. We know that during the later months of pregnancy, as well as during the puerperium, the blood undergoes certain alterations that render it prone to coagulation.

Tarnier in 1878 referred to the discoveries of Andral and Gavarret regarding the changes undergone by the blood during pregnancy, and emphasized the relative importance of the increase of fibrinous elements in the blood of pregnant women during the last three months—an increase always present and frequently in proportions almost pathologic. Without venturing into a discussion regarding the predisposing and exciting causes of these changes in the blood, it is sufficient here to call attention to the fact that they do occur, and that they exert an influence upon the course of many puerperal diseases.

It would perhaps be more difficult to assert that the "physiologic leukocytosis" of pregnancy first observed by Virchow proves another factor favoring thrombosis. We know that when coagulation occurs in living blood the white corpuscles play an important rôle in the initial process, by reason of their ready attraction and adhesion to portions of the intima that have undergone structural alterations, however slight. Their extremely rapid increase at the end of pregnancy is probably in anticipation of their requirement as carriers of waste-products subsequent to parturition.

This general inopexia in puerperal patients when exhibited in a pathologic degree is occasionally expressed in thrombotic formations within the pulmonary arteries, heart, and venous terminals.

Fordyce Barker[1] reports a case of arterial thrombosis occurring in the left leg, in which there had been no arteritis and no demonstrable cause for the accident. He attributes many sudden deaths during the third and fourth week of puerperal convalescence to occlusion of the pulmonary arteries by emboli.

With this general condition of the blood present, then, we are prepared to appreciate the profound impressions produced upon the circulatory system of parturient women by the invasion of the tissues by acute disease of any nature. The existence of high or prolonged temperature, with its resultant anemia, or influences of any nature that tend to vitiate the blood, would lead us to anticipate some such process as thrombosis, even regardless of the presence of micro-organisms.

A great deal of interest during recent years has centered upon the relationship existing between erysipelas and puerperal fever. Since the time when Fehleisen discovered the streptococcus erysipela-

[1] Puerperal Diseases.

tosus, bacteriologists have sought by experimental evidence to place these two diseases in their proper etiologic relation.

Gusserow reports the cases of a number of puerperal women who developed cutaneous forms of erysipelas without involvement of the genital organs. He also mentions several cases of puerperal fever complicated by erysipelas at a later stage. These cases, together with his experimental investigations, he considers as strong evidence that erysipelas cannot cause puerperal fever. According to Senn, Doyer and Winckel both determined to their own satisfaction, by means of cultivation and inoculation-experiments, that there does exist a direct relationship between the virus of erysipelas and that of puerperal fever. Doyer maintains the identity of the two bacteria. Senn himself concludes his article with the statement "that puerperal sepsis from infection with the streptococcus of erysipelas can only occur when the streptococcus is brought in direct contact with an absorbing surface in the genital tract."

Senn's deductions might at first glance appear to receive some clinical support from the history of the case herein reported. The inflammation extended almost to the vulva, and yet a protection of the genitals from outside infection appeared to avert the danger; still, while this precaution closed the most important avenue of invasion, we may readily see that independently of infection from this source secondary foci of suppuration might have occurred in the parametric tissues, or even in the uterus itself, giving rise to puerperal sepsis. In other words, the infected embolus might have elected one of the pelvic arteries in place of the popliteal.

The theory of Gusserow and others, that puerperal sepsis, due to the streptococcus of erysipelas, always implies direct contact of the germs with absorbing surfaces of the genital tract, is founded upon almost purely experimental evidence, the most valuable variety of scientific research, but at times misleading. These observers obtained pure and tested cultures of the streptococcus, and injected them into the peritoneal cavities of rabbits, producing no disturbance whatever, the local immunity being confirmed by post-mortem examination. Upon these experiments they base their conclusions. By somewhat similar methods Fehleisen and others claim to have practically demonstrated the non-pyogenic nature of the streptococcus of erysipelas, and that when suppuration does occur during the course of the disease it is due to mixed or secondary infection with pus-microbes. Other equally observing men, after conducting like investigations, have arrived at almost opposite conclusions. Such apparently non-reconcilable results are probably to be accounted for by the existence of physiologic and pathologic variations in the quality and conditions of the tissues in the individual animals employed. Aside from demonstrable morbid changes in tissues there remain certain intrinsic germ-neutralizing and combative elements that defy all attempts at analysis. This "physiologic resistance," as we term it, varies greatly in different normal individuals.

Results obtained by inoculation-experiments are definite and reliable in many instances; but in others they are extremely misleading and open to serious objection unless certain allowances are carefully made in summing up conclusions. I believe that in these experiments too little allowance is often made for the condition of the tissues in which the micro-organisms are found. Inoculation-experiments are usually performed upon animals in normal health, which naturally enjoy an immunity not found in patients from whom the cultures were obtained. Tissues weakened by chronic alcoholism, the cachexias of malignant disease, prolonged disorders of the excretory organs, as well as the zymotic diseases, lose much of their resisting and neutralizing powers when brought in contact with pathogenic micro-organisms; and an inoculation that yields negative results in a healthy animal would oftentimes produce profound impressions upon the tissues of a diseased individual.

An inoculation in the peritoneal cavity of a healthy guinea-pig with the streptococcus of erysipelas might give rise to no serious disturbance, but will anyone maintain that the injection of the same material into the abdomen of a typhoid-fever patient during the fourth week of the disease would result similarly? Could the same exhausting influences affecting the puerperal patient whose case I have related have been applied to the tissues of an animal previous to its inoculation the results would in all probability have been of a very different character.

The experiments of Gusserow, therefore, are wanting in proof regarding the non-transmissibility of erysipelas to the pelvic organs through the circulating fluids of the body in patients already suffering from the disease, and Senn's statement appears to me not sufficiently supported to be accepted without some qualification.

In a like manner, regarding the pyogenic properties of the streptococcus of erysipelas, may we not concede that while pure cultures of these bacteria injected into vigorous normal tissue do not give rise to suppuration, the same germs, introduced into tissues presenting a more favorable culture-soil and less resistance, might develop pyogenic qualities? In many cases of complicated erysipelas the streptococci have been found in abscesses in almost all parts of the body. Their presence there, even in company with other bacteria, should be evidence enough that they are in a measure concerned in the

destructive processes about them. There is no logical reason why the pelvic organs should escape infection through the medium of septic emboli when such accidents occur in other parts. I regret keenly that in the case herein reported cultures were not obtained from the abscess, and that our conclusions must therefore remain of a purely clinical character.

Endocarditis, more or less pronounced, was probably present in this case, although repeated examination of the heart yielded negative results. Judging from the precordial distress immediately preceding the blocking of the popliteal artery, however, as well as from the history of somewhat similar cases in which autopsies were obtained, we may assume the presence of a septic endocarditis resulting in thrombosis at some point within the left heart or aortic valves.

The transference of bacteria to this region presents another interesting feature, and implies in my judgment the existence of other factors than the mere presence of cutaneous erysipelas. The eruption in this case, while of extensive area, was not of a deep or phlegmonous type. There were no superficial suppurative points discoverable, no sloughing of the surface or overtension of the tissues.

In these less severe varieties of the disease the invading germs are believed to limit their ravages to the lymphatic vessels and perilymphatic spaces, and that only in those graver cases marked by deep infiltration and extensive tissue-destruction do the micro-organisms actually penetrate into the blood-channels. It is at this point that the puerperal state, in conjunction with the preceding weeks of illness, plays an important rôle in favoring invasions beyond the ordinary limit. The overworked secretory organs fail in elimination; the lymphatic vessels and the surrounding spaces are choked with swarms of active germs, and the debilitated tissues offer but feeble resistance to their advances. Conveyed in the substance of leukocytes or in free colonies circulating in the liquid portion of the blood, the streptococci select the surface of the endocardium as the site for mural implantation at some point probably roughened by previous disease. Their passage through the pulmonary tissues, without producing destructive changes, remains a remarkable fact.

From a clinical point of view the case that I have reported is of extreme interest to the obstetrician. It should remind us that unexpected accidents frequently occur in the midst of an apparently normal convalescence, and that the intercurrence of any disorder during the puerperium should be regarded with gravity and the prognosis be guarded; and we are also reminded that all complications of the lying-in state do not originate within the pelvic organs. While an ardent advocate of extreme aseptic precautions in all cases, I must aver that such attentions are often bestowed at the expense of the patient in other ways. The obstetrician must note carefully every condition of the pelvic viscera, but in the meantime must not forget the patient. I am also impressed with the well-known fact that while an ideal puerperal condition constitutes in reality a physiologic process, it certainly prepares the way most admirably for pathologic sequences.

CLINICAL MEMORANDA.

COMPLETE PROLAPSE OF THE UTERUS, WITH INCOMPLETE ABORTION, IN A GIRL SIXTEEN YEARS OLD.

By J. MASON HUNDLEY, M.D.,
of Baltimore, Md.;
Associate Professor of Diseases of Women and Children in the University of Maryland.

I report the case herewith detailed believing it to have some points of general interest. In an experience of eight years in dispensary-work, with a large amount of clinical material at my command, I have never seen a similar condition in one so young.

Ellen S., a colored girl, sixteen years of age, presented herself at the University of Maryland Dispensary, with the following history: She had always menstruated regularly and had been in good health up to a few days before her visit to the dispensary, on January 3, 1895, when she was seized with pain in the lower abdomen and difficulty in urinating. She was also obstinately constipated. An examination was not made at this time, but the patient was given a mixture of magnesium sulphate and compound tincture of gentian for the constipation. This combination, we have found, often relieves pelvic pain when dependent upon constipation, which is not infrequent. The girl returned in a few days, unimproved, and was again given the same solution. Upon her third visit, still not being relieved, she was examined. I was more than surprised to find a procidented uterus, and one presenting an appearance unlike anything I had ever seen before. The uterus protruded from the mouth of the vagina about three inches, and there was a rolling out of the mucous membrane of the cervical canal.

I first thought there was a chancroid of the cervix, but upon closer inspection I found the appearance to be due to the greatly thickened mucous coat of the cervical canal. I now questioned the girl more closely and she positively denied having missed her sickness. She maintained that she had had no bleeding from the uterus, that she had always been well up to a few days before presenting herself at the dispensary. The cervical canal easily allowed the introduction of an aseptic finger, which I introduced within the uterus and brought away nearly a handful of fetal remains, but no fetus. The pregnancy could not have been far advanced, for there was no well-formed placenta. There was no evidence of blood about the person of the girl, nor had there been any blood coming from the cervix before the extraction of the secundines; only issuing from the cervix drop by drop was a watery fluid. There was no

laceration or marked relaxation of the perineum. The cavity of the uterus measured four-and-a-half inches in length. After being thoroughly curetted with the finger the uterus was replaced and put in its normal position, where it remained. The girl was given fluid extract of ergot to assist in the process of involution, and told to go home and go to bed, where she was looked after until the uterus had nearly regained its normal size. Douches of hot water with borax were given in conjunction with the ergot, and the patient was not allowed to become constipated.

There are some points of interest in connection with this case. First, through ignorance or design, the histories obtained from the class of patients visiting dispensaries have often no bearing whatever upon the case in hand, and, therefore, it is always best to make a physical examination in each and every case, unless there be clear contraindications. The second interesting point in the case is a procidented recently pregnant uterus in a girl sixteen years of age who had never borne a child to full term. There was no evidence that she had given birth to a child, no striæ upon the abdominal walls and no evidence about the outlet of the birth-canal. The procidentia seemed to be of recent origin—whether it was brought about by the girl herself, or someone else pulling upon the vagina or uterus, thereby hoping to effect an abortion, I am unable to say—I could get only the meager history related. Another point brought out by this case is the curettement of the uterus with the finger. I do not think one can emphasize too strongly the great advantage this method has over that with the ordinary curet. With the finger one can appreciate what is to be done and where to do it. One knows when the uterus is thoroughly emptied of its contents, and, however soft and yielding its walls may be, there is no danger of going through them, as is now and then done, even in the hands of the best operators. I once had the misfortune of pushing a curet through the uterine wall, and since then I never use a curet without first introducing my finger within the uterine cavity to find out the true condition of things. If there be simply vegetations to be gotten away I may use the curet; otherwise I use the finger.

TRAUMATIC NEURITIS FOLLOWING FORCEPS-DELIVERY.

By J. C. WELCH, M.D.,
OF BELLEVUE, PA.

THE following case came under my observation while a resident physician at the Philadelphia Hospital, and is reported as an infrequent complication of the puerperium.

M. F., 20, white, Irish, a primipara, was of good family and personal history, so far as could be ascertained, with the exception that the mother died in childbirth. The fact is interesting in connection with the pelvic measurements of the patient; these were:

	Cm.
Iliac spines	24
Iliac crests	26
External conjugate	20
Right diagonal	19½
Left diagonal	19½
Between trochanters	29¼
Circumference of pelvis	88

The position of the fetus was the first position of the vertex. At 3 A.M. the patient fell into labor; the pains were regular and quite severe. At the end of 36 hours the os was well dilated, the membranes had ruptured, and the patient was quite exhausted. It was evident that the termination would not be a favorable one without interference. Forceps was applied at the superior strait and the head was brought down to the perineum without difficulty, but could be not delivered. After successive attempts at delivery with forceps it was finally accomplished after rotating the head considerably. The perineum was badly torn and there was a double laceration of the cervix on either side, extending into the vaginal vaults. The child was asphyxiated, but was resuscitated in the usual manner, and seemed to be doing well, but died suddenly about seven hours after its delivery.

After delivery the patient suffered greatly with pain in the back and particularly in the lower extremities, chiefly in the lumbar region and in the posterior portion of the limbs, and this was so severe as to prevent sleep. The external genitals became much swollen and on the third day the temperature rose to 101.4°, but these symptoms did not continue.

The pains gradually lessened in intensity and at the end of 2 weeks had disappeared from the right limb; at the end of 7 weeks she left her bed and was able to walk with difficulty. A vaginal examination at this time revealed no swelling or induration or the lumbosacral plexus, but there was exquisite tenderness on the left side. There was marked tenderness on pressure along the course of the sciatic nerve of the left limb, particularly at its emergence from the pelvis. There was also soreness of the muscles of the entire posterior surface of the limb, more intense between the great trochanter and the tuberosity of the ischium and gradually diminishing toward the heel. The patient stated that she had a dull aching pain, constantly present from the lumbar region along the posterior portion of the limb to the heel, and at times suffered with short paroxysms of a sharp, darting pain here. These paroxysms occurred at night when asleep as well as when the limb was being exercised.

The case remained under observation for 2 months, and during this time showed great improvement. The lameness disappeared, the pain became less acute, and the paroxysms very infrequent.

EPILEPTIFORM CONVULSIONS OF MALARIAL ORIGIN.

By E. W. LUDLOW, M.D.,
OF URBANA, O.

F. S., aged seventeen years, gave no history of epilepsy in the family or of attacks previously. In August, 1894, the patient was seized with sudden pain in the head and neck, and then became unconscious and so remained for about two hours. After the attack, which occurred in the afternoon, the lad was stupid and drowsy, and slept during the ensuing night. The next day he had mild convulsions at intervals of a few hours, the headache continuing. This condition kept up for about two weeks. During the fall and winter of 1894 the young man had chills and fever, with fits at irregular periods. About the first of January, 1895, his con-

vulsions occurred every other day, always in the afternoon between four and five o'clock. The fits were severe, and he would not be able to resume work until the next day. During this time, from the beginning of the fits until January 1st, the patient was away from home working, and his condition, except for the fits, was good. I saw him first on his return, January 4th, and he had just had a fit. I could not get a satisfactory history, and lost sight of the case until June 25, 1895, when I obtained the history given. The lad had been having fits at regular intervals for over six months since I had seen him. The indications were that the cause of the convulsions was malaria, and quinin was given so as to anticipate the next seizure—which never came. Anti-malarial treatment was continued for about two weeks, when the patient disappeared. He turned up about September 1st, and reported that he had had no more fits. Quinin sulphate was used in fairly large doses, and had not the least ill effect.

MEDICAL PROGRESS.

The Pulse of Mitral Stenosis.—As the result of an elaborate study, Steel (*Medical Chronicle*, September, 1895, No. 6, p. 409) sums up as follows his views upon the character of the pulse associated with mitral stenosis: In healthy individuals the pulse varies; some have a normal pulse—tension fairly "high;" others a normal pulse—tension fairly "low." In mitral stenosis this physiologic individual difference must not be lost sight of. It would appear that most cases of the lesion pass through three stages: (*a*) A stage in which auscultatory signs (presystolic murmur, etc.) are best developed, while symptoms of disturbed circulation are feebly developed or absent, and in which the pulse is regular and of high tension, showing a well-developed tidal wave. There is, of course, nothing characteristic of the lesion in such a pulse. (*b*) A stage in which symptoms of disturbed circulation are more or less pronounced, and which is accompanied by an irregular pulse of the kind that may be indicated as "typical." A tracing of such a pulse shows a series of low-tension ill-developed curves, interrupted from time to time by a curve of fairly good tension with the tidal wave developed; or a series of good-tension curves may be interrupted by an occasional low-tension and ill-developed curve—that is to say, one or other curve may predominate. A similar tracing is met with in simple muscle-failure of the heart. It is not pathognomonic. Many patients die in this stage. (*c*) The pulse of the second stage becomes one of low tension, and may be regular or irregular as regards the height of the upstrokes of the tracing, etc.; more often the former. In many cases this stage is never reached, the patient dying in the second stage. On the other hand, the third stage is often reached and recovered from, stage two and even stage one being resumed. A low-tension pulse (third stage) is often temporarily assumed from a variety of causes (pyrexia, etc.). Few patients die with a first-stage pulse, except from some complication. Physiologic low tension must be borne in mind in estimating the prognosis. Certain patients have low-tension pulses from first to last. The three stages referred to are mere generalizations. It must not be supposed that exceptions are infrequent. The bigeminal pulse is frequently met with in mitral stenosis, but is also common in simple "muscle"-cases. In aortic incompetence even, it is by no means rare. It should not be associated with any one lesion, and digitalis is commonly a factor in its production. No pulse is pathognomonic of mitral stenosis. Each type of pulse is also met with in other diseases. A patient with mitral stenosis may show at different times and under different circumstances extremely high tension (especially under the influence of digitalis) and extremely low tension. In the stage described as the second the pulse-tracing may be regarded as a combination of the characteristic curves of the first and third stages. The second stage may not be represented.

A Case of Acute Leukemia.—Seelig (*Deutsches Archiv für klinische Medicin*, Band 54, Heft 6, p. 537) has reported the case of a boy, eleven years old, who at the age of nine had an attack of scarlet fever, complicated by nephritis. From this illness the boy had never wholly recovered, remaining pale and eliminating considerable albumin in the urine. For a period of five weeks there had been excessive fatigue, with nausea, headache, and mild gastric disturbance. Examination disclosed enlargement of the spleen, but the blood presented no abnormality. There was a brief interval of remission in the symptoms, but these returned with their previous intensity in the course of sixteen days. The pallor was now marked; the face and especially the eyelids appeared edematous, but did not pit upon pressure. The gums were swollen, and in places bled readily on pressure. The lymph-glands in the axillæ, groins, and flexures of the elbows were distinctly enlarged. The liver was enlarged, and the spleen was also increased in size. Examination of the blood showed an enormous increase in the white corpuscles, with a preponderance of myelocytes. As the case progressed, pain and tenderness appeared in the right ankle and the foot, together with enlargement of the veins. Small movable nodules appeared behind the ears and in various situations upon the thorax and abdomen. The temperature rose above normal, and petechiæ appeared upon the anterior surface of the body. Hematemesis occurred, the patient grew progressively worse, and finally died. Upon post-mortem examination, in addition to the superficial hemorrhages and nodules, the spleen and liver were found to be enlarged. The thymus was persistent. The heart was enlarged, and the precordial surface presented many white, moderately firm nodules, in the midst of which were numerous hemorrhages. The lungs were slightly emphysematous, and presented ecchymoses beneath the pleuræ. A number of small indurated lymph-glands occupied the hilus of the spleen. The mesenteric glands were enlarged. The kidneys also presented upon the surface nodules and hemorrhages. The mucous membrane of the stomach and intestines contained prominent white lymph-follicles and a number of small hemorrhages. A collection of enlarged lymph-glands occupied the transverse fissure of the liver.

Fetal Endocarditis in Association with Deficient Interventricular Septum.—Railton (*Lancet*, No. 3754, p. 327) has reported the case of a boy, four years old, who had

always been delicate, and did not walk until the eighteenth month, and subsequently was unable to play about like other children, being easily exhausted and out of breath. He had frequently complained of pain in the region of the heart, but had not suffered from articular rheumatism or shown any blueness of the lips or fingers. For three weeks following exposure to cold the child had been worse, and on coming under observation presented well-marked symptoms of broncho-pneumonia. The area of cardiac percussion-dulness was greatly increased. No murmur was audible. The patient grew steadily worse, the temperature rose to 106°, and death took place after twenty-seven days. Four days previously a systolic murmur was audible over the right ventricle. Upon post-mortem examination the lower lobes of both lungs were found consolidated, while islets of broncho-pneumonia were scattered over the rest of the lungs. The heart was large, principally upon the right side. The tricuspid valve was the seat of large verrucose vegetations covered with a deposit of fibrin. Close to the tricuspid orifice were a few other vegetations on the auricular edge, and one recent irregular ulcer. The remaining orifices and valves were normal and the ductus arteriosus and foramen ovale were closed. There was a deficiency of the interventricular septum about the undefended space large enough to admit a quill. This opening was larger at the side of the left ventricle than on the right side, where it ended between the insertion of two cusps of the tricuspid valve nearer to the right auricle than to the ventricle. The edges of this orifice were quite smooth. It seemed evident that the lesion of the tricuspid valve had started during fetal life, and that the endocarditis had also continued its evolution subsequently to birth.

Successful Bilateral Ovariectomy during Pregnancy.—MERKEL (*Münchener medicinische Wochenschrift*, 1895, No. 37, p. 864) has reported the case of a woman, thirty-six years old, who during her seventh pregnancy presented melancholia of progressive character. Upon examination the uterus was found to be enlarged in a degree corresponding with the fourteenth week of pregnancy. To its right was a movable, tensely elastic tumor, as large as a child's head, which was taken to be a degenerated ovary. The left ovary appeared to be cystic, and about as large as a fist. The mental symptoms became aggravated, and the patient threatened to commit suicide unless released from the hospital and sent home. This was accordingly done, and, in view of the possibility of rotation of the pedicle of the right ovary, operation for the removal of the ovaries was undertaken. That state of affairs was found to exist. The twisting was released and the pedicle ligated and severed. Upon the left was found a parovarian cyst, which was removed. The uterus was not disturbed. The abdominal wound was closed, and an appropriate dressing applied. Upon emerging from the anesthesia the mental disturbance was entirely gone. There were no complications, and the pregnancy pursued a normal course, delivery of a living child being successfully effected, and the patient's health, both mental and physical, continuing undisturbed.

Retention of Urine of Malarial Origin.—OCHEVSKY (*Bulletin Médical*) has reported the case of a young man, living in a malarial locality, who had suffered with complete retention of urine for two days. The patient had for five years suffered from malarial fever, was anemic, and presented enlargement of the liver and spleen. Attempts at catheterization were ineffectual, evidently from contraction of the sphincter vesicæ. Both quinin by the mouth and morphin beneath the skin failed to bring relief. By the third day the bladder had become enormously distended, and the suffering was intense. From time to time, at fairly regular intervals, the patient was seized with paroxysms of vesical spasm. During the night coma set in. Upon the conviction that the disturbance was of a malarial origin 7 drops of Fowler's solution of potassium arsenite, followed by 15 grains of quinin sulphate, were injected subcutaneously. The result was remarkable, the patient urinating spontaneously an hour later. The urinary retention reappeared a week later, but was finally dispelled by renewed injection of quinin and arsenic.—*Ann. des Malad. des Organes Gen.-Urin.*, 1895, No. 9, p. 854.

Syringomyelia of Akromegalic Type.—LORRAIN (*Progrès Médical*, 1895, No. 17) has reported the case of a man, forty-two years old, who presented enormous enlargement of the hands with decided kyphosis. There existed, besides, atrophy of the muscles of the upper extremities and of the shoulder-girdle, derangement of sensibility, involving especially pain and temperature, and atrophic change in the bones and skin of the upper extremities. Numerous nodular thickenings were detectable in the course of the right ulnar nerve.—*Centralbl. f. Inn. Med.*, 1895, No. 37, p. 906.

For the Preservation of Organic Urinary Sediments.—FISCHEL (*Prag. med. Wochenschr.*, 1895, No. 12) recommends centrifugation, followed by washing of the sediment to the point of decolorization with a physiologic salt-solution. After decanting the supernatant fluid a mixture of equal parts of glycerin and water is added, containing 2 per cent. of a saturated alcoholic solution of thymol. The organic matters may thus be preserved for months, and are as susceptible to stains as those contained in recent urine.—*Ann. des Malad. des Organes Gen.-Urin.*, 1895, No. 9, p. 853.

THERAPEUTIC NOTES.

The Employment of Borax in the Treatment of Epilepsy.—As the outcome of a considerable clinical experience, FÉRÉ (*Revue de Médicine*, 1895, No. 9, p. 750) has arrived at the conclusion that while borax frequently has little or only passing effect in the treatment of epilepsy, the drug is useful in some cases and may be employed when the bromids fail. Some care must be exercised in the use of borax as it is capable of causing derangement of renal function.

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 19, 1895.

MEDICAL STATISTICS.

WE have on several occasions called attention in these columns to the faulty and irrational way in which statistics are often used to prove medical theories. Figures are not so stubborn as they are commonly accredited to be, but are as yielding as dough and can be kneaded into any form that one desires. They can be made to prove or disprove anything, if one's audience is unlogical enough to accept his reasoning. It was the sophists of old who, with figures, proved that the elephant could never overtake the tortoise, if the tortoise had ever so little advance, and ever since, though we may not wilfully seek to deceive our hearers, we appeal to statistics as the final tribunal to prove that one is two and black is white, and that one medicine has curative powers and that another has not.

Counting heads is a very simple procedure, and a schoolboy in the lowest grade can do it; but before we begin we must have an intelligent conception of a head, for surely it would be a grevious error under the circumstances to count feet as heads.

Enumeration, however, is a comparatively easy task, and our most serious mistakes are made when we endeavor to judge of the relation of one group of aggregates to another.

First, we have a quantitative relation. If, for example, we have in one year x deaths from a given disease, and in another year a greater number, represented by y, the question arises, Is y greater relatively or absolutely? If the population were to remain stationary, then a comparison could at once be made, but an increase in population might in itself be sufficient to account for the greater number of deaths. Having then made certain that y is *relatively* greater than x, we may look about for the causes of this increase.

In his *Theory of Statistics*, Meitzen states that "the judgment of causal connection is reached only after we have taken up in succession the possible causes and carefully analyzed them, much in the nature of an experiment;" beginning with the most probable cause and examining successively each probable one until a cause sufficiently well grounded is found. How seldom do we see this rule observed in medical statistics? It may be that an increase of crime has "been shown to coexist with an increase in the importation of wool," that the number of marriages in a country increases as the price of rye decreases. Are these facts in causal connection or are they unrelated?

Vienna has a death-rate of 43 per 1000, London of 18 per 1000. In the former city an average of 42 persons inhabit one building, in the latter only 6.5 persons. Are these two sets of facts in causal relation, or is it that Vienna has such a high death-rate because every year one-third of all the births occurring in that city are illegitimate, and, as is well known, illegitimate children have a very high mortality? This example is cited merely to show how in any case there may be a complexity of operative factors and, unless all are considered, how erroneous may be the conclusions arrived at.

With these facts in mind let us view the statistics of the antitoxin-treatment of diphtheria, and see if all sources of error have been eliminated in their collection and presentation.

As scientists we must consider the matter without prejudice one way or the other. Neither the favorable results that have been experienced in individual hands, nor the enthusiasm of others, nor yet the dogmatic opinions of authorities ought to influence the study of figures.

From the remarks that follow we trust that our position on the question of the antitoxin-treatment

of diphtheria will not be construed as in any sense antagonistic. This particular therapeutic procedure is used merely as an example, and our words are equally applicable to any new form of medication, whatever may be its merits. We merely ask that medical men, before placing reliance on statistics, presented indiscriminately, view them from all sides and refuse to express judgment until a careful analysis has been made. It is because we feel that there is some efficacy in the antitoxin-treatment that we are all the more anxious that it should not be brought into disrepute by its overzealous friends.

We find it stated, for instance, that under the use of the antitoxin the mortality of diphtheria has been greatly reduced. What are the proofs? First, in hospitals in which the remedy is used the figures show a great diminution of the death-rate as compared with former months or years when it was not employed. Here is a fact. What are the possible causes at work?

Gottstein in commenting upon a paper read before a Berlin medical society, showed how easily errors creep in when we judge figures with a biased mind. It was maintained that the mortality of diphtheria in the city of Berlin was formerly one-half that of the Berlin hospitals, because only the severer cases were sent to the latter for treatment. With the beginning of the new treatment the patients were sent in much greater numbers to the hospitals, almost twice as many admissions being recorded, and the mortality-rate fell. Now, if the premises are correct, and every case of diphtheria in Berlin had been sent to the hospitals, irrespective of any treatment, the death-rate from this disease in the hospitals would have been the same as that of the whole city—a reduction by this means alone of 50 per cent.

Thus it will be seen that before we can judge of the value of a remedy from hospital-statistics we must have a correct idea whether or not the general relation has been disturbed. It is claimed by some that the total death-rate from diphtheria in New York and Boston has been much lower in the past six months than in any previous year, and the result is attributed to the somewhat general use of the antitoxin. Henry W. Bettman, in THE MEDICAL NEWS of August 10, 1895, p. 145, clearly shows how this reduction was brought about in Boston by improved methods of diagnosis. "Cases of diphtheria that formerly would have been called simple sore-throat" are reported now, because of bacterial analysis and efficient inspection, so that in 1894 there were nearly twice as many cases on record as in any previous year. Of course the death-rate must fall under these circumstances. The wonder is that it does not fall more. But let it be established without a doubt that under the use of the antitoxin the percentage of cures has increased, are there no other factors that contribute to this result?

We have spoken of bacterial analysis. Now it is pretty nearly certain that many persons who were considered to be suffering from a mild form of angina were in reality infected by the Klebs-Loeffler bacillus, and thus coming under treatment early were speedily cured or saved from becoming seriously affected. Again, when a greater number of all the cases occurring in a city are sent to the hospitals, the better nursing and attention that those who are sent there receive must materially affect the general mortality.

But another factor may influence the result, and it is applicable to all new remedies and operations. The physician when making trial of the antitoxin is extremely solicitous for the recovery of his patient, and it is unfortunate that he cannot devote to every patient that comes under his care that close attention that he gives when a new remedy or treatment is upon trial. Under the latter conditions visits are made oftener, work that is usually relegated to the nurse or attendant is performed personally, the temperature is more frequently recorded, and all little changes that occur are noted. Can anyone doubt that this must be productive of better results than when some routine plan of treatment is indulged in and left for performance largely in the hands of untrained caretakers?

Supposing that the antitoxin and a syringe were given to the mother of a diphtheric child, with instructions to inject a dose three times daily as directed, and the doctor would drop in once in twenty-four hours to watch the case, would we have such favorable results to chronicle?

Until we have two sets of cases side by side, both equally well nursed and attended to, the one treated with the antitoxin, the other without, we must be extremely guarded in our opinion as to the probable cause of the diminished mortality.

We shall not speak of those wilful misrepresentations of statistics that omit such cases as are beyond cure, much after the fashion of a celebrated reformatory-superintendent who sent all his bad boys to the penitentiary, and then reported a high percentage

of reform in the remaining number. It is perfectly proper, when a new remedy is on trial, to leave out of consideration those unfortunate cases in which death occurs before sufficient time has elapsed to study the effect, but it is extremely unfair and dishonest to compare such selected cases with the remainder, good, bad, and indifferent. There is danger, on the other hand, that we will employ a certain remedy only as a last resort, and then condemn it, quoting in justification our failures.

The root of the whole matter lies in the fact that *statistics* is a *science*, with laws as well established as other sciences, and amateurs who dabble in it make mistakes as amateurs in other fields are likely to do.

To accept a remedy, to utter dogmas concerning it, or to reject it as a failure on the basis of figures alone, when such figures have not been carefully studied, is too much the tendency of many of our time, and because of this unscientific haste the medical profession is often held up as a laughing-stock before the world.

A HUMBUG AT LOURDES.

It is scarcely worth while for a medical journal nowadays to call attention to cases of alleged faith-healing at a religious shrine or under any form of religious excitement. The essential characteristics of these cases are so well known to science, and generally so well understood by intelligent men, that to dwell upon them is usually only to waste space and opportunity. The flagrant offenders in these cases are not, as a rule, the patients themselves, for in most instances these are self-deluded; but they are the ecclesiastic authorities, who persistently parade these cures and obstinately palm them off as evidences of a supernaturalism which they themselves should know well enough has had no hand in the business.

It is rather the mode now, in our *fin de siècle*, for ecclesiastics of all denominations to affect to believe that theology has no real quarrel with science; that when each is shown in its true light the lines of convergence are seen to be approaching to a gratifying extent. Scientists await the evidences of this approach with judicial calmness; but meanwhile they note that no spurious cases of demon-possession, witchcraft, and faith-cure arise in any quarter of the earth, but that they are hailed by the ecclesiastic party with unbounded delight and vociferous acclaim as the theologic contribution to the love-feast of science and religion. It is therefore a matter of considerable interest and importance to note the recent exposure of a fraud at Lourdes, because the case for a short time baffled common sense as well as science, and gave the priestly party a conspicuous opportunity for unctuous but premature jubilation.

We refer to the case of Delannoy. This impostor was a warder in the Paris hospitals from 1877 to 1881. He thus became familiar with the superficial appearances of many diseases, and also became so enamored with hospital-life that this became for him the ideal of existence. With almost nothing to do and with others to do it for him—this in brief was to be Delannoy's elysium. He resolved to enjoy it to its full extent. He therefore made his plans, which were extremely simple, and began to sham the early stages of locomotor ataxia. We do not know what he did with his knee-jerks, but he evidently did not reinforce them, and we suppose that his pupils had not yet become involved; but all the other early symptoms of tabes, especially of the sensory type, being easily simulated, he assumed his rôle, and made his début at the Salpêtrière, where he promptly victimized Charcot. After this eminent savant had made a diagnosis things were evidently easy for Delannoy in Paris. Charcot's diagnosis was a *passe-partout*. The doors of all the hospitals stood open to the malingerer. Who, in Paris, would dispute the diagnosis of the great neurologist?

From this period Delannoy's course was steadily onward and upward, until he almost attained saintship. Some of his adventures, however, were harrowing and almost bring a tear—probably *did* bring Delannoy's tears. He was for a time in Callard's wards in the Hotel Dieu, but, liking change of scene, he went, in an evil hour for him, to the Necker Hospital, where Rigal awaited him with the inevitable hot iron. Here he was burnt in a red-hot fashion, and in the intervals was blistered in order to keep up the revulsive effects. The impostor endured this as long as he could and then fled. Later, under Ball he was treated with belladonna and morphin, much to his satisfaction; but apparently tiring even of morphin in a year he professed himself cured and left. Relapsing, he once more encountered Rigal with his hot irons, but soon sought more congenial quarters, and passed successively through the Beaujon, the Charité, the Lariboisière, and other hospitals. Some of these institutions he entered more than once. He was finally captured by Dujardin-Beau-

metz in the Cochin Hospital, and was hung up. The suspension-treatment was then all in vogue in Paris, and Delannoy, probably knowing that he could not escape it anywhere, submitted to this benevolent and optimistic therapeutist, who strung him up fifty-eight times in two months.

But these various therapeutic adventures need not detain us, although they occupied Delannoy for several years. Finally, either because he wearied of this burden of pathology or because he was convinced that tabes is practically an incurable disease, and will not yield to hot irons and suspension, he resolved to give up the game. It occurred to him that the easiest and most rational way to give it up was to go to Lourdes and be cured. He foresaw fame and even gain at the shrine; and then, too, it offered him a neat way out of one deception by helping him to slip gracefully into another, and so to return to the world with the posterior columns of his cord all right, and no questions asked. He resolved to abandon medicine and to seek the church.

Accordingly Delannoy went to Lourdes. He arrived there in a most pitiable condition. He was carried to the Virgin Mary's Grotto, kissed the ground, and remained a long time prostrate before the Holy Sacrament displayed at the altar. Suddenly, according to his own veracious statement, he had a feeling of a mysterious inner force, which caused him to stand, to walk, to drop his crutches, and, we suppose, to resume his reflexes. This transformation was of course the signal for the other pilgrims (poor dupes, probably mortally diseased) to sing hymns of praise. The beaming fathers of the Grotto were not slow to take the bait. They treasured up all the details and proofs of this modern "miracle," and prepared to confute the infidels. They supervised an appropriate spectacular display; and in the evening a torchlight-procession of pilgrims was seen "threading its way up the zigzag paths of Massabielle, rejoicing for the miracle." Delannoy was of course in the front rank of this procession. The next day the impostor was examined medically in the presence of an archbishop and a bishop, and was declared *ex cathedrâ* to have been cured of locomotor ataxia. The miracle was duly recorded in the register of Notre Dame de Lourdes, and Delannoy, without undue delay, returned to Paris as an honored guest of the national pilgrimage.

It is needless to say that the physicians of the Paris hospitals were staggered by this case. They examined Delannoy again and again after his return, and not one of them seems to have suspected the truth even then. A telegram was sent from Paris to Lourdes expressive of this medical perplexity. It said, "He walks like a country postman." Thus in homely phrase science bore testimony to the truth of the miracle.

In the following year (1890) the fathers of the Grotto appointed Delannoy overseer of a home for invalids awaiting to be miraculously cured. Such an institution might, we submit, be henceforth called a "Hôpital Delannoy." It would thus help to preserve a unique reputation, which soon spread over Europe, America, Asia, Africa, and Australia. From all these parts of the world the ex-tabetic was soon in receipt of rich presents, with prayers that he would intercede with the Virgin, with whom he was supposed to have extraordinary influence. The rogue was now at the pinnacle of his fortunes.

But Delannoy was evidently not made to endure either fortune or tabes. He wearied of one as he did of the other. In about a year he stole 400 francs of the good fathers' money. As there was nothing miraculous about the theft Delannoy decamped. He again sought Paris and gained admission at St. Anne's Asylum as a lunatic; was discharged, and admitted again on a doctor's certificate, and this time stole 1800 francs of the hospital-funds. This was the beginning of the end. Having devoted himself so successfully to medicine and theology he was now about to try his experience with the law. There was to be no humbugging the law, however. He was arrested by the police, and was pronounced by some shrewd police-surgeons to be a malingerer of extraordinary skill. He was tried, convicted, and sentenced to four years' imprisonment and ten years' police-surveillance.

Not the least notable feature of this case is the fact that Delannoy deceived Zola. The realistic novelist could not explain the "realism" of this supposed cure. It is to be predicted in conclusion that while Delannoy deceived both the physicians and the priests, there will yet be seen this difference: The former will acknowledge their error, but the latter will not abolish Lourdes.

EDITORIAL COMMENTS.

Medical Advertising in Austria.—The Vienna Medical Chamber has recently adopted regulations governing advertising by medical men. The commission of any of the following acts on the part of a physician will constitute an offence against professional dignity:

Causing or permitting, or refraining from preventing (when he has the power) the insertion of advertisements in newspapers, journals, indexes, guide-books, annuals, leaflets, circulars, or any other description of printed matter. This article, however, does not refer to medical publications, nor is it meant to hinder a medical man from publicly proclaiming his entry into practice, his return after a prolonged absence, or his change of domicile, provided the notification is not repeated more than three times. The same information may also be conveyed by means of a circular, but in both cases the notice must contain nothing additional beyond the name of the advertiser, his academic qualifications and legal medical designation, an indication of the specialty he professes, his address, and the hours he is at home for consultation. Publishing, or allowing to be published, letters of thanks and expressions of gratitude from patients who have been treated by him; recommending, either directly or indirretly, in pamphlets and popular publications, his own system and methods of treatment in preference to those of other practitioners; allowing commissions to midwives, waiters, commissionaires, porters, etc., in return for their services in procuring him patients; drawing public attention to himself by means of a charlatan's sign-board; endeavoring in an unbecoming manner, after the fashion of quacks, to attract notice to the medical establishment he either owns or directs.

In commenting upon these regulations and their adoption by the Medical Chamber of Vienna, the *Lancet* points out that far more latitude in the way of advertising is thus allowed to the medical profession in Austria than is the case with the English profession. It further expresses the opinion that the best way to safeguard professional dignity is by drawing up hard and fast regulations prohibiting personal announcement of every kind and description. With these views we are in hearty accord. When it shall become necessary for medical men to exploit themselves by advertisement, surely will medicine bave degenerated into a business.

The Revival of the Index Medicus.—The following subscriptions to the *Index Medicus* received up to October 8th have not been included in any of the several lists already published in The Medical News:

Detroit: H. O. Walker	$25
Milwaukee: R. Newton Hawley (Milwaukee Medical Society)	25
Philadelphia: H. A. Hare	25
Edward Martin	25
Santa Barbara, Cal.: R. J. Hall	25

A total of two-hundred subscriptions will be required before December 1st to complete the guarantee-fund for the revival of the *Index*, and it would be a disgrace—not to speak of the actual loss—to the medical profession if the requisite number were not secured within the stipulated time. Every medical society with a membership of twenty-five and more, and every reputable medical college in the country, owes it to the profession to subscribe annually for one copy.

We are informed by Dr. J. B. Roberts that the Committee, of which he is Secretary, has received the following additional subscriptions:

Dr. L. McLane Tiffany, Baltimore	$25
American Medical Missionary College, Battle Creek, Mich.	25
Dr. George R. Fowler, Brooklyn	25
Library Medical Department University of Buffalo	25
Dr. M. D. Mann, Buffalo	25
Dr. J. H. Etheridge, Chicago	25
Dr. E. Fletcher Ingals, Chicago	25
Dr. Joseph Ransohoff, Cincinnati	25
Dr. J. T. Eskridge, Denver	25
Dr. W. M. Polk, New York	25
Dr. Thomas G. Ashton, Philadelphia	25
Dr. Ernest Laplace, Philadelphia	25
Lea Bros. & Co., Philadelphia	25
Library of the College of Physicians of Philadelphia	25
Mr. W. B. Saunders, Philadelphia	25
Dr. John D. Roe, Rochester	25
Dr. E. C. Burnett, St. Louis	25
Dr. H. H. Mudd, St. Louis	25
Dr. E. L. Trudeau, Saranac Lake	25

Climate and Health.—On p. 134 of The News of February 2, 1895, we called attention to the proposition of the Weather-bureau of the United States Department of Agriculture to undertake the collection and periodic publication of data bearing upon the relation of disease and death to meteorologic phenomena—a matter of great interest and much importance. This plan has reached fruition, in so far as the first number of the new journal, designated *Climate and Health*, and edited under the direction of the chief of the Weather-bureau, Prof. F. Willis S. Moore, by Dr. W. F. R. Phillips, has been issued. This contains a summary of statistics covering the four calendar weeks that began June 30 and ended July 27, 1895. The data presented consist of climatic charts and tables obtained from the records of the meteorologic observatories of the Weather-bureau; statistics of mortality and morbidity furnished by special reports of public-health officials and of physicians made directly to the Weather-bureau; and some mortality-statistics taken from reports made to the Marine-hospital Service. We welcome this new addition to scientific literature which reflects credit upon the government, the Department of Agriculture, and the Weather-bureau.

The Need of Animal Experimentation.—We commend to the consideration of our antivivisection-friends and to others the following concluding remarks of the elaborate and comprehensive article on "The Treatment of Diphtheria with the Antitoxin," by Dr. W. H. Welch, the distinguished Professor of Pathology in Johns Hopkins University, published in the *Bul. of Johns Hopkins Hospital*, vol. vi, Nos. 52, 53, p. 97, and from which we quoted some statistics in The News of Oct. 5th:

"The discovery of the healing serum is entirely the result of laboratory-work. It is an outcome of the studies of immunity. In no sense was the discovery an accidental one. Every step leading to it can be traced, and every step was taken with a definite purpose and to solve a definite problem.

"These studies and the resulting discoveries mark an epoch in the history of medicine. It should be forcibly brought home to those whose philozoic sentiments outweigh sentiments of true philanthropy that these discoveries, which have led to the saving of untold thousands of human lives, have been gained by the sacrifice of the lives of thousands of animals, and by no possibility could have been made without experimentation upon animals."

Cropping Dogs' Ears.—There is now before the American Kennel Club a proposed amendment to its bench-show rules to prohibit the cropping of dogs' ears, which, if adopted, will prevent all dogs cropped after a fixed date from being shown at any of our bench-shows. Cropping has now been declared by the English courts to be an illegal cruelty, and the Irish Terrier Kennel Club has the great merit of having inaugurated a systematic reform by excluding cropped dogs from its bench-shows. It is certainly desirable on all grounds—for the sake of kindness, for the health of the animal, and for esthetic reasons—that this cruel and disgusting practice of mutilating animals should be stopped.

SELECTIONS.

A LITTLE CONTROVERSY.

MR. GEORGE M. GOULD seems to be the editor of THE MEDICAL NEWS. The other day in his paper he made an exaggerated and somewhat stupid assertion in defence of the manly art of vivisection,[1] reflecting on the usefulness and sincerity of a universally respected association whose object is the suppression of cruelty to animals. This assertion was politely and ably corrected by Mrs. Caroline Earle White in a letter to the aforementioned editor. The letter was not long, but was concise and to the point. It ended with these words:

"Begging you to do me the favor to publish this letter, I remain yours truly,

"CAROLINE EARLE WHITE,
"Cor. Sec. Am. Antivivisection Society."

The chivalrous recipient, however, not handicapped by any ideas of professional etiquet, instead of publishing the letter, sent the following note:

"DEAR MRS. WHITE: I regret that owing to the crowded condition of our columns, it will be impossible for me to insert the letter which you have so kindly sent me, date of May 13th.

"Very sincerely yours,
"GEORGE M. GOULD."

Now, Mr. Gould, we all know that the columns of THE MEDICAL NEWS are not so overcrowded with interesting matter as to justify you in violating the ordinary laws of courtesy, and we would suggest, in a brotherly way, that even if not hampered by any sense of justice, both you and your publication might derive a lasting benefit from a closer observance of the established rules of your profession.

Your bravery in times of war might stir the nation, but the courage you have displayed upon this occasion is not of the kind to which monuments are erected.

It is possible that *Life* may be unjust in expecting a very tender regard for human rights from one who defends the cutting up of living animals for the entertainment of medical students.—*Life*, August 13, 1895.

The following communication is much too long for the space we should wish to give, but as the writer feels himself injured by our previous comments we prefer to print it entire.

The author signs his name at our own request.

Faddomania and Courtesy.

To the Editor of Life,

SIR: In *Life* (August 13th) you lampoon a physician for declining as editor to print in his journal a letter from a correspondent, and you read him an illustrated lesson in etiquet. By all rules of humor and literary exegesis the vignet you use, a hog reading books of etiquet, can only be construed as setting forth your own office and mental condition. It is a praiseworthy and admirably frank personal confession. But that you do not choose good books is evident from the fact that every line of your article violates the rules of courtesy and good breeding practised by gentlemen. Your books should teach you:

1. Not to vilify a brother-editor for a courteous rejection of a manuscript written by a (to you) unknown correspondent. To mind one's own business is simple decency.

2. Not to drag a physician's name into public print (lay journals) without his consent.

3. Not to name an editor personally, instead of his journal, when discussing editorial action.

4. Not to indulge in personalities instead of discussing principles.

Please now ask yourself:

1. Is it good editorial judgment, especially as editor of a humorous journal, to be a faddomaniac? Does not zealotry destroy the sense of humor? Please let us yet read our *Fliegende Blätter* and *Life* for many years to come.

2. Is intense conviction any proof of sound judgment? Have you taken the least precaution to know the truth, either as to the question of vivisection or as to that of the rejection of a manuscript by a distant brother-editor? All good men will join with you in stopping the abuses of vivisection, which, to a limited degree, all physicians will recognize to have occurred in the past, but let us have no fanaticism! Remember that the great vivisectionist, Ludwig, was the greatest promoter of kindness to animals in all Europe.

3. Should not the vain editorial portrait you reproduce have much longer ears, without, of course, losing the characteristic face given? *Life's* article is as non-intellectual as it is boorish. *E. g.:* A little exercise of judgment would have brought you proof that both the Antivivisection Society and the malicious creature who sputters her pitable nonsense in every possible journal of the land, and who has so egregiously duped you, are the butts of ridicule with those of any degree of understanding. You also charge a gentleman with "defending the cutting up of living animals for the entertainment of medical students." This person, however, never did defend the practise of vivisection for didactic purposes, and has always and publicly argued against it. Injustice and calumny are bad, even in a good cause—a fact you two have yet to learn.

Finally, let me ask you:

1. If your child falls ill with diphtheria will you call a vivisectionist-physician, and will you permit him to use the antitoxin-treatment to save its life? Even your

[1] The reference is to an editorial article in THE NEWS on "The Capricious Mutilation of Animals," April 27, 1895, devoted entirely against a fashionable form of cruelty to animals, with not a word in defence of or about vivisection.—ED. THE NEWS.

poorly informed self must know that this boon to humanity could only reach you through vivisection.

2. Are you a meat-eater? If so, you live by the death of animals. You are a butcher as well as a vivisectionist. Is the nourishment of your individual body of more good to humanity than the progress of medical science? The animals you have butchered and vivisected for this purpose were not, as almost always in the laboratory, painlessly killed, but were either brutally pounded to death, or (lobsters, etc.) often ended their lives after long hours of atrocious torment for your palate's sake.

3. Do you not know that every line you write about the vivisection-controversy is loaded with error and falsehood—the often exposed charge of cruelty and pain? The fact is that pain would destroy the value of nine-tenths of all vivisection-experiments, even if the sympathy of the experimenter were not active to prevent it.

4. Do you not know that such rabid and ill-informed faddists as you and Mrs. White are the greatest provokers of cruelty to animals? You disgust people with a movement they would otherwise aid, and you make everyone with a grain of sense or indignation wish to kick all dogs and horses for having such "defenders" and "friends" as your illogical and foolish selves. Luckily we have pity despite you, and are not haters of all womankind because of one virago.

Sincerely yours, George M. Gould.

Philadelphia, September, 1895.

It is, perhaps, only fair to give our readers both sides of a question, and we honestly regret that our fervid correspondent should have displayed so much more heat than logic in the space at his disposal. We also regret his questionable allusions to a universally respected lady whose disinterested labors in a splendid cause have won an enviable fame.—*Life*, October 15, 1895.

A COMBINATION OF SCIENCE AND SUPERSTITION.

There is now a Chinaman practising in Los Angeles, Cal., who is well versed in medicine, having been a student of the English Mission Medical School. The man first studied a Chinese translation of *Gray* by Dr. Dudley and the translations of *Bartholow's Practice*, and other medical works by Dr. J. G. Kerr. He is a very bright fellow and an observing student. Being of a business turn of mind and learning of the insatiable appetite for occultism and for the marvellous that existed in the United States, he studied English systematically and emigrated to America to fill a long-felt want. Were he to practise Western medicine in an open manner he would find a great practice among his own countrymen who invariably prefer intelligent medicine; but Americans pay far better, so he assumes to practise Oriental medicine and carefully keeps in the unseen background both his knowledge of medicine and of English. Were it known that he practises intelligently he would soon lose all of his American *clientèle*. This man certainly practises under many advantages, as he brings to his aid all that scientific knowledge or skill can give, supplemented by all the psychological influence that the mind and imagination through suggestion can exercise over the individual. He has here a great advantage over his Chinese brother-practitioner of Chinese medicine who is completely at sea as to scientific medicine, or over his American fellow-practitioner who can neither impress nor mystify the imagination of his patient. Like his Parisian *confrère* with the astrolobe, magic mirror, and of occult and mystic surroundings, he can perform cures or miracles which are not given to be performed by either ignorant pretenders or by educated men. To admit that this combination is right and proper or necessary, as some might conclude, is to admit that our masses have not risen above the level of the general human understanding of the masses of the sixteenth century, when magic of all sorts formed the basis of medical practice, and when demoniacal possessions were common beliefs both in the practice of medicine and in the exercise of the theology of the times.—*The National Popular Review.*

A DEATH-PREVENTING INVENTION.

An ingenious and investigating genius, named Auguste Theiss, has invented a machine through which life may be prolonged indefinitely—at least this is the modest claim of the inventor, as original in his conceptions as the San Diego physician, who, in the *American Gynecological and Obstetrical Journal* for April, 1895, claims to have "discovered *a primipara, eighty years of age;* discovered accidentally while endeavoring to pass a catheter," in a case of misplaced urethra—and which he is attempting to bring to governmental notice. The authorities of New York State have been besieged by this philanthropist, but it would seem that so far he has been unable to secure an investigation of his machine, or even an interview with the Governor, and he has solemnly notified Governor Morton that he will hold him accountable for all the deaths occurring in New York State for the coming year. The machine has not been seen nor its details made public, but the inventor has allowed it to be known that the principle upon which it operates depends upon the retention in the body of a proper degree of animal heat.—*The National Popular Review.*

SPECIAL ARTICLE.

LUDWIG AND THIERSCH.

At the beginning of the last semester, within one week, the medical faculty of the University of Leipzig was deprived by death of two of its oldest and most eminent members.

The names of Ludwig and Thiersch stand out prominently in the short list of illustrious men, who, during the last fifty years, have earned for themselves the honor of having inaugurated a new era in scientific medicine. Though each worked in a special field, both have opened up entirely new channels of investigation in which, through long lives of unwearied activity, they have been able not only to make fundamental observations and discoveries themselves, but also by virtue of their personalities to establish schools and to stimulate younger minds to undertake researches and to attempt

the solution of problems first rendered accessible by their pioneer work.

While everyone is compelled to admire the many-sided talent of the surgeon and pathologist, the intellectual superiority of the great physiologist, regarded at least from a scientific standpoint, will generally be admitted. Ludwig was one of those phenomenal personages who at rare intervals in the history of science stand out head and shoulders above their contemporaries, possessing a clearness and wideness of vision that to ordinary mortals seems incomprehensible—almost abnormal. Though the search-light of his energies was turned in the most varied directions, the results attained by him in any one would have sufficed by themselves to rank him as a genius in the scientific world. The discoveries he made were by no means accidental; the new facts that he brought to light were always the result of some well-planned research in which the end was often seen even before the work began. There is scarcely any department in the broad field of physiology in which our views have not been extended, improved, or entirely reshaped by Ludwig and his pupils, and several doctrines that owe their origin to his early work have remained unchanged and are practically the same as when formulated by him thirty years ago.

Carl Friedrich Wilhelm Ludwig was born at Witzenhausen, December 29, 1816. After studying in Marburg and Erlangen, in 1839 he took his doctor's degree at the former university, where two years later he was appointed second prosector in the anatomic institute. In 1842 he received the *venia legendi* for physiology, his thesis being entitled "Contributions to the Doctrine of the Mechanism of the Secretion of the Urine" (Beiträge zur Lehre vom Mechanismus der Harnsecretion). In this monograph he put forward a physical theory of excretion, based upon anatomic investigation, a subject that occupied his attention later on at intervals for many years afterward. In his earlier studies he had familiarized himself with the physical conditions regulating the endosmosis of fluids through animal tissues, and this knowledge he now utilized in order to elucidate the hitherto puzzling phenomena connected with the activity of the kidneys. In 1849 he accepted the Chair of Anatomy and Physiology at the University of Zurich, the years spent there proving particularly fruitful. One can heartily sympathize with Gaule, who, when writing of the period from 1849 to 1855, during which the secretory function of the nerves was discovered and the foundations for the doctrines of the interchange of gases during respiration, and of the movements of the lymph were laid, openly declares his envy of Ludwig's companions at that time, whenever they spoke of his energy and single-heartedness in discussing his experiments, theories, and plans.

In 1855 he was appointed Professor of Physiology and Zoology at the Medical Military Academy (the Josephinum) in Vienna. Ten years later he succeeded Ernst Heinrich Weber as Professor of Physiology at the University of Leipzig, where he continued to work and to teach till within two months of his death. His great friend, Helmholtz, preceded him only by a few months. Last year Ludwig, writing to Gaule in Zurich, had spoken of him as follows: "Helmholtz recovers only slowly from his attack. I hope at all events that he may not suffer; the sudden death which befell Hoffman is a good fortune granted, alas, to few."[1]

The good fortune of which he spoke was not destined to fall to Ludwig's share; the severe attack of influenza from which he suffered weakened and rendered him prostrate for several weeks before his death.

No biography of Ludwig, however brief, could be satisfactory unless some mention were made, not only of his personal work, but also of that of certain of his friends and contemporaries and of their immediate followers.

Quite early in his youth, Ludwig had become firmly established in most of the fundamental principles that must be recognized as underlying all his subsequent work. For a century before his time the theory of the so-called "vital force" had been brought forward to explain those phenomena connected with the animal body, to deal with which chemistry and physics had seemed to be powerless. *Vitalismus* was an officially recognized dogma, almost too sacred to be attacked with impunity. Ludwig and his three friends—Helmholtz, Ernst Brücke, and E. du Bois Reymond—were firmly convinced that the processes taking place in living organisms conformed like all others to definite physical and chemic laws, and were not to be attributed to some mystic and indefinite vital force into the nature and workings of which it was sacrilegious to inquire. They not only had the courage to make public their opinions, but they also set to work to prove the truth of their beliefs. The early investigations of Ludwig concerning the mechanics of the urinary secretion, to which reference has been already made, represent one of the first and most important blows to the doctrines of the "vitalists." Looking back upon the achievements of these four scientists, each working by his own method and at his particular research, but all engaged with allied problems, one cannot but admire the genius, daring, and indefatigable industry of this circle of friends. Blow after blow was struck at the vitalistic theory; rampart after rampart fell, until finally the old dogmatic view appeared to be entirely demolished. Students flocked to join the successful contestants, each bringing his own contribution to the work, until one of Ludwig's students, speaking of the triumph, was able to write, "So complete has been the victory and so thoroughly has the new doctrine entered into the flesh and blood of the younger generation that nowadays when here and there a vitalistic idea is advanced its proposal is looked upon almost as something new."

These doctrines are universally accepted by the physiologists of to-day, and while it is not surprising that they should not, in so short a time, have had their full effect in other than medical circles, it must be admitted that the influence exerted by them upon the development of modern thought has already been profound. Nevertheless, it is still true that the struggle for emancipation from the obstructing Vitalismus, though practically over as far as most physiologic processes are concerned, is by no means ended in certain special domains, a fact which neuro-physiologists and psychologists realize only too well.

[1] "Helmholtz erholt sich von dem Anfall nur langsam. Möchte er nur nicht leiden; freilich so viel Glück wie von Hoffmann durch den raschen Tod verfuhr ist nur wenigen beschieden."

Of those generally recognized as great men, some have gained their greatest renown as investigators; others have been most successful as teachers; not all have possessed an admirable personality. Ludwig was a great investigator, perhaps greater as a teacher; while as a man he was a wonder and a surprise to all who came in contact with him. The researches carried to a successful termination by himself or under his direction are far too numerous to permit of even a short reference to each one here. The subjects they deal with are most diverse, and include many of the most important contributions to general and special physiology, physiologic chemistry, and microscopic anatomy of the past fifty years. The literature is for the most part accessible, a large proportion of the articles having been published in the *Zeitschrift für rationelle Medicin*, *Wiener Sitzungsberichte*, and *Arbeiten aus dem physiologischen Institut zu Leipzig*.

If a man of such wide interests can be said to have had a hobby, it was the study of the circulation. In it he found manifold opportunities for his exact methods of measurement, and particularly for the transference of the laws of hydrodynamics. It was his delight to take a firm hold of things, to grasp something tangible, and where for others rough estimations might suffice, for him weights, linear measures, measures of capacity, curves, and written records were an absolute necessity.

His epoch-making invention of the kymograph in 1847, to which the sphymograph owes its origin, really makes him the father of the so-called graphic methods of investigation, by means of which not only the physiologist and experimental pathologist, but also the clinician, is enabled to follow and accurately record many of the processes that go on in the living organism. The blood-pressure and the velocity of the blood-current were measured, and the effects of internal and external influences upon the blood-pressure and the pulse-frequency could now for the first time be satisfactorily studied. In 1864, in conjunction with Thiry, he published his important monograph, "Concerning the Influence of the Cervical Spinal Cord upon the Circulation," in which it was proved that the pressure in the arterial system could be regulated through the varying distention of the vessels of the portal circulation.

In 1873 Dittmar, under Ludwig's direction, determined approximately the site of the vasomotor center in the medulla, and at the latter's suggestion Mosso, in the following year, registered the independent movements of the peripheral bloodvessels in the kidney. As a result of this research were developed later the beautiful plethysmographic methods, by means of which Mosso and others have been able to make important contributions, many of which have an interesting psychologic bearing. As early as 1866 Ludwig, with E. Cyon, had demonstrated a sensory nerve—the depressor nerve—connecting the heart with the medulla, which, when stimulated, could perceptibly lower the tonus of the vasomotor centers, and through which "the essential motor of the circulation—the heart—is able to regulate the resistance which it has itself to overcome." This monograph excited much comment and admiration, and was crowned by the Paris Academy.

In 1871 Bowditch proved, so far at least as the frog's heart is concerned, that any stimulus, no matter of what strength, so long as it is as high as the minimal, would call forth a maximal contraction. Luciani, in 1872, introduced a method by which the "over-living" organ artificially nourished could be studied for a long time after being separated from the rest of the body. With the important results, especially with regard to the relations of the tissues to the blood and lymph, which this method has yielded when applied to other organs, muscle, kidney, liver, intestine, etc., everyone is now familiar. The fruitful researches of von Frey and Krehl upon the pulse are so well known that they need hardly be mentioned here. The investigations made by Ludwig and his students concerning the gases of the blood and the relations of the individual tissues to the general gaseous interchange are full of interest. Quite recently (1894) one of his students, Franz Tanzl, published the results of a research which, along with other things, proved that the ligation of the intestinal arteries can diminish the respiratory gas-interchange by over 30 per cent.

In enumerating the points bearing on the circulation ordinarily demonstrated by experiment in our best schools in a course of practical physiology, one cannot help being struck with the fact that almost everyone is included in the researches to which we have referred. A perusal of the work of Tigerstedt, a former pupil of Ludwig, on the circulation will give an excellent idea of the scope of the work done by the master and his followers in this field.

Almost as astonishing as his brilliant discoveries regarding the circulation and respiration were the results attained by him when he directed his attention to the subject of glandular secretion. His publication in 1851 concerning the relation of the nerves to the secretion of the saliva furnished an entirely new standpoint from which glandular activities could be studied. With the aid of his students he established the fact that the salivary glands can actively secrete quite independently of the height of the blood-pressure. Of his studies and those of his students upon the gastric and intestinal digestion and the secretion of the bile, it will suffice here to say that a great part of what stands in the modern text-books of physiology concerning these points has emanated from the Physiological Laboratory of Leipzig. In addition to his own early work upon the excretion of the urine he directed several important investigations upon this subject in his laboratory. Among these may be mentioned the researches of Ustimowitsch, and later those of Slosse, upon the effect of ligation of the mesenteric arteries on urinary secretion, and that of Grigus, in 1893, which proved that the heat-production in the kidneys was directly proportionate to the amount of urine excreted.

The Ludwig school has also made contributions of the highest order to the physiology of muscle and nerve. Ludwig himself, however, as it would appear, was especially interested in the effects of muscular movements upon the circulation and respiration. Lauder Brunton, in an address delivered in London, in September, 1894, which dealt more especially with this subject, referred in a most touching manner to the work and character of his former teacher. Ludwig further directed his acute powers of observation and his exact methods to the subject of the various reflexes, and the immediate excitability of the gray matter of the spinal cord by mechanical irritants was proved by his pupils. The sensory

nerves, both general and special, have been submitted to frequent studies in his laboratory. Of these the recent investigations of von Frey concerning the sensations of touch, pain, and temperature, an epitome of which will be subsequently published in THE MEDICAL NEWS, are especially worthy of mention.

In the allied field of physiologic chemistry—a favorite "hunting-ground" of the master—we find between the years of 1856 and 1894 a whole host of publications, many of which contain the results of researches of fundamental significance. The work of the Ludwig school, both in its exactness of method and in the practicability of its results, would even by itself be sufficient, notwithstanding the occasional criticism of the so-called "pure chemist," to refute the charge that "all physiologic chemistry is mere dilettantism." In 1856 the occurrence of inosite and of uric acid in the animal body was determined by one of Ludwig's pupils. In 1871, by means of newly devised methods, the lime and phosphoric acid in the blood were quantitatively determined. In 1874 he directed a research concerning the constitution of the fats which enter into the blood from the alimentary canal, and in 1876 himself investigated the flow of fats through the thoracic duct while the subject was upon a fatty diet. The absorption of acid fats by ways other than the thoracic duct formed the subject of a special research, the results of which were published in 1891, while in 1894 the splitting up of fatty acids, independently of ferments, was experimented with.

In looking over the list of publications from Ludwig's laboratory it will be noticed that the chemistry of the liver was not forgotten. Thus, in 1887, we find an article on "The Origin of Lactic Acid from the Over-living Liver," and in 1890 one entitled "The Impoverishment in Glycogen of the Anemic Liver." Among so very many important publications—for no article published with his sanction can be called unimportant—it seems almost invidious to single out any particular one. But the work of Scheremetjewski in 1868, and that of Harley in 1893, on the decomposition of easily oxidizable substances in the blood must be mentioned. The results of Mall's work upon the chemistry of the connective tissues, with particular reference to the reticulum, have already passed into the text-books. Comparatively recently Siegfried has separated an important constituent from muscle, and his *Fleischsäure* promises to be of more than ordinary interest to physiologic chemists and physiologists. The fate of the products of proteid digestion, during and after absorption, was a task assigned to Schmidt-Mühlbein and to Salvioli. Fano in 1881 studied the remarkable effects of peptone upon the blood and lymph, and some of the best work of the talented but ill-fated young English physiologist, Wooldridge, was done in Ludwig's laboratory and under his direction.

But even in the briefest summary it would be an injustice to omit altogether his researches in yet another branch—the department of anatomy—a subject for the problems of which Ludwig always retained the highest reverence. As a physiologist he never forgot that his branch was an offshoot of anatomy, and he recognized the fact that without the anatomic basis and the possibility of applying to it physics and chemistry there could be no physiology. On undertaking his work at Leipzig and in organizing a physiologic institute he expressly stipulated for the establishment of three distinct departments—one for minute anatomy, a second for physics, and a third for chemistry. In this way arose the histologic department of the Physiologic Institute of Leipzig, with which Schweigger-Seidel, Schwalbe, Flechsig, and Gaule were connected. It was here, under the influence of Ludwig, that these men received the precise and methodic training which, together with the spirit inspired by their master, led in great part to the fruitful results that have characterized their labors.

Even in the later years of his life Ludwig kept fully abreast with the advanced researches in the histology of the various organs of the body. Only a short time before his death he was at work upon a model in which were represented the latest investigations concerning the structure of the cerebellum as brought out by the silver-method. His library was rich in anatomic monographs, and those who worked with him were often astonished at his familiarity not only with the titles and dates of articles on histologic subjects, but also with the minute details contained in them. He regarded each of the various organs as a delicate mechanism, the structure of which must be thoroughly known before a perfect understanding of its functions could be reached. It was his special delight to start with a recent microscopic finding and ferret out for it a physiologic explanation. Quite early in his career he made valuable contributions to our knowledge of the nervous structures contained in the septum of the frog's heart, and in his laboratory at Zürich the work of Peyer on the brachial plexus and that of Rahn on the secretory nerves were noteworthy. In Vienna, in conjunction with Tomsa, Leber, and McGillavry, he began to investigate the finer distribution of the bloodvessels and lymphatics, and ever afterward during his lifetime he had some one or other of his students busily engaged in this field. It was his aim to find if possible in every organ what he was accustomed to speak of as the "vascular unit," and to compare this in glandular structures with the "secretory unit." The structure of the kidney, the liver, the salivary glands, the intestine, the pancreas, the skin, and of voluntary and involuntary muscles, as well as of different parts of the central nervous system, were thoroughly explored. The bloodvessels and lymphatics of the muscles, of the skin, and of the larynx were exhaustively worked out. Similar studies for the eye had been made by Leber in 1865, and for the ear by Prussak in 1868, and again by Eichler in 1893. Under Ludwig's direction Mall completed his studies on the blood-supply and the general structure of the intestine of the dog. Giannuzzi, von Fleischl, von Mihalkovics, von Asp, Stirling, Gaskell, Spiess, Hesse, Altmann, Spalteholz, Fischer, and Fick are among those who worked at minute anatomy at Leipzig at his suggestion. His anatomic colleagues at various times, Professors His, Meyer, and Braune, were always glad to acknowledge the profit as well as the pleasure of intercourse with him.

Ludwig possessed in a high degree the rare power of successfully utilizing men and materials. He seems to have always known how to employ to the best advantage the knowledge possessed by the men who came to work with him. It is sometimes the case in laboratory-experience that a subject with which the director is imperfectly acquainted is best kept in the background. Not so with Ludwig. He hailed with pleasure the advent of a man trained in special methods, physical or

chemic, with which he himself had had little or no experience. By these means he often gained an opportunity of solving a problem that had long puzzled him.

But it was in his capacity as a teacher that his powers showed themselves at their best. In his ability to attract and to retain around him the picked men, and to call forth from brain and hand the very best work of which they were capable, Ludwig stood second to none. Ever painstaking in the teaching of his ordinary students, with whom he was always a favorite, he reserved his main energies for more advanced students, and found his chief delight in training the men who, having finished their preliminary studies, or already holding teaching-positions elsewhere, came to him to be taught how to investigate, how to undertake and to carry out research-work. Among these, who numbered in all more than 300, are to be found the names of many of the leading physiologists of Russia, Germany, England, America, Austria, Italy, Sweden, Denmark, Switzerland—in short, of the civilized countries of the world. It is stated that up to within a few years ago all the professors of physiology in Russia, and many of the clinicians of that country, had been trained in his institute.

Ludwig's knowledge was so broad, his interests so many-sided, and his personality so charming that naturalists of the most varied nationalities and specialties were anxious to have him as a guide, and proud to proclaim him as their master. His laboratory was the home of an international circle, and even in troublous times his magic influence was sufficient to maintain among all the friendliest relations.

The willingness of Ludwig to sacrifice himself for his pupils and to hide his own personality behind that of his pupil affords an example of abnegation seldom, if ever, paralleled in the history of science. He is a great man who can make clever men willing to direct all their energies to the working out of his ideas. He is a greater man who gives them all the credit of the results obtained. When we think of Ludwig, not only when his reputation was made, but even when he was a comparatively unknown man, leaving his own particular work to assist a pupil in solving a problem, of which the idea was his own, sometimes even writing the article for publication without sharing any part in the title, we encounter a generosity, an absolute unselfishness which, in these days and judged by what we call high standards, seems almost more than human. It has been suggested by Gaule that if one sought to find fault with him it would be that sometimes he devoted too much of his own strength to the service of others, and thus brought credit and renown to quarters where it was not fully deserved.

In his intercourse with his students he knew how to gain not only their respect, but, what is often far more difficult, their love. A well-known American anatomist, from whom much of the information contained in this sketch was derived, spoke more especially of the generous sympathy which he showed toward strangers, whether his own countrymen or foreigners, who came to work in his laboratory. Even the most timid student soon felt at ease in his presence, and it was characteristic of him that he welcomed in his working-room and was willing to devote his time to a newly fledged graduate, provided only that he was an earnest worker and was willing to learn. It was Ludwig's custom to let fall ideas so gradually and so casually, if one may say so, in the course of conservation that it often became difficult for the student when he had grown with them to recognize them as those of his master rather than as having been evolved by himself.

The same extreme delicacy of sensibility, of which his sympathetic manner was an outcome, also rendered him extraordinarily quick in reading the characters and aims of others. With him, the words of Goethe, *Vor den Wissenden sich stellen, sicher ist's in allen Fällen*, had a peculiar aptness. A student could not be long with him without exposing to his master's view his real qualifications and his ideals. He was an enemy to any secrecy connected with a research. It was not Ludwig's custom to take a number of new pupils at one time; in fact, he preferred to have only one beginning investigator in order that he might be with him and launch him safely upon the sea of independent research.

Professor His, who, through the deaths of Ludwig and Thiersch, is left the senior member of the medical faculty, in his eloquent panegyric said of Ludwig: "He gave to his students the highest gift vouchsafed to a teacher to impart, the power of investigating by themselves." His acquaintance with the development of modern physiologic thought, his own bitter experiences in the long struggle against dogmatism for freedom of thought and speech, his keen appreciation of the limits of knowledge, his recognition of what for technical reasons for the moment must be unknowable, all these were among the factors, which, together with his far-reaching knowledge of men and things, rendered him eminently fit to be the guide and instructor of the young naturalist.

The courage and enthusiasm with which Ludwig, even at an advanced age, attacked the most difficult problem provoked the admiration of all who knew him, and with this hope, this belief of being really able to do something worth while, he never failed to imbue his co-workers.

One of them, in a recent eulogy, tells an interesting anecdote in this connection, which is quite worthy of repetition here. A well-known investigator, who had himself grown old, once asked him: "Have you then actually the hope that physiology will eventually attain the end at which it is aiming?" and on receiving to his surprise an answer in the affirmative, immediately said: "Ah! you must be one of Ludwig's men." ("Freilich Sie kommen von Ludwig.")

Ludwig during his lifetime had seen medical ideas completely revolutionized, and, in fact, had himself played no small part in this revolution. He had seen the brilliant discoveries in electricity which have been evolved in the past fifty years. "Why then," he asked himself, "should not the next half-century achieve in the explanation of the cell as much as the last has done in the elucidation of the organs?" And so he went on day by day in his laboratory, ever hopeful himself, cheering the discouraged, repressing gently the overelation of the too zealous, above all setting to those around him the best of examples.

It is to be hoped that ere long a competent biographer will be found among those who knew Ludwig best to give to the world a full account of this brilliant and useful life. It is difficult to imagine a subject which

could be made to give more entertaining or inspiriting reading. Kronecker, in his eulogy, especially dwells upon the fact that pathology and internal medicine always found in Ludwig a very warm friend and supporter. He looked upon every case of disease as a physiologic experiment, which was all the more interesting in that, as a rule, it could not be produced artificially, and, *vice versâ*, he regarded every physiologic experiment as an artificially produced disease, which since, as regards cause and effect, it can be better understood than the natural disease, must be for the pathologist of the highest significance. He understood that the aims of pathology are closely allied to those of physiology, and that while the former would restore the diseased organ to a healthy condition, the latter seeks to perfect and multiply the functions of the sound organ. Thus he regarded pathology as inseparately linked to physiologic experiment, and physiology in turn to clinical observation.

While devoting his life in the main to physiology and its problems, he was in the widest sense a man of liberal culture, and rejoiced that physiology had been able to make no mean contributions to music, painting, philology, and, not least of all, to psychology. In Leipzig, where he spent the last thirty years of his life, he was widely known and loved outside of scientific circles, and on the fiftieth anniversary of his doctorate he was granted "the freedom of the city" (Ehrenbürgerrecht).

Two friends with whom Ludwig lived in the most intimate relations were the painter Knaus and the writer Gustav Freytag. The latter, speaking in 1887, said: "If I have learned to think highly of German character, to despise dissimulation, to prize a love for and a confidence in humanity, I have been much helped in it by my two trusty friends, Ludwig and Wachsmuth,[1] for widely separated as are their occupations, both practise in them the same code. The great scientist, who for the success of his students makes his knowledge and his powers serviceable, with a self-sacrifice unexampled even among us, and the unselfish leader of great enterprises, the man whom many make their confidant and counsellor, the pride and favorite of his fellow-citizens, both men live in the same high-minded devotion to the welfare of others. They have often given courage to the heart of their friend, and through their lives have often corrected his judgment of others. The same holds true for the wives of these two men. Though neither Frau Ludwig nor Franziska Wachsmuth have ever been directly portrayed in any of my works, yet to the ideal type of the affectionate and brave German wife, who so often is pictured in my stories, both have without knowing it richly contributed."

It would seem as though destiny could not long keep apart these two friends, for only a few days after the death of Ludwig that of the great writer was announced.

Karl Thiersch was born in Munich in 1822. He came of a celebrated literary family, his father being Fried. Wilhelm Thiersch, who is so well-known in connection with the study of philology in Bavaria. Young Thiersch studied in Munich, Vienna, Berlin, and Paris, taking his doctor's degree in 1846 at the age of twenty-four. In 1850 he became assistant to the distinguished army-surgeon Stromeyer, and, having at his suggestion directed his attention to the study of pathologic anatomy, in 1854 he was appointed to the Professorship of Pathology in Erlangen. Thirteen years later he was elected to the Chair of Pathology at Leipzig. In 1870 he took an active part in connection with the Franco-Prussian war as consulting *Generalarzt* of the 12th Army Corps.

If Thiersch as a scientist was not so creative as Ludwig, he was not lacking in independence of thought, and the extent of his mental grasp is well shown by the diversity of his investigations. As has been the custom among surgeons in England and also to a certain extent on the continent, Thiersch, like Billroth and Langenbeck, spent a long period in pathologic studies before giving himself up entirely to surgery. Of his earlier works, that on pyemia, the result of investigations made while prosector at the city hospital in Munich, is one of the most important and sheds new light upon the nature of septic processes. His best known pathologic research, and that which will probably be longest remembered, dealt with the microscopic structure of carcinoma. He made a most painstaking study of epithelioma, and demonstrated its constant epithelial origin. He opposed the doctrine of Virchow that a carcinoma could arise from connective tissue, and proved synchronously with Waldeyer, then working in Breslau, that a genuine primary carcinoma never developed except in situations in which epithelial cells are normally present.

His three greatest contributions to surgery proper were: (1) His investigations concerning the healing of wounds; (2) the operation of skin-grafting; and (3) the introduction of aseptic surgery into Germany. He devised numerous new operations and improved many of the older ones, particularly in the domain of abdominal surgery. The use of the solution containing salicylic acid as an irrigating fluid first suggested by him became widely known and was formerly much used in America. To Thiersch is also due the credit of being one of the first to recognize the advantage of the pavilion-hospital which had developed during the Civil War in the United States. It was mainly due to his influence that the large hospital in Leipzig was remodelled after this plan, and Thiersch, in talking to his students, was always wont to emphasize and to beg them never to forget that fresh air and sunshine were necessary adjuvants in the successful treatment of surgical cases. With his surgical colleagues he was always a favorite. He was chosen President of the *Deutsche Gesellschaft für Chirurgie*, and was recently elected Ehrenmitglied, an honor which has been bestowed upon only a few, and those the most distinguished men in Germany. His patients loved him, and it is said of him that even as a surgeon the children never feared him.

Like Billroth and Richard von Volkmann, Thiersch occupied his leisure hours with the study of art and literature, for which he had a marked and perhaps an hereditary predilection. He has more than once appeared in the rôle of literary historian, for example, as interpreter of Shakespeare's heroes.

His pleasing personality and sparkling humor, together with his origin and high culture, assured him the friendship of those in high places in the land. King Albert of Saxony numbered him among his personal friends, and as his body was borne to the grave, with an accompaniment of military honors seldom wit-

[1] Director of the Creditanstalt.

nessed in Leipzig, among the massive floral decorations could be seen a huge laurel wreath interwoven with white azaleas and bearing the crown and initials of the king.

That the death of these two giants among men has been keenly felt throughout the civilized world is evidenced by the numerous addresses that have been delivered and the articles that have appeared in so many widely separated countries. Nevertheless, however paradoxic it may appear, the loss is by no means an irreparable one. Each lived to accomplish more than is generally permitted to a single individual. Both laid the foundations of structures on which future generations can safely build. Both have gone to their well-earned rest, full of years and honors. But their works survive them, and perhaps no more fitting epitaph for them could be found than that of Sir Christopher Wren, in St. Paul's Cathedral, "Si monumentum queris, circumspice." L. F. B.

SOCIETY PROCEEDINGS.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-third Annual Meeting, held in Denver, Col., October 1, 2, 3, and 4, 1895.

(Continued from page 419.)

THIRD DAY—OCTOBER 3RD.

DR. W. P. MUNN, of Denver, read a paper entitled

NATIONAL LEGISLATION FOR THE CARE OF PUBLIC HEALTH.

He declared that the failure of Congress to support a National Board of Health was a source of deep regret to the working sanitarians of the whole country. For years the medical profession had asked Congress to establish a department of public health, which shall give human beings as much attention, at least, as is bestowed upon animals. Dr. Munn's proposed law has been cast in definite form, and reads: "An act to establish laboratories of hygiene in connection with State boards of health, existing by law in several States." The drafted bill cites the object and duty of the projected laboratories to be the conducting of original researches or the verifying of experiments upon human diseases, and methods of prevention; upon the advantage of residence in certain localities under particular climatic conditions; as to the effect upon the health of soil, atmosphere, altitude, occupation, food, drink, clothing, and dwelling-places. In this connection it should be the duty of the Supervising Surgeon-General of the Marine-Hospital Service to furnish forms for the recording of the results of all investigations, and the duty of the laboratory to make the Governor of the State in which it is located a detailed report of its operations, and that copies be forwarded to the Marine-Hospital Service and the Secretary of the Treasury. Bulletins should be published every six months to be transmitted in the mails of the United States free of charge.

The proposition is to establish in each State and Territory, in connection with the State boards of health, a State laboratory of hygiene, to be supported by an annual appropriation from the government. This plan is similar to the agricultural experiment-stations in connection with the various agricultural colleges of the different States. The paper suggests that in States having no State boards the congressional appropriation would be stimulating in that State boards might be placed in existence, and finally that $15,000 per annum be appropriated by the national government to each State.

Many advantages would accrue to sanitary science from the co-operation of laboratories working by co-ordinated methods upon similar problems.

DISPOSAL OF THE DEAD.

The Committee on the Disposal of the Dead made a report through its chairman, Dr. C. O. Probst, of Columbus, Ohio, detailing the order of the building of all crematories and the number of dead bodies consumed to within recent date:

		Bodies.
Washington, Pa.,	1884	89
Fresh Pond, N. Y.	1885	1554
Buffalo	1885	250
Pittsburg	1886	100
Cincinnati	1887	314
Detroit	1887	183
Los Angeles	1887	182
St. Louis	1888	437
Philadelphia	1888	399
Baltimore	1889	84
Swinburne Is., N. Y.		109
Troy	1890	56
Waterville, N. Y.	1891	5
Davenport, Ia.	1891	86
San Francisco	1883	200
Chicago	1893	87
Boston	1893	118
San Francisco	1895	28

There has been a total of 4281 bodies consumed since the foundation of the first crematory, of which 2783 were males and 1498 females. The cost of burial is usually $25, though in San Francisco $60 is charged. The only States in which there are laws governing cremation are Massachusetts, Michigan, Pennsylvania, and Ohio. Dr. Probst said that the only objection that had been advanced against cremation was a legal one, claiming that this method destroyed the evidences of crime, while on the other hand it killed all germs of contagion.

DR. G. T. SWARTZ, of Providence, R. I., contributed a paper entitled

BACTERIOLOGIC RESULTS FROM MECHANICAL FILTRATION.

He related in detail the results of a series of experiments conducted by the city of Providence, which proved conclusively that mechanical filtration to remove bacteria from water was possible, and that it had been successfully done in the experiments referred to.

A paper on the

MEDICAL INSPECTION OF SCHOOLS

was read by DR. S. H. DURGIN, of Boston, who last year introduced the system of medical inspection of the schools in Boston. He gave the results of a four-months' trial of the plan, showing that it was actually a necessity in the schools if the health of the pupils was to be protected. The figures given showed that over 1000 cases of infectious diseases were detected in time to prevent a spread of the contagion.

DR. A. W. SUITER, of Herkimer, N. Y., followed with a contribution entitled

DISPOSAL OF THE DEAD, WITH ESPECIAL REFERENCE TO THE PREVALENT PRACTICE OF EMBALMING,

in which he called attention to the fact that the embalming methods of to-day were not successful, and only resulted in filling the body with poisons which eventually contaminated the soil and streams of the cemeteries. For example, a recent examination of the waters of Scajaquada Creek, which flows through Forest Lawn Cemetery, Buffalo, showed that they were impregnated with considerable quantities of arsenic of the kind used in the prevalent method of embalming. A law to regulate embalming was considered imperative.

DR. S. E. SOLLY, of Colorado Springs, read a paper entitled

INFLUENCES PECULIAR TO HIGH ALTITUDES UPON SANITARY CONDITIONS.

He argued that the special effects of altitude are directly produced neither by reduced pressure of the atmosphere nor by a reduced amount of oxygen affecting the lungs and heart, but by the amount of oxygen-pressure. When air is inhaled into the lungs a certain proportion of the total amount of oxygen contained in the air is absorbed by the hemoglobin. The endeavor was made to show that the peculiar effects of high climates are to increase the number of red blood-corpuscles and the amount of hemoglobin and the power of blood-absorption. The chest-expansion is also increased, the latter being admitted by all observers, who have remarked frequently upon the almost emphysematous character of the breathing, especially at the apices of the lungs of the native-born children and old residents.

As to the effect of altitude upon disease, it is found that better results are obtained in high than in low climates upon all diseases where anemia is the most important factor in the disease, and also in chronic germ-diseases, such as tuberculosis, provided, of course, that in either case some of the conditions do not exist.

DR. FELIX FORMENTO, of New Orleans, Chairman, read the report of the Committee on the

ABUSE OF ALCOHOL FROM A SANITARY STANDPOINT.

The ground was taken that alcoholism does not apply to taking a glass of pure wine at meals, or a glass of pure whisky. Alcoholism was defined as meaning the chronic excessive use of alcoholic drinks. The habitual use of strong liquors cannot be too strongly condemned. The report showed the difference between the effects of pure and impure liquors on the system. Good wine cheers and strengthens, but does not inebriate. Alcoholism is one of the potent factors in crime, suicide, and poverty. It peoples our hospitals; it is responsible for cripples, epileptics, and, while it exists mostly among the poorer classes, the wealthy and intellectual do not escape.

DR. CHARLES DENISON, of Denver, read a paper on

DEGENERATIVE HEREDITY, OR SOME DEGENERATIVE INFLUENCES OF MODERN CIVILIZATION UPON HEALTH.

He discussed the subject under five propositions, as follows:

1. Life-saving and life-prolonging means tend to suspend the law of natural selection.

2. Extremely intellectual and nervous lives propagate physically defective offspring.

3. Confined occupation, hindering development, leads to physical degeneracy in subsequent generations.

4. The growing independence of women, involving the withdrawal of desirable women from motherhood, tends to cripple the race.

5. The young must be forewarned, the people physiologically enlightened, and the State has a duty to perform.

FOURTH DAY—OCTOBER 4TH.

DR. MANUEL CARMONA Y VALLE, of Mexico City, Mexico, read a paper on the

PROPHYLAXIS OF YELLOW FEVER.

He said that in 1882 he began subcutaneous injections of urine into the cellular tissues of the back part of the arms of those afflicted with this malady. He found that he could vaccinate, so to speak, a sound person with the fluid from a patient who had had the fever for four or more days, and that those submitted to this process were immune from any further danger of contagion. He has made 1358 inoculations, and there has never followed any other consequence than the formation of a single abscess at the site of injection. This method has been used successfully in Panama by Dr. Garcia del Tornel. From 1882 to 1883, while first experimenting, 208 persons were treated, and a relative of the author, employed in the Custom House, although attacked, was not compelled to go to bed. Surgeon-General George M. Sternberg, of the United States Army, who has been in correspondence with the author, proposes that the residuum of urine be obtained by the evaporation of the liquid in a vacuum. Dr. Bouchard, of Paris, has for some time been investigating the treatment, and reports successful results in his experiments on animals.

Before making an inoculation Dr. Carmona dissolves 5 centigrams of residuum in 1 gram of pure water, and injects with a Pravaz syrine.

DR. EDUARDO LICEAGA, of Mexico City, made a further contribution to the study of yellow fever in connection with its medical geography and prophylaxis in the Mexican Republic. He said there are only two points on the Atlantic Coast where yellow fever is epidemic, and none along the Pacific Coast—Vera Cruz and the district situated at the extreme northern point of the peninsula of Yucatan. It commenced last January with 9 cases, reaching its maximum in July, with 225 cases. In 1894 thorough measures were taken to disinfect fever-scourged districts.

Dr. Liceaga claims that the means of combating the disease must be sought in the inoculation of blood-serum from persons already attacked, or who have already suffered from the disease, or by inoculation of blood-serum from animals that have already acquired immunity.

A paper was read in Spanish by DR. JESUS E. MONJARAS, of San Luis Potosi, Mexico, on

THE NECESSITY FOR THE ESTABLISHMENT OF SANATORIA TO PREVENT CHLOROSIS AS THE BEST PROPHYLACTIC AGAINST PULMONARY TUBERCULOSIS IN PARTICULAR AND CONSTITUTIONAL DISEASES IN GENERAL.

Several papers were read by title and referred to the Publication Committee.

The following officers were elected:

President—Dr. Eduardo Liceaga, Mexico City, Mexico.

First Vice-President—Dr. A. A. Woodhull, Denver, Col.

Second Vice-President—Dr. Henry Sewall, Denver, Col.

Secretary—Dr. Irving A. Watson, Concord, N. H.

Treasurer—Dr. Henry T. Holton, Brattleboro, Vt.

The place of the next meeting will be Buffalo, N. Y.

REVIEWS.

Remote Consequences of Injuries of Nerves and their Treatment. An Examination of the Present Condition of Wounds Received in 1863-65, with Additional Illustrative Cases. By John K. Mitchell, M.D. Philadelphia: Lea Bros. & Co., 1895.

The volume before us is of peculiar interest because it deals not only with a certain class of injuries, but especially with the remote effects of these injuries. It is one of the misfortunes of hospital-practice that patients often remain under observation for an insufficient period of time. It can therefore readily be seen that observations embracing such an extended period as that from the late War up to the present time must possess a special value. The injuries dealt with range from mere contusions and commotions of nerves to nerve-section, neuritis, and spinal injuries.

Space forbids a detailed account of the subject-matter of the various chapters. Suffice it, however, to say that numerous interesting facts are presented, especially such as deal with the trophic changes following nerve-injuries, some of which, such as overgrowth of hair and nails, are somewhat unexpected. Other observations, for example those relating to persistent local elevation of temperature after nerve-injury, are very valuable. Some of the cases of spinal injury detailed are important, because some of the phenomena observed resemble those occurring in railway-spine or traumatic neuroses; thus hysteroid convulsive seizures occur closely resembling those occasionally observed in railway-cases. In the chapter upon ascending and migratory neuritis the author details a number of cases in which not only extensive spreading of inflammation along the nerve-trunks occurred, but also various trophic changes ensued. Regarding this form of neuritis, the author believes that the following inferences will be borne out by more extended observations:

1. Pressure, however brought about, whether by inflammatory exudate, external injury, by blow or weight, may be looked upon as a frequent factor, though not a constant one, in the production of spreading nerve-inflammation; but the presence of inflammation in the surrounding tissues, even in direct contact with the nerves, exerts, curiously, little bad influence.

2. The larger nerve-trunks are more prone to present the phenomena of spreading inflammation after injury than small ones.

3. Neuritis may spread either centrifugally or centripetally, the latter, in traumatic cases, being the much more common form.

In brief, this volume contains a large amount of very valuable information gathered at a great expenditure of time and industry upon the part of the author. We may safely predict that for many years to come it will constitute a source of reference for facts regarding the subject with which it deals.

Clinical Lectures on Diseases of the Nervous System. By W. R. Gowers, M.D., F.R.S. 12mo, pp. 279. Philadelphia: P. Blakiston, Son & Co., 1895. Price, $2.

This group of twenty post-graduate lectures, delivered at the National Hospital for the Paralyzed and Epileptic, deals with a number of interesting subjects in the attractive and lucid manner that characterizes all of the work of this distinguished author. The individual lectures have already been published in various medical journals, but Dr. Gowers has rendered the profession a service by collecting them into a single volume and presenting them in connected form. The following subjects have been considered: The Principles of Diagnosis of Diseases of the Nervous System, Mistaken Diagnosis, Argyria and Syphilis, Spastic Hemiplegia, Bulbar Paralysis, Facial Paralysis, Facial Contraction after Palsy, Acute Ascending Myelitis, Locomotor Ataxy, The Foot-clonus and its Meaning, Syringomyelia, The Treatment of Muscular Contraction, The Infantile Causes of Epilepsy, Neuralgia, Lead-palsy, Saturnine Tabes, and Optic Neuritis. The volume, as a whole, is characterized by Dr. Gowers' pleasantness of style, clearness and simplicity of expression, and wide range of acquaintance with all of the details of his subject, and takes a place alongside of other works by the same author. Dr. Gowers expresses the belief that the knee-jerk is never absent unless there is structural disease in muscle, nerve, or cord, or (rarely) within the skull, apparent absence in health being attributable to some defect in method. In the treatment of locomotor ataxy the first place is given to arsenic, and the second to aluminum in the form of the chlorid. In the treatment of neuralgia a combination of strychnin with cannabis indica or gelsemium and nitroglycerin is highly spoken of.

CORRESPONDENCE.

"AN ACT TO PROVIDE FOR THE MORE EFFECTUAL PROTECTION OF THE PUBLIC HEALTH."

To the Editor of The Medical News,

Sir: Justice and injustice, care and carelessness, studied forethought and equally studied disregard characterize the recent "Act to provide for the more effectual protection of the public health," etc.; copies of which have been recently sent by the Board of Health to all Philadelphia physicians.

By it a doctor cannot avoid acting as the agent of the board, even when he has done nothing to signify his willingness to assume responsibility. "Cases" brought to him or her for examination, even if treatment be refused, must be immediately reported, or the penalty incurred; and full particulars as to name, location, and disease must be given, "together with such other in-

formation relating thereto as may be deemed important by said health-authorities," and no man can foresee what they may deem important, and so this clause is open to many grave abuses.

SEC. 2. "They may at once place, or cause to be placed, in a conspicuous place or places . . . . a placard or placards." Evidently they are not obliged to do so, the "may" is permissive rather than mandatory; as and in lieu of the placard they may establish a quarantine "with guard or guards."

Now the cost of this protection falls all too heavily upon the poor man. His occupation is too often in his own dwelling; his small grocery, his cobbler's bench, his tailoring is ruined by the placard. Does he, as a jobbing mechanic, go out on calls for his services, he is shunned. The women of the houses are dressmakers and milliners, do sewing by hand or machine, or wash and iron; go out for daily work in families, and their means of obtaining a living are taken away, and often their whole run of business is fatally ruined. In the tenement-houses, filled with many separate families, one case of contagious disease, one small child in some remote, unvisited room, would suspend the avocations of all indefinitely. No wonder that with such legislation the poor dread the doctor as the entering wedge for the Board of Health, and that doctor becomes most popular with them who conceals his cases. Perhaps no scheme short of an order for the general slaughter of the infected family would so thoroughly defeat its own intention as this, coupled as it is with the indefinite power "to establish such rules and regulations regarding the destruction and disinfection of infected bedding, clothing, or other articles which have been exposed to infection" as may be necessary. For no compensation is given for such articles—the hardly earned and carefully guarded treasures of the poor household; and, again, as in the matter of placards, the poor pay too dearly, too exclusively for the so-eagerly sought general safety of the community. There is no crime in contracting disease, but misfortune more deadly than crime. Why should this loss fall upon one alone, which to the public is so great a gain? Every article destroyed should be paid for at a fair valuation; for every store closed there should be moderate compensation; for all enforced idleness from this cause half-wages; and, for the quarantined, rations which will prevent starvation.

Destruction and disinfection are words which have in times past too often conveyed to their victims one and the same meaning; and carpets, blankets, curtains, bedding, and household linen—the pride of the thrifty—have gone to disinfection "where the woodbine twineth." This, too, in the period when the disinfecting apparatus of the city was but an old iron pot in which to burn sulphur, or later a questionable oven at the smallpox hospital, where antagonistic bacteria had a struggle for supremacy, with the odds decidedly in favor of the unknown germ of variola.

SEC. 3. "The head of the family shall be liable for the fine or penalty in any case where such placard or placards are removed, defaced, covered up, taken down, or destroyed with his or her knowledge or consent," etc.

Evidently when the placard disappears, it will not be by orders of "him or her." Oh, no! The householder will rage and throw his or her religion to the winds, and flood the air with denunciations of the culprit, but the small boy will seize the golden moment when the "copper" is resting from his labors, and the beautiful, bright placard, yellow as a dandelion, will flaunt no more on the white front door or the garden-wall.

SEC. 4 provides kindly for the physical rest of the weary undertaker, except "between the hours of five ante-meridian and eleven post-meridian." When are those hours; for except in this definitely marked period he may rest in the bosom of his family; happy undertaker—would that beneficent legislators would do as much for us. At all other times, however, he must hurry up the funeral within thirty-six hours, unless, as in Sec. 5, "special permission be granted by the health-authorities extending the time during which said body may remain unburied, for special and satisfactory cause shown."

What special and satisfactory causes may often exist may be surmised when it is known that in that remote past, already alluded to, a physician who had given a certificate of death from diphtheria in a most aggravated and well-known case was visited by the health-officer in person, and implored by that high official to withdraw his certificate and substitute one of croup, in order that there might be a public funeral; for otherwise he "would lose many votes."

SEC. 6. "All services must be private." Possibly this might mean that nurses should not swab throats at windows in view of the public, nor undertakers cool corpses in backyards; but if it means religious services we cannot make it agree with the next paragraph—"And the attendance thereat shall include only the immediate adult relatives of the deceased and the necessary number of adult pall-bearers." We must remember that this applies to any death from smallpox, cholera, diphtheria, diphtheric croup, membranous croup, scarlatina, typhoid fever, typhus fever, yellow fever, epidemic cerebro-spinal meningitis, relapsing fever, and last, but not least, leprosy. Even the leper is apparently deprived of the services of his spiritual advisers, and yet leprosy is a peculiarly religious disease, all we actually know about it being in the Bible, and almost the only people we remember to have had it being Naaman the Syrian and Miriam the sister of Moses. No Father Damien, according to this law, could recklessly risk his life for it now, for even despised altruism would suggest that while he might sacrifice himself he could scarcely sacrifice the undertaker with propriety, and in Section 9 no undertaker or other person or persons "shall in any case furnish or provide for such funeral more than the necessary number of conveyances for said adult relatives and pall-bearers," there evidently leaving the corpse "without benefit of clergy." Of course, it may be said that the mention of said funeral services implies the clergymen as well as the corpse, as neither is specified; but for the conveyance of the latter there is special provision for in Section 9. It is given, a vehicle "used for the purpose of conveying a corpse only." Surely there might have been added to the scanty train another vehicle "for the clergyman only," as by the terms of the act, unless he feign death, he cannot get in with the corpse, the word "only" forbidding him.

In fairness we can say that the regulations for schools and Sunday schools are good so far as they go, but time enough after recovery is not allowed, knowing, as we now do, how long the reluctant bacillus of diphtheria

lingers in the fauces. But if longer than thirty days were allowed the attendance in the beloved schools would suffer. Yet the schools, as has been amply proved, are the very hot-beds and culture-fields of disease, of course excluding leprosy, whose spread is mostly in the imagination.

Wisely the power of granting return certificates is given to medical inspectors rather than to the family-physician.

In Section 15 we find the question raised as to the use of vehicles to convey the sick. When the city shall have on call a reasonable number of ambulances for hire or free service, then will be the time to enforce these provisions of the act against conveyance of contagious disease in hired vehicles. We begin at the wrong end. People are always ready to do the safest and best thing when they know how and when it can be done. Give us good hospitals, where one disease can be safely isolated from another; good ambulances, to convey the sick from place to place; and *then* legislation to enforce their use. Till then such laws will only excite derision and disappointment.

To refer once more to placards. The section concerning them applies to the great apartment-houses, hotels, and boarding-houses, as well as to private dwellings, and will make landlords and agents still more reluctant to let rooms or give board to families with children.

It will also result in the enforced exit of cases of contagious disease from such houses to their only refuge—the Municipal Hospital. And how will they get there? For the "victim of disease" must not, according to Section 16, "wilfully expose himself or herself in any street or public place or public conveyance." So that unable to stay and unable to go, unable to walk, for that is "exposure," and unable to ride, there will be left for "him or her" only to promptly die. There seems to be no fine for dying, but for living under all these conflicting circumstances "not less than five or more than one-hundred dollars."

Is the world becoming a world of cowards, or has religion been so utterly, though silently, overthrown that we center all our hopes on this life and fight with a mad eagerness for every additional moment? The old courage that faced disease, contagion, and death seems rapidly disappearing with the advent of the vaunted "new age," and the kindergarten illustrations of bacterial life have struck sudden terror to the hearts of the children of men. With knowledge has come fear, and the bravery of the eld was, it seems, but ignorance of danger. Fatalism is gone and the stolid heart of the fatalist; bacteria and bacilli have come, and our courage oozes from our sterilized finger-ends. We evidently believe the appeal to Bichlorid more potent than the appeal to an overruling Providence.

Sincerely yours,

An Old Physician.

THE USE OF APOMORPHIN IN NARCOTIC POISONING.

To the Editor of The Medical News,

Sir: In your issue of Sept. 7th Dr. Brown protests against the use of apomorphin in opium-poisoning, citing a case that terminated fatally after the exhibition of $\frac{1}{8}$ gr. hypodermically.

If I may criticise the case quoted, the apomorphin was given in too large a dose and too late to be effectual. If $\frac{1}{12}$ instead of $\frac{1}{6}$ gr. had been given immediately, instead of after the lapse of more than an hour, the result would possibly have been different. I hold the opinion that apomorphin used cautiously and promptly is indispensable to the proper treatment of some cases of narcotic poisoning. Recently I was summoned to see a case in point: a woman, who during a fit of acute mania, had, with suicidal intent, swallowed 12 grains of opium-extract with chloroform and Indian hemp, in the form of chlorodyne. I found her sleeping soundly, and when aroused she endeavored to jump out of the window. After a violent struggle we succeeded in throwing the patient on the floor, and with the utmost difficulty a subcutaneous injection of $\frac{1}{10}$ gr. apomorphin was given. Profuse emesis resulted and within a minute the patient was out of danger. To have used the stomach-pump or to have followed any other method of treatment would have been impossible. Truly,

Robert W. Haynes,

Los Angeles, Cal.

The Revival of the Index Medicus.—The following circular-letter has been issued:

1627 Walnut Street,
Philadelphia, October 1, 1895.

Dear Doctor: The *Index Medicus*, as you doubtless know, has ceased to exist, because the number of subscribers was not sufficient to pay for its publication. Its value was so great that the undersigned, a self-constituted committee, have concluded to appeal to the literary workers of the medical profession to unite in reviving it. The nature of the *Index* is such that it can never obtain a large subscription-list, but it is invaluable to those engaged in literary research. It will require about $5000 annually to publish it. The former editors are willing to take up the work again if 200 subscribers at $25 per year can be obtained. We have each agreed to subscribe for a period of five years; will you not do likewise, and mail the accompanying blank, duly signed, to the Secretary of the Committee? If the term seems too long, will you not fill in the blank for three or less years? The Committee also begs you to get as many of your friends as possible to subscribe, and to send to the Secretary the names of any person, society, or library likely to become a subscriber. Yours truly,

William Pepper,	J. William White,
S. Weir Mitchell,	W. W. Keen,
H. A. Hare,	George M. Gould,
DeF. Willard,	John H. Packard,
J. C. Wilson,	E. Laplace,
H. C. Wood,	

John B. Roberts, Secretary,
1627 Walnut Street, Philadelphia.

The appended copy of the blank mentioned can be cut and used by any who contemplate subscribing:

.. .. .. 1895.

I, the undersigned, hereby agree to subscribe for one copy of the *Index Medicus* for ..... year..... at $25 per year, subject to the following conditions: viz., When

200 subscriptions have been received by the editors the publication is to commence, and upon notification of this I will send $25 to them. If by December 1, 1895, the 200 subscriptions have not been obtained, the attempt to revive the publication will be abandoned.

(Address)

The New York State Association of Railway-Surgeons will hold its fifth annual meeting in the Academy of Medicine, New York City, November 12, 1895. The following program has been arranged:

Preparation of Patient for Amputation, with Remedies Used or Useful in the Treatment of Shock, by Dr. Frank H. Caldwell, Sanford, Fla.; Physical Endurance, by Dr. C. M. Daniels, Buffalo; Multiple Synchronous Amputations, by Dr. W. L. Estes, South Bethlehem, Pa. Discussion on foregoing papers opened by Drs. J. B. Murdoch and N. Y. Leet. Important Unsettled Questions in Railway Surgery, by Dr. M. Cavana, Oneida; President's Address; The Responsibility of the Railway-Surgeon from a Lawyer's Standpoint, by Judge A. H. Dailey, Brooklyn. Discussion opened by Dr. George Chaffee and Clark Bell, Esq. The Importance of a Physical Examination of an Applicant Before He is Placed in the Railway-Service, by Dr. R. H. Reed, Columbus, Ohio. Discussion opened by Dr. G. P. Conn. What is Shock, and How Shall We Treat It? by Dr. R. H. Cowan, Radford, Va.; Arterial Anastomosis, by Dr. F. H. Peck, Utica; First Aid to the Injured, by Dr. C. S. Parkhill; Shock and Its Proper Treatment, by Dr. W. V. R. Blighton, Tonawanda; Why Amputate? by Dr. Stephen Smith; When Shall We Amputate? by Dr. J. B. Murdoch; Where Shall We Amputate? by Dr. J. S. Wight; How to Amputate, by Dr. J. A. Wyeth.

Decreased Mortality from Diphtheria in New York City.—Mayor Strong has received from President Charles G. Wilson, of the Board of Health, a table of vital statistics, showing a large decrease in the number of deaths from diphtheria and croup since the Health Board began the use of antitoxin. The figures showing the number of cases, the deaths, and the percentage of deaths to cases in the first, second, and third quarters of the years from 1891 to 1895, inclusive, are as follows:

Year.	Cases.	Deaths.	Per Cent.
1891 . . .	3686	1349	36.59
1892 . . .	4156	1540	37.04
1893 . . .	4721	1763	37.34
1894 . . .	7446	2264	30.67
Totals 1891–1894	20,011	6936	34.66
Totals 1895 .	7921	1643	19.43

President Wilson says: "The reduction in the mortality-rate in the first, second, and third quarters of 1895, as compared with the average death-rate for the corresponding periods of the previous four years, has been 43.94 per cent. This large reduction in the mortality-rate from diphtheria and croup for the first three quarters of 1895 is attributed mainly by the medical officers of this department to the introduction and use of diphtheria-antitoxin, and, if this remedy had been generally or universally employed, the reduction in the mortality-rate would, doubtless, have been larger."—*N. Y. Herald.*

A Gift of Valuable Medical Journals will be made to the medical library that appears to offer the best means of service to the medical community in which they may be placed. The conditions attending the gift are that the library shall not have duplicates of the journals to be given them and shall agree to bind them substantially. The journals offered are files of THE MEDICAL NEWS, the *American Journal of the Medical Sciences*, and the *Medical Record* for the past ten years. Correspondence is solicited. Address the editor of THE MEDICAL NEWS.

Baron Felix Hippolyte Larrey, the distinguished French Surgeon, died at Paris, October 8th, at the age of eighty-seven years. In 1841 he became Professor of Surgical Pathology at Val de Grace. During the Second Empire he was Surgeon to the French Emperor. He was also a member of the Institute and of the Academy of Medicine.

Dr. William Macpherson died at Philadelphia on October 13th, at the age of fifty-five years. He was an assistant surgeon in the army during the civil war.

BOOKS AND PAMPHLETS RECEIVED.

The Medical Millennium. The Doctorate Address of the Medical Department of the University of Louisville, Session of 1894–95 By H. A. Cottrell, M.D. Reprinted from the American Practitioner and News, 1895.

Report of Seven Cases of Double Castration for Relief of Enlarged Prostate Gland. By H. O. Walker, M.D. Reprinted from the New York Medical Journal, 1895.

Proceedings of the Medical Examining Board of Virginia, First Semi-annual Session of 1895. Held in Richmond, Va., May 8 and 9, 1895.

Annual Report of the Department of Health of the City of Chicago for the Year ended December 31, 1894. Arthur R. Reynolds, M.D., Commissioner of Health. Chicago, 1895.

The Deformities of the Human Foot; with their Treatment. By W. J. Walsham, M.B., C.M. Aberd., F.R.C.S. Eng., and William Kent Hughes, M.B. Lond., M.B. Melb., M.R.C.S. Eng., L.R.C.P. Lond. New York: William Wood & Co., 1895.

Modern Methods in Cataract-operations. By J. O. Stillson, M.D. Pamphlet. Read before the Indiana State Medical Society, June 7, 1895.

Suprapubic Cystotomy for Calculus of the Bladder. By A. H. Meisenbach, M.D. Reprinted from the Journal of the American Medical Association, 1895.

The Right to Question Authorities and the Value of Medical Testimony. By James W. Keiser, M.D. Reprinted from the Medical and Surgical Reporter, 1895.

REFLEX IRRITATIONS FOLLOWING EYE-STRAIN.[1]

BY DAVID H. COOVER, M.D.,

OF DENVER, COL.;

OCULIST AND AURIST TO THE UNION PACIFIC, DENVER AND GULF RAILROAD, DENVER, LEADVILLE AND GUNNISON RAILROAD, AND TO ST. ANTHONY'S HOSPITAL.

IN the last fifteen years the importance of the study of the eye in functional nervous diseases has been more and more recognized by the ophthalmologist, neurologist, and the general physician, who have side by side proved the importance of ophthalmologic examinations in general medical diagnosis. I do not pretend to say that all reflexes are produced by the eyes. Nevertheless the cases that I shall report will demonstrate that unsuspected eye-strain is frequently the true cause.

It is universally admitted that the pathologic conditions of the eye and other parts of the organism are in very intimate relation with each other. To overcome a strain requires an effort. A constant or ineffectual effort of any abnormal organ will produce strain, with the resultant irritation. It is, therefore, not at all remarkable that abnormal conditions of the visual organs should cause reflex irritations of so annoying a character as headache, vertigo, nausea, gastric disturbances, nervous irritations, and depressions, or even those of a more serious nature, as choreic, epileptic, and cataleptic forms of convulsions. When one considers the close relation existing between the delicate nerves of special sense and those of motion and sensation, besides the great vascularity of the optic apparatus, with the deep-seated nervous centers, it is readily understood why the true cause of such varied symptoms should be rendered obscure.

The eye is bountifully supplied with nerves and vessels having their origin in the brain; and, in connection with others, the sympathetic system produces through the organs of sight symptoms of irritation from one to the other. In congestions, inflammations, and growths in the brain there result from this close proximity changes in the anatomic and functional behavior of the eye. In tumors there is the choked disc or paralysis of some of the ocular muscles or suspension of the function of some part of the retina.

[1] Read before the Colorado State Medical Society, June 18, 1895.

In congestion and inflammation of the brain there is the flushed disc and hazy retina, and, *vice versa*, ocular disease not infrequently extends to the brain. An irritation set up in a nerve gives rise to a variety of disturbances in one or more parts of the body, however distant from the seat of cause.

The normal or emmetropic eye can passively take in objects more than twenty feet away without an effort of accommodation. Anything closer requires a slight adjustment of its delicate mechanism, by calling into action the ciliary muscle.

One of the most distinguished botanists, James, an authority upon mosses, actually transformed his eyes to conform them to his studies by constant alteration of the natural focal distance. Sailors are proverbial for their ability to see long distances.

The eye is an important index to the practitioner in determining diseased conditions, both topical and systemic. The black eye of a brawl is so patent that its possessor must explain its cause to his friends, while the listless, expressionless eye of low fevers is an indication of excessive physical depression.

The defects that cause eye-strain are hyperopia, high grades of myopia, astigmatism, and insufficiency of the ocular muscles. Hyperopia is the "short eye." Here the refractive power is too low when the eye is adjusted for distance, and parallel rays of light are not brought to a focus upon the retina as in the normal eye, but behind it. The eye is never at rest except when it is closed, an effort of accommodation being called into action for distant vision. Hence, in looking at objects near at hand the demand upon the ciliary muscle is very great, and it has no chance to regain its power as in emmetropia. This muscle soon gives way and eye-strain becomes manifest.

It is not so in the myopic eye, the "long eye." Here the conditions are reversed. The refractive power is too high; the antero-posterior axis is too long, and parallel rays of light are brought to a focus in front of the retina. The effort of accommodation for distant and near objects is less than in the normal eye, so that very little eye-strain is experienced, except in high grades, when near work, such as reading, sewing, etc., requires very close use of the eyes. Then we find there is an extra amount of convergence, thus overtaxing the internal rectus muscle, which when weakened will give rise to fatigue, and reflex manifestations follow.

Astigmatism is a defect in which the refraction varies in the different meridians of the cornea, owing to the inequality of its curvature. or as a result of an imperfect lens or irregular contraction of the ciliary muscle. It is the greatest mischief-maker and produces more asthenopic symptoms than any other error of refraction. With this defect the strain is very great upon the ciliary muscle, as it must act very irregularly, as the eye always endeavors to obtain as distinct vision as possible.

To obtain binocular vision we must bring into action the ocular muscles, which play an important part in giving rise to various irritations and depressions. The muscles that control the movements of the eyes must act in harmony. If any one is at variance with the others, either from overwork, loss of power or other weakness, so that the equilibrium cannot be preserved, then it is that the demand is greater than the nervous supply, and the consequence is an inability to unite images upon corresponding points of the retina of each eye, and single vision is not maintained. If there is any disturbance whatsoever of the normal relation between the power of convergence and that of accommodation, there will be a strain upon one or the other muscle. The ciliary and recti muscles become weakened by being overtaxed, just the same as any other in the body; as a natural consequence, eye-strain with reflex irritation must follow. The following cases illustrate the various phases of my subject:

CASE I.—Maud F., aged fifteen years, was sent to me on June 4, 1887, by her family physician, with the following history: Five weeks before, while in school, she had been seized with a convulsion, was unconscious, and foamed at the mouth. She had five attacks after the first one. The aura consisted of pain in the head, dizziness, and blackness of vision, and after this she passed into a general tonic spasm, which lasted for five minutes. After steady use of her eyes at her studies or after much concentration she was subject to these seizures. They occurred usually at school or after school on her way home. She had constant frontal headaches and was sometimes very nervous. There was no nausea. The general health was fair.

Examination of the eyes revealed compound hyperopic astigmatism. The following glasses were prescribed for constant use: R. E. + 1. S. ⌒ + 0.50 C., axis, 180°; L. E. + 1. S. ⌒ + 0.25 C., axis 90°.

While wearing these glasses the girl had no attack. Unfortunately she lost them, and for five days was without the correction; during this time she had four attacks. Upon wearing the glasses again there was no return, nor has there been up to this time.

CASE II. Mary B., aged eleven years, consulted me, November 14, 1889. For a year before she had been complaining of headache, vertigo, and nausea, especially in the morning. She was very nervous and anemic. Her appetite was poor and she was restless at night. She had a short, hacking cough, which was increased by nervous attacks to which she was subject. Two months prior to consulting me she became suddenly unconscious, her body was convulsed, and she foamed at the mouth. This attack lasted about ten minutes; preceding it she became very nervous and suffered from severe headache. She had had, in all, seven attacks. They usually came on in the evening after school.

Examination of the eyes showed hyperopia of 2. D. in each eye. I ordered a correction of 1.50 S. for constant use. After the girl began wearing the glasses prescribed, headache and cough disappeared, and there was no return of the convulsions. The general health improved. Three months later the girl had one attack of convulsions. I then increased her glasses to full correction, which has given perfect relief.

CASE III.—Dr. M., aged twenty-eight years, a dentist, consulted me, November 3, 1889, on account of constant pain over the brows and nape of the neck. Objects became blurred while he was at work. The eyes were sensitive to light, and the man at times became very melancholy, so much so that he dreaded going to his office. He frequently contemplated suicide. He was restless at night, and his appetite was poor. He had complained of this condition for six months.

Examination of the eyes showed hyperopia of 1. D., with exophoria in accommodation of 3°.

The following glasses were ordered: + 0.75 for distance, + 1. S. ⌒ prism 1° in each eye for reading.

After wearing the glasses for one month the man was entirely relieved and was able to follow his profession.

CASE IV.—Miss L., aged nineteen years, consulted me, January 1, 1891. From her seventh year she had suffered from nausea in the morning, lasting for several hours; she then became faint and was compelled to seek a recumbent posture. She had no desire for breakfast, but if any food was taken she would vomit. By noon she would feel fairly well. Her general health was poor; she was extremely nervous and she slept poorly. Her parents had tried a variety of treatments without any relief.

Examination of the eyes revealed a high grade of compound hyperopic astigmatism.

The following glasses were prescribed: R. E. + 4.50 S. ⌒ + 2.75 C., axis 75°; L. E. + 4.50 S. ⌒ + 3.00 C., axis 105°.

These glasses were directed to be worn constantly. After wearing them a month the girl wrote me that her nausea had disappeared and that she could enjoy her breakfast with the rest of the family.

CASE V.—Mary S., aged twelve years, came for examination on April 20, 1884. She complained of headache, which was constant, and at times accompanied by nausea and vomiting. She was not able to attend school, as close application of the eyes always aggravated her headache. She had been under medical care for a year before consulting me. The girl was pale, without appetite, very nervous and restless at night, and suffered from palpitation of the heart.

Examination revealed hyperopia: R. E. V. 20/20; L. E. V. 20/20.

Under the influence of atropin for seventy-two hours vision was 20/20, and the headache had ceased. With + 0.25 spherical the vision was as perfect as without. The spherical lens + 0.25 was ordered for constant use. The result was that the headache, nausea, and vomiting disappeared and the general health improved rapidly.

Case VI.—S. A., a young man, aged sixteen years, consulted me, February 13, 1891. There was no history of nervous tendency upon the part of his parentage. He had never suffered from headache or vertigo. The eyes were sensitive to light. Otherwise the lad had always enjoyed excellent health. He had been working very hard at school, and had first noticed that his right hand and arm began to jerk. The right corner of the mouth twitched, and there was a peculiar jerking gait of the right leg. It was difficult for the patient to keep the hand and foot of the right side quiet, except by a strong effort of the will, and even then any distraction caused motion of greater or less degree. These symptoms had been noticed for several weeks before the lad was sent to me.

Examination of the eyes showed simple hyperopic astigmatism.

The following glasses were prescribed: R. E. + 1.25 C., axis 90°; L. E. + 0.75 C., axis 90°.

These glasses were ordered for constant use. At the end of a week the twitching and jerking of the hand, mouth, and leg had materially lessened, and after a month all choreic movements were absent.

Case VII.—Miss G., aged twenty-two years, consulted me, April 1, 1894. She had been a sufferer from frontal headache for a year. The pain would pass through the temples to the nape of the neck. There were also nausea, constant twitching of the eyelids, and choreic movements of the muscles of the face. When very tired the girl stammered. This was more noticeable when she used her eyes at school. She was very nervous and sleepless at night.

Examination of the eyes showed exophoria at 20 ft. of 3°, in accommodation of from 4° to 6°; with simple hyperopic astigmatism.

The following glasses were prescribed:

R. E. + 0.25 C., axis 180°
L. E. + 0.25 C., axis 180° } for distance.

For reading a prism of 1° was added to the distant glasses. After wearing these glasses for two months the symptoms detailed wholly disappeared.

Case VIII.—Mr. P., an insurance-agent, aged forty-five years, consulted me November 23, 1892. He gave a history of having had a cough for twenty-five years, which was always worse in the evening and at night. During business-hours he had to cough more or less, but at night the coughing attack usually lasted until midnight. He never could lie on his right side. The cough was a very peculiar one, dry, hollow, and retching. There was no expectoration except after coughing for some time; then only mucus would be raised and relief followed for a time. The days the man was busiest in his office corresponded with the days and nights he coughed the most. He was told by his physician that the trouble came from his liver and stomach, and was treated accordingly. The greatest relief ever received was when he went away; his cough was then much less—but as soon as he returned to his office the cough came back. Living in the same house with him I studied the cough, and concluded that it was reflex, and told him that I thought his eyes were the cause. Naturally he laughed, but finally consented to have them examined. I found that he had compound hyperopic astigmatism, with 6° of insufficiency of the internal rectus in accommodation (exophoria). The defect was corrected and the following glasses ordered:

R. E. + 1. S. ⊖ + 0.50 C., axis 180°
L. E. + 1. S. ⊖ + 0.50 C., axis 180° } for distance.

R. E. + 1. S. ⊖ + 0.50 C., axis 180°, prism 1° base in
L. E. + 1. S ⊖ + 0.50 C., axis 180°, prism 1° base in } for reading.

The glasses were worn constantly, and at the end of three months the cough had disappeared and he could sleep on his right side as well as on the left. He has had no return of the cough to the present time.

Case IX.—A. F., aged fourteen years, was sent to me by his family physician in April, 1888. During the preceding four months he had complained of attacks of blindness while at school. Preceding these attacks he had vertigo; then he would see red and then all became black before him. The eyes became fixed, and when spoken to the boy would not respond. The seizures were of short duration, and were repeated three or four times a day. After the attack there was headache.

Examination of the eyes showed hyperopia of 2.25 D., and + 1.50 S. was ordered for constant use.

On wearing the glasses no further trouble was experienced.

Case X.—Mrs. W., wife of Dr. W., aged fifty years, consulted me, December 26, 1894. She had been a constant sufferer from headache confined to the supra-orbital and temporal regions, with pain in the nape of the neck. She suffered also with dyspepsia for years, and her general health was poor. She was very nervous and irritable, and suffered at times from palpitation of the heart.

Examination of the eyes revealed simple myopic astigmatism.

The following glasses were ordered:

R. E. — 3 C., axis 165°
L. E. — 3 C., axis 30° } for distance.

This correction gave perfect vision.

R. E. + 2. S. ⊖ — 3 C., axis 165°
L. E. + 2. S. ⊖ — 3 C., axis 30° } for reading.

After wearing the glasses for three months the woman wrote me that she was perfectly well. Even the dyspepsia had disappeared.

Case XI.—Miss W., aged twenty-two years, consulted me, October 5, 1893, with the following history: In the preceding year she had been suffering with headaches over the brow, with pain in the nape of the neck, with vertigo and nausea, and was extremely nervous, sleepless at night, with the eyes

sensitive to light, and confusion of objects at a distance. For the last two years she had suffered from dysmenorrhea.

Examination of the eyes revealed the following: Exophoria at 20 ft. of 3°, in accommodation of 12°, and compound myopic astigmatism.

The following glasses were prescribed:

R. E. — 1. S. ◯ — 2 50 C., axis 180°
L. E. — 1.25 S. ◯ — 0.75 C., axis 60° } for distance.

R. E. — 2.50 C., axis 180°, prism 2° base in
L. E. — 0.50 S. — 0.75 C., axis 60°, prism 1° base in } for near.

The constant use of these glasses wholly relieved the symptoms, and menstruation became normal after the first month.

CASE XII.—Mr. W., aged thirty-six years, consulted me, November 30, 1883, with the following history: He complained of a glimmering before his eyes; then objects become indistinct and floating specks would appear before him. There were also vertigo and nausea, and the man would fall if he did not sit down. He had a sense of numbness in the hands, sometimes only in one, but more often in both. His tongue felt numb; his speech was thick, and he expressed himself differently than he intended. His mind was confused, though he never lost consciousness. He feared that he was about to lose his mind. Preceding these attacks the man suffered from severe headache. He had had two attacks a week in the preceding six months. He had gone six months without an attack, but this was when he was farming. He had lately been engaged in the grocery-business, and during this time had had the attacks more frequently. He gave up the grocery-business and became an attendant in an insane-asylum, thinking some day he would be one of the inmates.

Examination of the eyes revealed hyperopia of 1.25 D. Glasses were ordered: R. E. + 1. S.; L. E. + 1. S. On relief of the eye-strain the man became perfectly well.

CASE XIII.—Mrs. W., aged twenty-eight years, consulted me, July 1, 1894, complaining of frontal headache and vertigo. Her general health was fair, although her appetite was poor and she suffered from nausea. There was confusion of objects at a distance, and the woman was afraid to go on the street alone on account of this. She had a sense of numbness, beginning in the left hand and spreading over the body. She also had a sensation of sinking upon lying down and closing her eyes. She was extremely nervous. She slept very little and cried a great deal. It was impossible for her to use her eyes for near work.

Examination showed hyperopia 1.25, with exophoria, insufficiency of the internal rectus of 6° in accommodation, and left hyperphoria of from 2° to 4° at 20 ft.

The following glasses were ordered:

R. E. + 0.75 S.: L. E. + 0.75 S., prism 2° base down, for constant use. These glasses relieved the confusion at once, and exercise of the internal rectus was practised daily. The woman gained in weight, and at the end of a month was well.

CASE XIV.—Mrs. G., aged thirty years, consulted me, May 9, 1894. She had always been near-sighted. In the preceding six months she had been very nervous and irritable, and occasionally had fits of crying. She was unable to sleep at night, and complained by day of vertigo, nausea, and mental confusion. She had pain in the nape of the neck and down the spine. Her general health was poor, and she was losing weight.

Examination of the eyes disclosed compound myopic astigmatism, and exophoria of 6° at 20 ft., of 9° in accommodation.

For the correction of the defect glasses were prescribed:

R. E. — 3 50 S. ◯ — 0.50 C., axis 170°.
L. E. — 3 50 S. ◯ — 1 C., axis 45°.

These glasses were ordered for constant use, and ocular gymnastics were practised daily until the ocular equilibrium was established, when the symptoms named disappeared and the woman began to gain in weight.

CASE XV.—Mrs. L., aged forty-two years, consulted me, April 11, 1894. For six years she had complained of headache over the brows and through the temples. She had also pain in the nape of the neck, with vertigo and nausea. There was loss of memory and mental confusion. At times the woman had fits of melancholy and suffered from dyspepsia and palpitation of the heart.

Examination of the eyes revealed exophoria at 20 ft. of 10°, left hyperphoria of from 2° to 3° at 20 ft., of 1° in accommodation, and hyperopia of 1. D.

Gymnastic exercises with prisms were practised daily until the ocular equilibrum was established for 20 ft., and the left hyperphoria and hyperopia were corrected.

R. E. + 1 S.
L. E. + 1 S. Prism 1° base down.

In ten days after the treatment was instituted the woman began to improve, and so continued until she was entirely well. She is to-day in better health than she has been for years.

SPONTANEOUS DISLOCATION OF THE HIP-JOINT IN CONNECTION WITH TYPHOID FEVER,[1]

With Report of a Case.

BY LEONARD FREEMAN, B.S., M.D.,
OF DENVER, COL.;
PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF SURGICAL PATHOLOGY, GROSS MEDICAL COLLEGE; PATHOLOGIST, COUNTY HOSPITAL.

THE hip-joint is one of the best protected of the larger joints. Owing to its construction, to its thorough support by ligaments and muscles, and above all to the pressure of the atmosphere, it is comparatively seldom subject to dislocation. Nevertheless, even spontaneous luxations sometimes occur, and there are certain individuals who possess the power of dislocating their hip-joints at will. The

[1] Read before the Colorado State Medical Society, June, 1895.

great majority of spontaneous luxations appear in connection with some pathologic lesion, and are generally known as pathologic dislocations. Spontaneous dislocation would seem to be a better term, as in some cases disease of the joint is slight or absent; and, in addition, all dislocations are in a sense pathologic.

Spontaneous luxation of the hip may arise from: (1) Intra-articular effusion, with stretching of the ligaments and capsule, as may occur in typhoid, typhus, smallpox, scarlet fever, measles, erysipelas, diphtheria, puerperal fever, pyemia, dysentery, mumps, etc. (2) Destructive processes involving the head of the femur, the acetabulum, the cartilages, or all of these (tuberculosis, osteomyelitis, malignant growths, etc.). (3) Deformative processes (arthritis deformans, newgrowths, possibly rachitis). (4) Paralysis. (5) Trophic changes in the structure of the joint (tabes dorsalis, etc.). (6) Long-continued malposition of the lower extremity during some wasting malady, with relaxation of ligaments, etc., and without effusion or other joint-lesion. This has frequently been disputed, but Pitha claims to have personally observed eight cases, in one of which an autopsy was obtained. It is likely, however, that more or less effusion, perhaps temporary, generally exists, as it is otherwise difficult to understand how the atmospheric pressure can be overcome. (7) The deposit of granulation-tissue, etc., in the acetabulum, which forces the head of the femur from its position. König has observed this in the first stage of coxitis. Dislocations produced at will scarcely belong to any of these divisions, as they can be regarded neither as "spontaneous" nor as "pathologic."

In this brief paper I propose to consider spontaneous dislocation of the hip-joint in connection with typhoid, although the accident may take place with other continued and exanthematous fevers. It has been observed in adynamic forms of the disease, generally in male children, is an exceedingly rare occurrence, and attacks the right or left hip with about equal frequency.

In 1877 W. W. Keen, of Philadelphia, collected all the reported cases. Among 43 instances of arthritis due to continued fevers, there were 27 spontaneous luxations of the hip-joint, 15 of which could be definitely traced to typhoid, and 7 to typhus. The confusion in nomenclature that formerly existed as regards these diseases may have led, however, to inaccuracy in these figures. Dr. Keen informs me in a recent letter that he himself has seen but one hip-dislocation following typhoid. Most of our textbooks do not refer to the subject at all, or but very briefly, although its importance certainly warrants attention.

The phenomenon is clearly related to the arthritis that at times complicates typhoid. This arthritis is generally monarticular, but may be polyarticular, when it closely resembles acute rheumatism, with which it may easily be confused. Suppuration may occur, but often resolution takes place without the formation of pus. There is usually, however, considerable effusion within the synovial capsule, either serous, serofibrinous, or purulent. There may be more or less serious changes in the bones, cartilages, ligaments, etc. The ligaments and capsule are likely to be stretched and weakened, which is an important feature in the affection. Our data, however, lack accuracy, as no autopsies have been made in this connection. In view of the fact that the Koch-Eberth bacillus has repeatedly been found in the periosteal affections complicating typhoid, in medullary inflammations of bones, and in various other lesions, it is not unreasonable to suppose that arthritis may also be due to its presence, epecially as arthritis is at times secondary to a contiguous ostitis or periostitis. As has been demonstrated, other micro-organisms may find their way from the intestines into the joints, so that a mixed infection might easily occur. It is claimed by some, however, that the joint-affections of typhoid are always pyemic in their nature. In cases that recover without suppuration, perhaps the typhoid-bacillus alone may be present, as occurs in non-suppurative typhoid periostitis; or it may be that a mild infection with some other germ exists.

As to the way in which the dislocation takes place, most writers agree that the prime factor is overdistention of the capsule with fluid, which weakens and stretches the supports of the joint and forces the bones apart. (Bonnet and Parise have demonstrated that by injecting fluids into the semi-flexed hip-joint the bones may be forced apart from ⅛ to ¼ inch.) Then some slight wrench, such as turning in bed, or lifting the patient with a hand beneath the back and one beneath the thighs, causes the dislocation. Or the trouble may possibly take place gradually by a combination of overdistention and relaxation, with malposition of the limb and reflex muscular tension. The malposition consists usually in adduction, flexion, and inversion. Stimson adds clearness to the explanation by showing that the fluid that fills the capsule flows into the acetabular cavity as the head of the bone leaves it, thus preventing a vacuum and relieving the pressure of the atmosphere. The ligamentum teres is not necessarily ruptured. Moore has demonstrated that it may be sufficiently elongated by an intra-articular effusion to allow of complete dislocation. Paralysis or degeneration of muscles, as sometimes occurs from typhoid, may play a part in the accident.

As the luxation usually takes place during severe

fevers, after the third week (Keen), when the patient is delirious or unconscious, it may not be observed at once—perhaps not until convalescence has set in and locomotion is attempted.

Whatever the mechanism of dislocation, it is nearly always upon the ilium near the sciatic notch, and is probably in most cases intracapsular. Sometimes the head of the bone is found higher up on the ilium; rarely beneath the anterior superior spine, and very rarely in the thyroid foramen. Keen cites four cases in which the femoral head was movable in all directions, showing great relaxation of the capsule and ligaments.

In most cases there is little or no pain in the joint at any time, while in some the pain is excruciating, although it may suddenly cease when dislocation occurs. It may be felt elsewhere than in the hip, even in the entire lower extremity, but it is rarely reflected to the knee as in coxitis.

The history of a typical case of typhoid-dislocation would be somewhat as follows: A child passes through a severe fever, accompanied by swelling of a hip-joint (it must be noted, however, that swelling in this deep-seated part is not always easily detected, even in an emaciated subject). While still in bed, or later on, it is noticed that one of the patient's legs is shorter than the other, usually from 1½ to 2 inches, especially when flexed at the hip, and that it is held in a position of partial flexion, adduction, and inversion. Keen mentions that owing to the extreme relaxation of the parts about the joint the limb may rarely assume other positions.

Without consideration of the symptoms and attention to the history, the affection may be mistaken for a late stage of ordinary tuberculous hip-disease, especially after a few weeks have elapsed and atrophy of the muscles with flattening of the nates and dropping of the gluteal fold has supervened. Hip-joint disease, however, does not come on suddenly, and its first stages are characterized by abduction and apparent lengthening, although dislocation may very rarely occur (König).

In the course of time the femur forms a socket for itself in its new position, and considerable mobility may be acquired, especially as regards flexion and extension. This is fortunate, as it is an exceedingly difficult matter in many cases to reduce the dislocation, owing to the joint-lesions and to frequent non-recognition of the trouble until firm fixation on the dorsum of the ilium has occurred. Even if reduction be accomplished, it is likely that it cannot be maintained.

In the recent *Traitè de Chirurgie*, by Reclus and Duplay, Lagrange mentions but two cases of reduction of typhoid-luxations, one by Lannelongue and one by Capelle. In Lannelongue's case prompt recurrence ensued, while in Capelle's the bone remained in place. Keen, however, says that reduction was accomplished in 11 of the 27 cases due to continued fevers in general, but that it is always difficult and often impossible if not attempted at once.

The prognosis as regards restoration of the joint to its normal condition is absolutely bad according to Lagrange, although Keen refers to but 2 cases in which recurrence of the dislocation took place.

The treatment should consist in a prompt attempt at reduction under anesthesia. Delay is perhaps more dangerous than with ordinary dislocations, for the pathologic lesions may lead to rapid and embarrassing alterations. But however long the trouble may have existed, an attempt should always be made to correct it. Pitha mentions a successful reduction of a spontaneous dislocation of the hip from rheumatism after the lapse of six years. Manipulation should be thoroughly tried, having regard to the fact that the bones of children are more fragile than those of adults, and that an epiphysis may easily be separated. It is advisable to first loosen up adhesions, if any be present, by flexion and extension of the thigh, combined with careful rotation. A fracture may perhaps be avoided, as suggested by Pitha, by grasping the thigh close to the joint, and not employing the flexed leg as a lever.

In case these efforts fail, it would certainly be justifiable to open the joint, clean out the acetabulum, sever the adhesions, and replace the luxated bone, although few attempts have been made in this direction.

If there is a tendency to recurrence after reduction, retentive splints may be employed, or, better still, extension by weight and pulley. It is perhaps a wise precaution to apply extension for a time in any case. If these measures fail, an arthrodesis would be in place. There is no reason, in these days of aseptic surgery, why a dislocation should remain unreduced without operative interference. Lannelongue has obtained the production of new bone about the defective rim of the acetabulum by the deep injection of his 10 per cent. solution of zinc chlorid.

Keen suggests, as a prophylactic precaution in cases of typhoid when there is reason to fear luxation, that the suspected limb should be confined in a position of abduction and eversion.

Considering that we cannot know how extensive the joint-lesion may be, or of what character, it is wise to maintain fixation of the limb for several weeks by extension, by splints, or at least by tying the knees together. The patient should not be permitted to walk for 6 or 8 weeks, and in some cases not for a longer time. It would seem best that the first attempts at locomotion should be made on crutches, with an elevated shoe on the foot of the sound leg,

thus avoiding the bearing of weight upon the affected member and giving ample time for the repair of a possibly defective acetabular rim. Cautious passive motion can be instituted in 2 or 3 weeks in order to prevent stiffness or ankylosis.

The case I desire to report in this connection was that of a girl of 10, who developed well-marked typhoid fever about the first of February, 1895. She was placed in the competent care of Dr. Heimberger, of Leadville, Colorado. She was a well-developed and well-nourished child, in excellent health, and with normal lower extremities. Symptoms of meningitis were prominent during the height of the disease, with delirium and at times marked stupor. Near the end of the third week the temperature in the rectum arose rapidly to 110° and as rapidly fell again. Paralysis of both lower limbs, involving sensation and motion, but lasting only 2 or 3 days, occurred during the fourth week. Following this there developed tenderness along the femoral veins. During the end of the fourth and beginning of the fifth week slight pain, tenderness, and swelling manifested themselves in the right hip, followed shortly by similar symptoms in the left. Much pain was felt in the tendons beneath the knees, especially when attempts were made to straighten the limbs, and it seemed to be due to contraction of the posterior muscles of the thighs. Marked emaciation occurred, and some small bedsores appeared on the sacrum.

The child left its bed in between 6 and 7 weeks, and it was not until then that any decided trouble with the hip was noticed, although it had been observed that something was wrong during the latter portion of the illness.

When the child came under my observation on April 25th, 9 or 10 weeks after the probable date of the accident, she was emaciated and peevishly irritable. The left lower limb was partially flexed on the pelvis, strongly adducted, and rotated inward. There was from 1½ to 2 in. actual shortening, when the thighs were flexed at a right angle with the pelvis. There was ½ in. difference in the circumference of the thighs, showing atrophy of the muscles to that extent. The gluteal mass was also atrophied and the gluteal fold shallow and depressed. In fact, there was a dislocation of the femur on the ilium near the sciatic notch. The case presented a marked resemblance to the third stage of coxitis, which we at first supposed it to be. There was no tenderness, however, about the hip, either on strong percussion or on decided manipulation. Neither was pain developed by forcibly striking the heel on the affected side. The popliteal tendons, however, were very tender, and much pain was aroused by attempts to straighten the knee.

I diagnosticated a "typhoid-luxation," and placing the child under an anesthetic an attempt at reduction was made, with the assistance of Drs. Hawkins and Heimberger. Flexion and extension of the thigh were possible, but absolutely no adduction. The head of the bone could be felt grating against the ilium while breaking up the adhesions. Considerable force was necessary during the manipulation, although reduction was accomplished at the second or third attempt, no sudden "snap" being perceptible. As soon as the bone was replaced, all the motions of the joint returned to normal, including abduction. There remained, however, a slight prominence of the great trochanter and a shortening of the limb, amounting to less than ½ in. The latter was afterward found to be manifest throughout the entire member, including the leg and foot, and was probably the result of a lack of growth during the time the dislocation was present. I have not found this symptom mentioned except in the account of a case of spontaneous luxation of the hip following puerperal fever, described by Baker. In fact, Keen states that the leg after reduction of the dislocation may be longer than its fellow. As a precautionary measure an extension of 4 or 5 pounds was kept on the leg for 2 weeks, after which the knees were simply tied together at night for another fortnight. All pain and irritation rapidly disappeared, and within 48 hours the child was perfectly comfortable, and free from the sharp pains previously caused by sudden contractions of the posterior muscles of the thigh.

Passive motion of the knee and hip was begun about the fourth week. The marked weakness and atrophy of the muscles were slowly overcome by massage and electricity, and by the sixth week the patient was sitting up and moving her limbs about with considerable ease and comfort, the power of flexing the thigh upon the pelvis, however, being but slight, with much general weakness of the muscles of the entire limb. The length of the left limb, as compared with that of the right, had in the meantime slowly increased until the difference was scarcely appreciable. At the end of ten weeks the child was walking fairly well, although sufficient weakness and stiffness remained to give rise to a marked limp.

At the end of five months the limp has markedly decreased, although stiffness of the joint is still present. The limb is strong enough to permit of the most active exercise, but is somewhat less than half an inch shorter than its fellow and somewhat less in circumference.

In the case detailed, the luxation probably took place during the third or fourth week, being due to an arthritis of the left hip-joint, aided by malposition of the left limb as the child lay on her right side. Paralysis may have aided in the accident, as did certainly general weakness and relaxation.

LYMPHOID HYPERTROPHY AT THE BASE OF THE TONGUE AS A CAUSE OF THROAT-AFFECTIONS, ESPECIALLY IN SINGERS.

BY DUNBAR ROY, A.B., M.D.,
OF ATLANTA, GA.;
PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE SOUTHERN MEDICAL COLLEGE.

Lymphatic glandular hypertrophy as a cause of many throat-affections is well known to all laryngologists. All lymphatic tissue in the oropharyngeal

and laryngeal cavities is a part of the lymphatic system recognizable in enlarged glands at the side of the neck and its contiguous parts. When we have amygdalitis the enlargements sometimes felt below the angle of the lower jaw are not always the tonsils themselves, but lymphatic glands in close relationship with this focus of inflammation. If one will take the trouble to dissect thoroughly the mouth, pharynx, nasopharynx, and larynx he will find a circle of glandular lymphatic tissue embracing the glands at the base of the tongue, extending up on the side by means of the tonsils, and united above either in adenoid vegetations or glandular hypertrophy, known as the third or Luschka's tonsil. The subject of tonsillar hypertrophy long ago received exhaustive study at the hands of some of the best physiologists and clinicians, among whom must be mentioned Professor Harrison Allen, of Philadelphia, who has published a most excellent article in *The American Journal of the Medical Sciences*, January, 1892.

The subject of adenoid vegetations in the nasopharynx has also been voluminously considered, and justly so, since the great importance has been established of recognizing and treating this condition in aural affections, especially in children. When these enlargements are centered at the apex of the nasopharynx, and especially as this form (which probably in childhood constituted the so-called adenoid vegetations) is recognizable in adults, it is usually termed hypertrophy of the third or Luschka's tonsil, and as such is capable of giving rise to many nasopharyngeal diseases. This subject has been very excellently treated by Prof. Fletcher Ingals, of Chicago, in a paper read before the American Medical Association two years ago.

The subject of glandular hypertrophy at the base of the tongue has not been so frequently written upon, nor has it received the attention that I think it deserves in the causation of many reflex laryngeal troubles. In none of the textbooks have I been able to find more than a mention of the subject. Lennox Browne, who is a very close and accurate observer, besides being an explicit writer, only mentions it as an anatomic point, without dwelling upon it as a causative factor in laryngeal troubles. Dr. Gleitsman, of New York, has been among the first to recognize this hypertrophy at the base of the tongue as a truly pathologic condition, and he has written some excellent articles on this subject.

As we know, there exists normally at the base of the tongue certain large papillæ, known as the circumvallate papillæ, whose presence and position must be distinguished from the true lymphoid or glandular tissue that occurs nearer the epiglottis and is especially prominent at the sides of the tongue. In every individual there exists a certain amount of this glandular tissue, but it is only when it becomes considerably hypertrophied that it can be considered pathologic. Normally there should be a free space existing between the epiglottis and the base of the tongue. In other words, when the epiglottis touches any enlarged lymphoid tissue at this point as seen in the natural laryngoscopic image there is an abnormality.

Coursing over the base of the tongue, usually between the lymphoid tissue and the papillæ, can always be seen numerous veins, and frequently they become so numerous as to form what is known as a "lingual varix," and in that case are said by Lennox Browne to be productive of many reflex laryngeal troubles. According to my observations the lymphoid glandular hypertrophy in the same position is productive of far more disagreeable symptoms than the so-called "lingual varix."

Lymphatic glandular hypertrophy is well known as a condition most frequent in childhood, and, as this glandular tissue is nothing more than a part of the chain in the general lymphatic system, it would be very natural to suppose that this pathologic condition would be especially common at this age. We know that tonsillar hypertrophy and adenoids are almost without exception most frequent among children, and that these same conditions decrease perceptibly after the age of puberty. Cases have been reported in which adenoids have spontaneously disappeared—a statement by all means questionable. It is certainly true that with age hypertrophied tonsils become smaller, and I have also noticed that this was most marked when the general system is likewise undergoing improvement. It may be that this lingual lymphoid hypertrophy is most common in childhood, but as we are seldom able to obtain a laryngoscopic image before the child has reached the age when he or she may be controlled, my own experience has been that it is a condition rather of adult life. Certain it is that this condition seldom gives rise to any reflex trouble until the individual is old enough to have begun some occupation. This hypertrophy is almost always coexistent with hypertrophy to a slight degree of the faucial tonsils. When this lymphoid tissue is very much enlarged it presents a perfect resemblance to the true tonsils, as was shown in one of my cases, in which crypts filled with white, cheesy substance were present, resembling in every respect the true tonsillar formation.

According to my observation, which, I think, is in accord with that of other observers on this subject, the glandular hypertrophy at the base of the tongue is much more frequent in women than in men. This is probably due to the occupation of the individual, as, almost without exception, it is found in the throats of those who sing—or attempt

to sing—and as this accomplishment is more universally confined to women, it is but natural to expect that the gentler sex should be more universally afflicted.

Of the four cases I present, three were in singers, and all were in women except one. The number of cases is of course not sufficient to draw from them any statistical results or definite conclusions, but they are recorded because of the prominence of the objective manifestations and subjective symptoms present. Of course there are many cases in which glandular hypertrophy in this position does not give rise to any uncomfortable symptoms, just as we find is the case in other departments of medicine, but when this condition does exist, and at the same time certain other symptoms, clinical experiences teach us to class the two together.

While I was in New York, my friend, Dr. R. C. Myles, showed me a number of professional vocalists whom he then had under treatment for this condition, and it was he who first called my attention to the importance of this glandular hypertrophy as a cause for many reflex symptoms in the throats of singers. The symptoms to which this condition gives rise are varied and for the most part subjective. To enumerate them all is beyond the scope of this article, but some of the most prominent I shall merely mention. They are:

1. A sensation as if a foreign body were present in the throat, not disappearing on deglutition.

2. A feeling of constriction around the throat at the upper portion of the thyroid cartilage.

3. An occasional reflex irritable cough.

4. Constant endeavor to clear the throat.

5. Laryngeal fatigue quickly coming on after using the voice either for talking or for singing.

6. Occasional hoarseness and many other subjective sensations too numerous to mention. I give in a succinct form the histories of the cases and the treatment used in each:

Case I.—Jennie A., nineteen years old, came South on account of throat-trouble. She had been a sufferer for the last 2 years, especially during the winter season. Her symptoms were a constant soreness of the throat on the slightest exposure, and hoarseness even with moderate use of the voice. There was a feeling of constriction around the larynx, and a constant endeavor to get rid of something filling up the throat. She was very fond of singing, though not a professional vocalist. Upon examination I found chronic granular pharyngitis; the tonsils were slightly enlarged, but there were marked degenerative changes in the tonsillar crypts. On making a laryngoscopic examination decided lymphoid hypertrophy could be seen at the base of the tongue. There was some congestion of the larynx. The treatment consisted for the first few days in relieving the congestion by sprays and producing a more healthy condition in the tonsillar crypts. Later the tonsils were reduced in size by destroying the crypts with the aid of the electro-cautery. The granulations were removed by the same means, as also the glandular hypertrophy at the base of the tongue. Under a month's treatment entire comfort was afforded the patient, which she writes has continued to the present time—now two years.

Case II.—Mr. C. E., twenty-five years old, consulted me in December, 1893, for some catarrhal affection of the nose, which in some way seemed to interfere with his singing. On examination I found large hypertrophies of both inferior turbinates, with a septum-ridge on the left side. Under the electro-cautery and sprays this condition was entirely relieved, so that he has never experienced any more discomfort from that source. The ridge was not removed, for I do not believe in destroying the mucous membrane unless it is absolutely necessary for the production of free nasal respiration. One year later the patient returned complaining that his throat felt continually "filled up," and this could not be relieved by any exhalation of expectoration. On laryngoscopic examination I found marked glandular hypertrophy at the base of the tongue, and the nodules coated with mucus. Under 4 applications of the electro-cautery and sprays the patient has remained entirely relieved, with a great improvement in the quality and strength of the voice.

Case III.—Mary M., forty-five years old, a cook, was sent to me with a note from the lady of the house saying that I must do something for Mary, or she would lose the best cook in the world. The woman had great difficulty in breathing, because the throat felt entirely closed. She was continually, but vainly, trying to get rid of something there. She had been treated for some time with sprays, gargles, etc., without any relief of the symptoms. On examination I found marked hypertrophy of the lower turbinates of the nose. On making a laryngoscopic examination there was found a condition of affairs I had never seen. The faucial tonsils, instead of remaining in their natural position, seemed to have spread across the base of the tongue. This glandular hypertrophy was so large as to give scarcely any room for the movements of the epiglottis. The whole mass resembled good-sized tonsils. The treatment consisted in reducing the intranasal hypertrophy by means of the electro-cautery, and the removal of the glandular hypertrophy at the base of the tongue, with both the cold-wire snare and the electro-cautery. The treatment extended over a considerable period of time on account of the size of this glandular mass, but with the final result of relieving all the symptoms from which the patient formerly suffered, and restoring the parts to a more natural appearance.

Case IV.—Mrs. H , thirty-three years old, a great vocalist, had suffered for years with her throat on account of a sensation as if there was a foreign body present. She was very nervous and hysterical. On laryngoscopic examination I found, in addition to some congestion, a glandular enlargement of the

base of the tongue. This was cauterized with the electro-cautery, thereby doing away entirely with the symptom as if a foreign body were present.

This condition of lymphoid hypertrophy at the base of the tongue is by no means uncommon. Sometimes it does not produce any unpleasant symptoms by its presence, while in others it is an important factor. The diagnosis is easy, and yet I have been surprised to find how often it has been overlooked by good laryngologists, or if recognized at least ignored. In all cases in which singers consult me for throat-troubles, I never feel sure of a thorough diagnosis until the base of the tongue has been thoroughly explored.

CLINICAL MEMORANDA.

A CASE OF AKROMEGALY.[1]

BY AUGUSTUS A. ESHNER, M.D.,
OF PHILADELPHIA,
ADJUNCT PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC.

THE pathology of the disorder first systematically described by Marie in 1886, and by him designated akromegaly, is yet an unsolved problem. The report of an individual case may therefore prove not without interest, if not profit. Besides, the case about to be detailed presents a feature not uncommon as a part of a number of diseases of the nervous system, but hitherto not frequently if at all described in connection with akromegaly.

J. S. S., a native of Scotland, thirty-six years old, and a blacksmith by occupation, presented himself at the Polyclinic complaining of pain and weakness in the shoulders and knees, which had been present for three weeks, and from which he had suffered from time to time during the preceding two years. The pain was at times so severe as to disturb sleep. The patient's appearance was at once striking. He was a tall man, and stated that he had always been unusually large. Close questioning only succeeded in eliciting the doubtful information that at the age of eighteen years the man was larger than an older brother was at the same age, and that he had "continued to grow until he was twenty-five." Photographs taken during this interval show the characteristic enlargement of the face. The man has three children, and these he thinks are also large. Upon further inquiry the patient stated that he had slight shortness of breath. He had, however, no derangement of vision, and not until the day before coming under observation had he complained of headache, and this was referred to the sagittal suture, and soon passed away. Memory and intelligence were preserved.

On inspection the man presented the characteristic elongated face, large forehead and nose, prominent zygomata, and massive and protruding lower jaw. The lower lip was relatively thick, and the tongue was broad and flabby. The hair of the head was coarse and rather dry; the ears small. There was a fair growth of hair on the pubes and in the axillæ, but little on the thighs and legs and arms and forearms, and almost none on the chest. The teeth were small. The hands were broad, the fingers thick and somewhat elongated. The nails presented no abnormality. A peculiar palmar curvature of the little finger was ascribed in the one hand to the use of the hammer, and in the other to the use of the tongs. The grasp of the hands was relatively impaired, in greater degree upon the right. There was some enlargement of the distal extremities of the radii and ulnares.

The following measurements were made:

	Right.	Left.
Circumference at the styloid process	8⅝ in.	8¼ in.
Circumference around body of hand	10¾ "	10½ "
Circumference around knuckles	10¼ "	9¾ "
From wrist to tip of middle finger	8 "	8 "
Circumference of second phalanx of middle finger	3⅛ "	3¼ "
Circumference of first phalanx of thumb	3¼ "	3⅛ "

The feet did not appear to be unduly long, but rather broader than normal; nor had the patient been required to obtain shoes of progressively increasing size. The great toe of either foot was notably large. The heels projected backward conspicuously.

These measurements were noted:

	Right.	Left.
From the heel to tip of great toe	10⅞ in.	11 in.
Circumference at ball of toe	10¾ "	10 3/16 "

There was some impairment of motility in the upper extremities, partly from pain and partly from weakness. The myotatic irritability was preserved. Movement at the shoulder-joints was attended with palpable grating, as if from the rubbing of thickened and roughened synovial membrane. In standing erect the forearms were held at an obtuse angle with the arms, in more pronounced degree upon the right. Both knees were tumid, though not discolored, and on palpation yielded a sense of elastic tension, as if from an increase of fluid in the synovial sacs of the knee-joints. The knee-jerks were preserved, deliberate, and reinforcible. The veins of the legs were varicose, particularly upon the left.

The chest protruded forward, was rather barrel-shaped, and appeared distorted. The scapulæ were quite enormous. There was slight right lateral curvature of the spine, but no considerble kyphosis. The circumference of the chest at the nipple-line, at rest, was 40¼ inches; after deep inspiration 41¾ inches. The apex-beat of the heart was conspicuous in the fifth interspace within the nipple-line, but the action of the heart was rhythmic and its sounds clear. No dulness could be detected at the upper part of the sternum, corresponding to the situation of a persistent thymus gland. The thyroid and cricoid cartilages were enlarged and firm. The isthmus of the thyroid gland could be felt, and the lateral lobes seemed to be present and of ordinary size.

Below the costal arch on either side laterally, about 2½ inches from the median line, was a slight tumefaction, apparently due in part to soft structures, and in part to a bony protuberance beneath, and thought to be an enlarged floating rib. A similar (fatty) mass was seated in the upper part of the left gluteal region. On

[1] Report and presentation made to Philadelphia County Medical Society, October 23, 1895.

the anterior aspect of the right side of the trunk, in the mammillary line, below the costal arch, was a depression corresponding to the situation in which it is customary for the blacksmith to hold the horse's leg in shoeing. The relatively small abdomen was protuberant and presented a constriction through the epigastrium, corresponding to the situation where the apron was tied. There was a notable disproportion between the size and the muscular development.

An examination of the eyes was made by Dr. J. T. Carpenter, who reported that vision, ocular movements, pupillary reflexes, and visual fields were normal. There was no nystagmus. The nerve-heads were horizontally oval, and normal in color and capillarity. The fundus presented no lesion. The refraction was abnormal by possibly 1/2 D. of hyperopia.

The urine was of acid reaction, had a specific gravity of 1028, and contained neither albumin nor sugar. The patient gave his height as 6 feet 1¼ inches. Strontium salicylate, in doses of gr. xv every three hours, mitigated the severity of the pain, while the headache appeared to be rather aggravated by the administration of thyroid extract, gr. v thrice daily. Under local applications of tincture of iodin, with ointments of mercury and belladonna, the swelling of the knee-joints subsided appreciably.

The features in this case that strike me as peculiarly interesting are the disparity between the weakness and the slightness of muscular development on the one hand, and the great size and the laborious character of the patient's work on the other hand; the peculiar deflection of the forearms as related to the arms; the absence of headache, eye-changes, and of other intracranial pressure-phenomena; and more especially the arthropathies.

The prevailing conception of the pathology of akromegaly associates the complex of symptoms with a morbid state of the pituitary body, in the same way as myxedema is considered to be due to derangement of the function of the thyroid gland—either through sending into the circulation certain toxic products of abnormal secretion, or withholding from the circulation some product of secretory activity capable of neutralizing certain other toxic matters. The pituitary gland, however, has not always been found enlarged; and a case has been reported by Packard[1] in which the pituitary body was after death found to be enlarged, while during life there existed blindness but none of the symptoms of akromegaly.

Recently the view has been propounded that the pituitary body represents a center controlling nutrition, and the removal of whose functional influence, it may be inferred, results in abnormal growth.

A French writer[2] has recently reported three fatal cases of akromegaly, all of which presented after death pathologic changes in the pituitary body. He raises the interesting question whether such changes may not really be secondary, representing a part of the effects due to a disturbance of higher centers governing the nutritive equilibrium.

SARCOMA OF THE LARYNX. LARYNGECTOMY BY AN IMPROVED METHOD. RECOVERY.

By JOHN A. THOMPSON, M.D.,
of Cincinnati, Ohio.

J. F., 35; formerly a blacksmith; unusually well-developed and very muscular; had had but one severe illness in his life before the present trouble, an attack of pyemia when he was 12 years of age. He has always been sober and temperate in his habits, with the exception that he smoked excessively. He has been on the police-force for 9 years; 8 years as a patrolman and 1 as a detective. The gymnasium-exercise required of the members of this force has kept him in splendid physical condition. I examined the man for the first time, June 20, 1895. At that time a large, pale-pink, lobulated tumor completely hid all parts of the larynx except the epiglottis and the membrane over the left arytenoid. He was very hoarse and suffered from dyspnea and dysphagia. The lymphatic glands were not involved. A portion of the tumor that projected above the right ala of the thyroid could be felt externally. The trouble had begun 6 months previously. The first symptom noticed was a scratchy sensation where the tumor now lay. He had had some cough, but it was never very bad. The growth was not painful except after prolonged exposure to the night-air; after running, the resultant coughing would cause the throat to ache. Dyspnea after exercising soon appeared. Pain and difficulty in swallowing had been felt for about four months. Two months previously the dyspnea became so severe as to interfere with his sleeping. There had been occasional slight hemorrhages of bright, fluid blood. There was also a free discharge of mucus from the throat. He has had occasional attacks of choking. He has had no pain in the chest.

The patient was told the growth was probably sarcomatous; the throat was anesthetized with cocain the first day I saw him, and three large pieces of the growth broken off with laryngeal forceps to give him room to breathe with comfort, and to obtain specimens for microscopic examination. There was but little hemorrhage and almost no pain resulting from the removal through the mouth. A portion of the growth sloughed in the next few days from the injury done by the forceps and was expelled by coughing. The microscopic examination was unsatisfactory. From the specimens mounted it could not positively be determined whether the growth was syphilitic or sarcomatous. To give the patient the benefit of the doubt, although there was no trace of specific trouble, he was put upon antisyphilitic treatment. At intervals of about a week, as soon as the wound from one operation would heal, successive portions of the growth were removed in order to obtain, if possible, some satisfactory specimens for microscopic examination. The dyspnea and difficulty in swallowing were much relieved by this course of treatment. The patient slept better and his general condition temporarily improved. A specimen finally obtained from the right ventricle of the larynx clearly showed the growth to be sarcomatous in nature. By this time the iodin-eruption from the internal medication had appeared, and I determined to give the patient the benefit of the clinical test and left the throat alone for one week. Although

fully under the influence of antisyphilitic remedies, the growth of the tumor was so rapid as to completely fill the larynx in ten days.

Laryngectomy was advised and agreed to and the operation was performed at the Cincinnati Hospital, July 31, 1895. As the plan of procedure adopted differs materially from the ordinary operation of laryngectomy, I shall describe the steps of the operation in detail. The patient was anesthetized in the usual way. When unconscious, the pillow was taken from under his head and the foot of the operating-table raised so that gravity would aid in preventing the entrance of blood into the bronchi. A vertical incision was made in the median line from over the hyoid bone to the thyroid gland. The superficial cervical muscles were separated by blunt dissection. I had intended to remove the perichondrium with the muscular attachments on the left side of the thyroid cartilage, but, finding the cartilage softened by the growth so that this could not be done, I cut loose all the muscles attached to the thyroid on both sides back to the posterior margin of the wings of the cartilage. A short transverse incision over the hyoid was necessary to give sufficient room. The ligaments of the cricothyroid articulation were next cut. A high tracheotomy was then made and a sterilized sponge inserted above the tracheotomy-wound. After the tracheotomy was made and the upper portion of the trachea packed, the anesthetic was administered by means of a funnel with gauze tied over the bell-portion. The funnel was connected with the tracheotomy-tube by a piece of stiff rubber tubing. The only difficulty experienced in giving the anesthetic in this way was that mucus would be coughed into the tube and it had to be removed occasionally for cleansing.

Sarcoma of the larynx after exsection. Viewed from behind.

The thyrohyoid and cricothyroid membranes were next divided. The superior cornua of the thyroid were dissected out. The origin of the lateral cricoarytenoid muscles of both sides was dissected loose from the cricoid. The arytenoids were disarticulated from the cricoid and the attachment of the cricoarytenoideus posticus cut. The ligamentous and membranous attachments along the margins of the thyroid were cut and the larynx removed. A small rubber tube was next put through the nose and into the esophagus. The margins of the inferior constrictor muscles were then stitched together from side to side, making a continuous passage from the base of the tongue to the esophagus. The skin over the upper portion of the wound was next sutured. The tracheotomy-tube was removed from the wound and inserted through the opening of the cricoid. The lower portion of the wound, including the tracheotomy-wound, was then closed. The ordinary dressings were applied and the patient put to bed in good condition.

The greatest difficulty experienced during the operation was from the free bleeding; all the parts around the larynx were intensely congested and the arteries and veins so dilated that numerous ligatures had to be applied in order to keep the field of operation clear enough for careful and accurate dissection. The time required to complete the operation was 2½ hours. The patient rallied well after the operation. Water was given through the tube in the esophagus to relieve the patient's thirst within 3 hours after the operation. Small quantities of hot liquid diet were also administered at frequent intervals to aid in recovery from shock. A half-ounce of whisky and a drop of a 1 per cent. solution of nitroglycerin were also given for the same purpose. This dose repeated once was all the medication of any kind given during his convalescence. There was some bronchitis with considerable cough and a rather profuse mucopurulent expectoration for 4 days after the operation. It was never severe enough to be the cause of any anxiety, as the patient's temperature never exceeded 101° F. His febrile attacks occurring in the afternoon rarely lasted more than 3 hours. The pulse-rate and the respiration were both rapid for about a week. This was due in all probability to the loss of blood and the prolonged anesthesia.

Most of the wound healed by first intention, but, owing to the large number of ligatures in the wound and to infection from the mouth, the upper portion of the wound reopened. A more serious feature was the failure to secure union of the inferior constrictor muscle by first intention. This failure left a direct communication between the trachea and the pharynx, so that on any attempt at swallowing the greater portion of the nourishment would enter the trachea and only a small portion the esophagus. If the wound was packed with gauze so as to close this opening the interference with the muscles of deglutition was so great as to make swallowing impossible. For the first 5 weeks nourishment had to be given through the rubber tube.

On the fourth day after the operation I removed the tube that was placed through the nose into the esophagus in order to clean it. A great deal of difficulty was experienced in replacing the tube, and it was not again removed until it was expelled spontaneously one night during my absence from the city. By this time the nose had become so sore that the tube could not well be tolerated, and, after a number of attempts to replace it had been made, Drs. Oliver and Castle succeeded in passing it into the esophagus through the upper portion of the external wound.

Five weeks after the operation the opposed surfaces had united by granulation and the patient was able to swallow semisolid food. The tube was then withdrawn from the wound and the upper portion immediately closed.

It will be observed that the cricoid cartilage was not removed in this operation, as is ordinarily done in laryngectomy. There were several reasons for adopting this course. There was no reason for taking it out, as neither the cartilage nor the membrane over it were involved in the malignant growth. Removing the cricoid destroys the support of the anterior longitudinal fibers of the esophagus. The inferior constrictor of the pharynx is also attached to the upper posterior portion of the cricoid, and one of its supports would be need-

lessly destroyed by removal of this cartilage. The danger of buttonholing the esophagus in dissecting the cricoid out is by no means a slight one. There is no slipping down or recession of the trachea if the cricoid is not disturbed. There was no necessity in this operation for stitching the walls of the trachea to the adjacent muscular tissue. The parts preserve their normal relations and the muscles of deglutition are much better able to perform their functions if the cricoid is not disturbed.

It will be noted, too, that the tracheotomy was made comparatively late in the operation, after most of the tedious dissection had been done. No apparatus for administering chloroform through the tracheal wound is very satisfactory. If sufficient pressure is maintained within the trachea to prevent the flow of blood into the bronchi, respiration is seriously interfered with. It is a distinct gain in the prevention of inspiration-pneumonia to open the trachea as late as possible, after most of the dissection has been completed and the bleeding stopped. In this case there was no more bloody expectoration than we expect to find after a tracheotomy. The position of the patient, with the head lowered and the foot of the table elevated, also aided in this result. At no time during the convalescence could even the smallest point of consolidation be found in either lung.

By giving a varied and liberal liquid diet, consisting chiefly of sweet milk, buttermilk, and beef-juice, the patient's strength had been maintained, although he lost some weight. So soon as solid nourishment could be taken he began to gain rapidly.

Laryngoscopic examination shows at the present time, internally, only a smooth cicatrix sloping back to the opening of the esophagus. Externally, we have a healthy cicatrix. The tracheotomy-tube has been worn since the hour of operation through the opening of the cricoid and has given the patient no trouble.

CEPHALHEMATOMA WITH CEREBRAL HEMORRHAGE.

By T. W. KEOWN, A.B., M.D.,
OF BALTIMORE, MD.

M. M., a strong and vigorous primipara, aged thirty-three years, of Irish parentage and medium height, and in good robust condition, was delivered of a female baby on July 13th, after a labor of twenty hours. The pains were normal in general, but owing to a rigid perineum they became very forcible toward the end of the second stage. The child weighed six-and-one-half pounds, and appeared in fairly good condition. Its circulation and respiration were normal. The caput succedaneum was not noticeably larger than would naturally have been expected in such a case. On the second day the child attempted to nurse and seemed to be as much alive as any other child of the same age. On the night of July 14th it became restless, and cried almost continuously in a low, feeble, whining manner. On the morning of July 15th it was much weaker, seemed to be wasting away, and was decidedly anemic-looking. The mother related that the baby had had fits, one of which occurred in my presence. The eyes of the child were rolled upward, and the arms and limbs were flexed and twitched spasmodically; giving, in general, the impression of a hemorrhage spread over both hemispheres of the brain. Examination of the head showed a soft fluctuating tumor over the right parietal bone extending to, but limited by, the sutures surrounding that bone. The child vomited frequently, had several spasms, no longer attempted to nurse, and died on the third day.

Dr. Wilmer Brinton was called in to see the child some few hours before death, and pronounced the case one of cephalhematoma with general cerebral hemorrhage. The anemia was then so pronounced that a very unfavorable prognosis was given. An autopsy was held on July 16th by Dr. Richardson, from whose report I have made the following extracts: On the right side of the head was a soft bluish swelling extending from a point 4 5 cm. from the external angular process upward and backward to the sagittal and lambdoid sutures and to the anterior fontanel, covering practically the whole parietal bone on the right side. On dividing the scalp there an effusion of dark blood was exposed. Over the parietal bone on the right side the pericranium was distended with blood, which spurted out on puncture. The extravasation of blood covered an area of 7.5x7.0 cm. On removal of the bone the dura mater was found firmly attached to the base and sides of the skull. Under the dura a large extravasation of blood forming a clot that extended over both hemispheres from the fissure of Rolando posteriorly to the occiput and into the transverse fissure. On both sides of the hemispheres in the parieto-occipital fissure were two spots about the size of the end of the index-finger in which softening and degeneration had occurred. These looked very much like abscesses, but Dr. Richardson was unable to say positively. The lungs were inflated and floated easily in water. The foramen ovale was still open.

Text-books regard cephalhematoma in infants as due to prolonged labor and mechanical injuries resulting therefrom. It is a particular form of caput succedaneum, but differs from the usual form in that the blood is poured out between the bone and the scalp, while in the ordinary type the blood is diffused into the surrounding tissues and gives rise to an edematous appearance of the scalp at that particular place where it happens to be situated, generally on one or other of the parietal bones.

In this particular instance we have these two forms of caput succedaneum existing together, as well as a large clot under the dura mater, pressing on the cerebral hemispheres. This pressure may have caused the softening and degeneration of the cerebrum in the parieto-occipital fissures, which looked so much like abscesses. The sub-dural clot contained about four fluidounces of blood, so that between the cephalhematoma and the cerebral hemorrhage it will be seen that the loss of blood was considerable.

The treatment in this case consisted in the administration of a little whisky in sweetened water, about ten drops to the teaspoonful, and such careful attention as the mother or nurse could give.

For the ordinary caput succedaneum no treatment is necessary, as it is entirely removed by absorption; but in the second form, the cephalhematoma, the absorption does not always remove the extravasation, and surgical interference is indicated. In such an event a linear incision ought to be made and the clot removed, with thorough antiseptic precautions. This form is generally confined to one bone, but may extend to two and very

rarely to three bones. The danger arises from the loss of blood. In the case reported, as the extravasation was confined to one bone, it was not sufficient in itself to cause the death of the child, which was chiefly due to the hemorrhage inside the cranium.

The diagnosis of cerebral hemorrhage is not always easily made in children, and in this case it was made too late to permit of benefit from surgical interference. What then could have been done? I do not think anything would have done much good, but if a case should arise that would allow time for medication I would suggest rest, to be secured by the use of bromids and chloral in warm dilute solution by the rectum and a little whisky by the mouth. These would secure an increase in the watery constituents of the blood by absorption and thereby counteract the loss of blood due to the hemorrhage. Later on, or immediately, if conditions indicated it, an operation might be attempted and the clot removed.

BONE-DISEASE DUE TO CONGENITAL SYPHILIS.

By PHILIP MILLS JONES, M.D.,
OF SAN FRANCISCO, CAL.

CASES of bone-disease due to hereditary or congenital syphilis, though they do not seem to teach any great lesson or give much promise of relief or cure, are perhaps sufficiently uncommon to be of interest. The case about to be reported was found in a district of Honduras seldom visited by foreigners, and through which I happened to be passing while on a hurried trip across that country. The impossibility of obtaining photographs or of more carefully studying the case is to be regretted.

The sufferer was a male, twenty-two years old, whose father had "died of syphilis" twenty years before, or when the boy was about two years old. The mother was still living, and said to have had the same disease as the father for twenty-five or thirty years. This statement was confirmed upon examination. For two years after birth the boy was to all appearances well and strong, but early in the third year a rash broke out all over the body, and persisted for some weeks, finally subsiding, and leaving the child well, but less strong than before. For the next five years nothing unusual was noted, except that the child was not very strong, and that small sores often made their appearance, lasting a few weeks and leaving spontaneously. When seven years old, however, a large sore developed on the ulnar side of the right forearm—as they expressed it, "the skin began to fall off"—and since that time for fifteen years the patient had never been without an ulcerating surface more or less extensive.

The condition of the young man, when seen on August 14, 1892, presented a picture that can never be forgotten. The head was large, with a small, infantile face and features, extremely large ears (the auricle measured 3½ by 2½ inches), and large protruding eyeballs. The body was rather small—about as large as that of a ten-year-old boy of ordinary development—and the genital organs were correspondingly small. There was a total absence of hair from the pubis, and the pelvis was on the same scale as the trunk. The shoulder joints and elbow-joints were unusually large, but the bones of the arms were small. The forearms measured nearly three inches more from elbow to wrist than the arms from shoulder to elbow, and the skin on the forearms was much more coarse and hairy than that covering the arms. A similar condition of the lower extremities was found, the legs being actually two inches longer (from knee to ankle) than the thighs, and covered with skin coarser and more hairy than that on the thighs. The knee-joints were large, but the feet and the ankle-joints were small. Until two years before, the patient could walk about quite well, but at that time his feet and legs commenced to swell, and became the seat of bone-changes, making walking impossible. The appetite was very good, and the alimentary tract did its work thoroughly, for he had never been troubled with any disturbance of the stomach or bowels. The man had always slept well, and complained of little or no pain, except from pressure on, or irritation of, an ulcerating area. When seen he was quite helpless, for degenerative changes had so far advanced in the knee-joints and ankle-joints as to make all forced movement very painful.

The head, except posteriorly to the parietal eminences, was one huge ulcerating sore. Destruction was most advanced over each eye, having apparently commenced just below the supraorbital ridge, and extending upward and backward, three inches on the right side and five inches on the left, covering both temporal regions. A strip of healthy tissue, about one inch wide, extended in the median line between these ulcers, but the bone on both sides was necrotic. Commencing immediately below the eyelids and ending on a line with the mouth was another ulcer, with the sloughing much more extensive and destructive on the left side.

Over the right scapula was an ulcer, measuring 5 inches by 3 inches, and on the left side, commencing at the angle of the scapula, extending upward over the shoulder and downward on the anterior surface of the arm for about 3 inches, was another necrotic patch. Large sloughing areas were found on the ulnar side of both forearms; from that on the right a piece of bone 2 inches long was discharged. On the right hand the terminal phalanx of the second and the whole of the third and fourth fingers had disappeared, but destructive changes seemed to have ceased for a time. The left arm was in pretty good condition, but the left hand presented a typical picture of active degeneration. There was far-advanced paresis of the second and third fingers, and an ulcerating stump was all that remained of the fourth or little finger. In the right foot the inflammatory process was apparently subsiding after an acute exacerbation which had resulted in a throwing out of a portion of the fibula just above the external malleolus; in the right foot the destructive change was progressive.

For three years previous to 1892 the man had taken mercury and potassium iodid in large doses without checking the sloughing process, and as, on the contrary, he continued to grow worse, all treatment had been discontinued. The sores were washed daily with warm water, and kept covered with cloths thickly smeared with lard, merely to keep out dirt and insects.

CROCKER BUILDING.

Dr. Hiram Woods has been elected Professor of Diseases of the Eye and Ear in the University of Maryland, in succession to Dr. J. J. Chisholm.

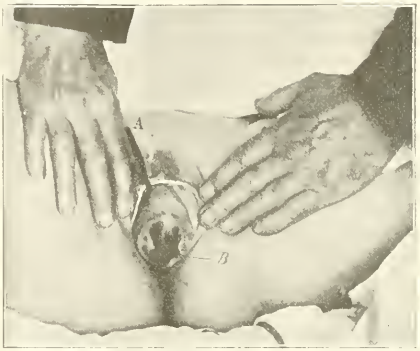
LARGE FIBROID TUMOR OF THE ANTERIOR WALL OF THE VAGINA.

By JOHN C. Da COSTA, M.D.,
OF PHILADELPHIA,
GYNECOLOGIST TO JEFFERSON MEDICAL COLLEGE HOSPITAL AND TO ST. AGNES HOSPITAL

Tumors of the vagina are so rare that Dr. H. N. Lewars[1] states that Hart and Barbour say that up to that time only 37 cases are reported in the whole literature. He was then reporting a case of fibroma of the anterior vaginal wall[2] that measured one-and-one-half inches antero-posteriorly and one-and-one-fourth inches transversely.

Dr. Alfred H. McClintock,[3] in 1845, reported a large tumor of the anterior wall that measured five inches in circumference; he ligated it with fishing-line around the base; it took four weeks altogether to remove it; there was sloughing and hemorrhage, and a small part of the urethra was cut off by the ligature. Mr. Paget,[4] of London, reported in 1861 that he removed a tumor "as large as a hen's egg" from the anterior right wall. The tumor was shelled out; recovery followed. Dr. Meadows,[5] of London, in 1868–9, removed one as large as a turkey's egg. He used an écraseur; the patient died in a few days. Dr. J. C. Moore,[6] of St. Louis, took out one in 1885 "as large as a California pear." He dissected it out and packed with carbolized gauze. Dr. Horatio R. Storer,[7] of Newport, R. I., in 1886 removed a large tumor of the vagina—probably the largest heretofore recorded—with an écraseur, by stretching the anus and pushing it out. Prof. A. R. Simpson,[8] in 1887 or 1888, took out a tumor "as large as two fists;" rooted along the entire anterior vaginal wall, upper two-thirds of the urethra, and part of the trigone of the bladder, to an extent in all of about five inches.

The patient upon whom I operated was a Pole, forty years old, who came into the Jefferson Medical College Hospital with a large tumor separating and projecting beyond the labia. A brief examination showed that it sprang from just in front of the cervix on the anterior wall of the vagina, and extended along the whole anterior wall to and even beyond the end of the urethra, and part of the way down on each side of the vagina. It was dense, and yet elastic, feeling something like a thick-walled cyst, but on incision it was found to be a fibroma. The measurements over the tumor before operation were: Antero-posterior diameter, six-and-one-half inches; transverse, four inches. It was quickly shelled out with knife and fingers. Only one artery needed to be tied. The large flaps that were left were cut off with scissors, the bed scraped with a sharp curet, and the incision closed just as in the operation for cystocele. There were no symptoms after the operation. In eleven days the stitches were taken out. There was perfect union from end to end, and a few days afterward the patient went home well.



Fibroma of the anterior wall of the vagina.
A. Sound in urethra.
B. Erosion from fricti

The photograph shows well the condition before operation. The black sound placed in the urethra shows the direction and how the tumor extended even beyond the opening. The dark spot on the tumor is an erosion caused by friction.

MEDICAL PROGRESS.

Early Ectopic Gestation with Rupture of the Tube from the Uterus.—Ross (*American Journal of Obstetrics*, vol. xxxii, No. 214, p. 567) has reported the case of a woman, thirty-four years old, who had borne three children, the youngest of which was five years old, and who, though not robust, had been in good health until a week before coming under observation. At this time she complained of a feeling of weight in the pelvis, but made little of it, until she was seized with sudden, violent pain in the umbilical region, soon followed by signs of collapse. The woman presented the appearance of a case of ectopic gestation with intraperitoneal hemorrhage, but no evidence of pregnancy could be found. The patient had menstruated naturally ten days before, and there had been no vomiting and no pain or swelling of the breasts. No urine had been passed for several hours, and catheterization brought away only a wineglassful. Vaginal examination revealed no tangible evidence, but palpation of the abdomen made it evident that there was a collection of fluid in the peritoneal cavity. The patient became almost pulseless and lay upon the right side, complaining of a dragging feeling when she turned on her back. The uterus was pressed toward the left, and the effusion of blood was upon the right side of the abdomen, although the ruptured tube proved to be upon the left side. In the hope that the woman would rally she was removed to the hospital and operation deferred. Her condition, however, remained so poor that ethyl chlorid was used as an anesthetic for the abdominal incision. The right tube was healthy; the

left could not be found. A drainage-tube was introduced into Douglas's cul-de-sac, and considerable blood escaped. The woman rallied a little, but symptoms of peritonitis developed. As the hemorrhage persisted ether was cautiously administered, and ethyl chlorid applied locally and ligature of the bleeding vessels undertaken. These were found in the isthmus of the tube close to the uterine cornu, a part of which it was necessary to include in the ligature. The tube was completely separated from the portion that remained attached to the uterus. The portion of the tube containing the ectopic gestation was no thicker than an ordinary lead-pencil, and the pregnancy could not have been of longer than two weeks' duration. The abdomen was speedily washed out and the hemorrhage ceased, but death took place twelve hours after the operation.

A Case of Pygopagus.—JACOBI (*Archives of Pediatrics* October, 1894, p. 721) has reported a case of pygopagus, together with the notes of thirteen other cases that he has succeeded in collecting from medical literature. The children were both females, and they lived for nearly five months. The labor was easy, the head of one fetus being soon followed by the lower extremities of the other and the rest of the joined twins. The placenta and the cord were single, the latter diving into two branches two inches from its velamentous insertion. The children were united below the third sacral vertebra, over an area having a diameter of an inch-and-a-half, in such a manner that the babies could lie almost alongside each other. The upper sacral vertebræ were distinct, the lower and the coccyx single. The backs of the infants were straight. There were two vaginæ, two clitorides, two urethræ, four labia minora, and but two labia majora. There was one anus, although the rectum was double. Tickling the soles of the feet of one of the infants elicited no response from the other. One cried by night and slept by the day; the other did the reverse. The pulse of one fetus was 122, that of the other 126. The sinistral child died eight hours before the dextral. Both children were markedly emaciated and presented numerous abrasions about the external genitals. The sinistral measured 48 cm. in length, the dextral 50 cm. The stomach of the latter was considerably larger than that of the former. The pelvic cavities of the two children were separated by fascia and peritoneum only. The lower ends of the spinal dura mater communicated through a space corresponding to the opening in the sacral canal, and both were greatly dilated. The spinal cords, however, were not fused. The band of union existed between the lateral masses of the sacrum, which was unusually developed. This part was partly ligamentous and partly cartilaginous. The external genitals could readily be separated. Each child had its own generative organs, and each its own distinct circulatory apparatus. The anus was common to both, but was largely situated in the dextral child. About ½ cm. above the anus was a well-developed antero-posterior septum, also more closely identified with the right child and thick enough to form a perfectly normal rectum for each.

Fatal Hemorrhagic Purpura in a Case of Tuberculosis.—At the recent meeting of the French Association for the Advancement of Science, GALLIARD and MARCHAIS (*Le Mercredi Médical*, 1895, No. 37, p. 439) reported the case of a man, aged thirty-seven years, in which thoracentesis had been performed for the relief of a right-sided pleural effusion. The general condition failed to improve despite the administration of creosote. While under observation hemorrhage took place from the gums; small bullæ filled with blood formed upon the tongue and the internal surface of the cheeks and lips; finally petechiæ appeared upon the lower extremities. Before death took place hematuria and melena occurred. Upon postmortem examination there was found, in addition to tuberculosis of the right lung, pericardial and gastric ecchymoses, and bloodclots in the pelvis of the right kidney.

THERAPEUTIC NOTES.

The Treatment of Ectopic Pregnancy with Injections of Morphin.—In the Section for Obstetrics and Gynecology of the recent Congress of German Naturalists and Physicians, PROCHOWNICK (*Deutsche medicin. Wochenschr.*, 1895, No. 40, Suppl. No. 25, p. 170) advocated the treatment of ectopic pregnancy during the first months by means of injections of morphin instead of by operation. He reported four cases successfully treated by a single injection through the vagina of from gr. ½ to gr. ¾ of morphin into the intact gestation-sac without aspiration. In three of the cases the pregnancy had not passed the twelfth week; in the remaining one, which was complicated by gonorrhea, this period had been passed, and in this case also an abscess formed that discharged through the rectum. In a fifth case the injection was made through the anterior abdominal wall, and the sac was infected by the needle passing through an adherent loop of bowel; septicemia developed and celiotomy was required, but recovery ensued. It is important to refrain from aspiration and to make but a single injection. The operation is contraindicated if the twelfth week has passed, if abortion is in process of occurrence, and if chronic gonorrhea or acute perimetritis exist. The vaginal is the only safe route of injection.

The Treatment of Prostatic Hypertrophy with Prostate Gland.—Stimulated by the results reported in the treatment of goiter by the administration of the thyroid gland of animals, REINERT (*Centralblatt f. d. Krankh. der Harn- und Sexual-Organe*, B. vi, H. 8, p. 393) was led to employ prostate gland in the treatment of prostatic hypertrophy. Four cases were thus treated: one was lost to observation after two weeks; in a second the treatment had to be discontinued for extraneous reasons; in the remaining two it was persisted in for six and eight weeks, respectively. In both of the last cases appreciable reduction in the size of the gland resulted, with corresponding amelioration of the symptoms. The size of the gland was determined by palpation, and a permanent record at once made in the form of a model. The prostate for administration was obtained from steers, and was prepared by being chopped in the fresh state and spread upon buttered bread. At first an eighth of a gland was given, but the dose was gradually increased to half a gland two or three times a week. The medicament can also be prepared in the form of a powder or tablets, or as a dry or glycerin extract.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including postage in U. S. and Canada.

Per Annum, in Advance	$4.00
Single Copies	.10
With The American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, OCTOBER 26, 1895.

ANOTHER PROPHET.

Who is Schlatter? Who is the prophet to whom belongs this euphonious cognomen? What is his divine right or his divine mission? All we know is that Schlatter is the New Mexican "Messiah," now starring somewhere in the remote West, and that he formerly lived on Long Island, where he was jilted by a girl.

It seems that Schlatter has assumed the somewhat threadbare rôle of a divine healer. He is a miracle-worker and a direct ambassador from on high. Like all his ilk, he displays no originality in his repertoire, but is content to work along on the old familiar ground as a conjurer who cures disease. There is, of course, some apparently deep-seated reason for this persistent reappearance of the therapeutic tendencies of these self-constituted prophets. They all run naturally to pathology. This reason, however, is not far to seek. It is found in the simple fact that disease is the universal heritage of mankind; the one inevitable and frightful opponent from whom no man escapes if he lives long enough. Hence the pseudo-Messiah always finds a favorable situation ready-made for him. The logic of fate is always his. He has the best *argumentum ad hominem* that was ever constructed. He has only to appeal to the sempiternal fear of death and to demonstrate his ability to control or to banish the hideous demon, disease, and all will be accounted to him for divinity, with a direct commission from on high. It has always been so in every age of mankind, and it will doubtless continue to be so. In the evolution of myths the heroes and the warriors have always been secondary to the prophets and priests who dispense healing.

It is thus readily seen that scientific medicine has but little concern with these practices and the claims upon which they are based. They teach her nothing but what she already knows. They demonstrate the meager facts that the human mind is easily possessed with strange delusions; and that the strangest of these is the delusion that disease can be abolished by a miracle. As a subordinate fact, they sometimes demonstrate the influence of hypnotic suggestion in controlling favorably some diseases in the psychic and psycho-motor spheres—but for these demonstrations science cares but little to-day. She can make such demonstrations for herself in the hospitals, without resorting to the jugglery and impostures of religious fakirs.

That Schlatter is an uncombed and uncouth humbug goes without saying. He lets his hair and beard grow long, of course, and inserts his picture in the newspapers. Before he went West, however, he observed tonsorial rites, and is shown at that period of his career in another picture as a smug-looking Philistine of Long Island, as yet unjilted by a girl.

Crowds wait upon Schlatter. The people who run after him are all intent upon one thing—the cure of their diseases. A press-dispatch says that a multitude in Denver attended upon him in order to merely touch the hem of his garments, owing to the report that fabulous cures had been effected in persons who had merely looked at the face of the healer. Such phenomena, of course, are as old as the hills. Denver is a comparatively young town, and probably wants to demonstrate to students of anthropology that she, too, partakes of some of the antique follies of the human race.

The enthusiasm of the Denver populace could not be tempered even by the unseasonably cold weather that swept down recently from the Rocky Mountains. The intense cold and the dire distress caused by it did not deter the crowd. At 10 o'clock at night people began to flock to the vicinity of Schlatter's house, so as to be in line early on the

following morning. The thermometer had just fallen to below the freezing-point from the height of eighty degrees. Five inches of snow covered the ground.

The crowd was not limited to the poor. Well-dressed and well-to-do people were foremost in the line, and pleaded for the condescension and regard of the hirsute prophet.

The effect of all this upon such a mind as Schlatter probably has can readily be foretold. Whatever sincere self-knowledge and humility he may possess will soon of course be hopelessly corrupted. The inner light of his own consciousness (if he has such an illumination) will soon be distorted and broken up through the prism of religious delusions. It is probable enough that he is not a man of mentally sound health; such men seldom are. But if he has any honest and sound intellect left, the Denver people will soon give the *coup de grâce* to it, and convert Schlatter into a fanatical lunatic.

These considerations suggest the only practical points in this affair of Schlatter. First, for his own good he should be saved from the Denver and every other rabble, which would soon convert him from an incipient paranoiac into a confirmed monomaniac. Second, he should be submitted to an examination before a commission to determine the degree of his mental unsoundness, and if he is found sincere in his delusions he should be committed to an asylum. Third, if he is at heart merely a perverted enthusiast, who obstinately persists in his alleged healings, he should be made either to produce a licence to practise medicine or to cease his present course.

The modern world is striving to rise above the stage of myth-culture. Modern society has a right to protect itself by an appeal to the well-established laws of medical science and of sociology. Tolerance of such archaic types as Schlatter is neither a kindness nor a duty. The State owes it to itself and to its citizens to control with firm and even-handed justice all such aberrations from a wholesome standard.

LIFE-INSURANCE STATISTICS.

THE great life-insurance companies of this country have stored up in their offices material which, if properly investigated, would be of inestimable value to the medical profession, and throw light on more than one problem now in need of it. A business that receives 300 medical reports daily, and writes 10,000 policies each year, as many of the old-line companies do, must have some statistics worth analyzing.

These statistics have a value not only because of their mass, but also because they deal with a class, or rather with classes, of individuals, that probably differ markedly from those usually studied in hospitals, in public institutions, and in the army and in civil service. The insurance-companies endeavor to select the healthy, the normal, the well-to-do, the successful, and hence any data compiled from their records must be of special value as an indication of the normal.

Dr. Marsh, Medical Director of the Mutual Life-Insurance Company of New York, has published three short papers on questions pertaining to medicine, utilizing the experience of the company, and subsequent pamphlets are to appear primarily for the benefit of life insurance companies, and it is hoped that, indirectly at least, they will be of service to the medical profession. At any rate, these papers may stimulate the medical officers of other insurance companies to give to the world the results of their experience, and to present statistical evidence in such form that it can be readily used by investigators.

In his paper on "Gout," as affecting the insurance of lives, Dr. Marsh finds that although the company has been careful to exclude applicants presenting a history of gout, and in some 300,000 policies has only written 58 on gouty lives, its experience with these few has been an unprofitable one.

The lives of 48 gouty persons were insured because there was some doubt in their history, or because an attack had not occurred for a long period, or because some other reason made the risk seem a good one; but even among this selected class the mortality-rate was greater than was expected, and the duration of life less than was calculated. The extra premium charged did not cover the cost.

The English companies have had a similar experience, gout, of course, being more common with them. The conclusion is reached that "in every case the presumption is against the acceptance of an applicant who has had gout, and the case must be proved to be suitable for an exception after more than ordinary scrutiny and investigation."

Exceptions might be made in cases in which there is an entire absence of hereditary tendency, when the first attack shall not have appeared before thirty years of age, when the attacks are few in number, slight in character, and several years have

elapsed since the last one; and when uric-acid deposits, gravel, and other symptoms of lithemia are absent.

In his paper on "Syphilis" Dr. Marsh has no statistics of his own to present, because it has been the rule of his company to refuse all applications for insurance when a history of syphilis was given. This rule, he thinks, can be modified in the light of experience so as to admit such syphilitics as have been subjected to proper treatment, and who have passed a period of six years without developing tertiary lesions. He quotes Fournier's statistics to show that in more than one-half of 2395 cases of tertiary syphilis the symptoms presented themselves within six years, and in only 28 per cent. were they delayed ten years. The results of this ruling if put in operation will be of great interest as bearing upon the question of the duration of the symptoms of syphilis (and the influence of these on the length of life), although many years must elapse before the figures will be of value.

The effect of disease, race, and occupation in influencing length of life and the importance or non-importance of hereditary taints are some subjects that can receive much light from life-insurance statistics, and it is to be hoped that the several companies will be less selfish than before, and that they will devote a portion of their surplus to scientific statistical investigation, with a view of enlightening the medical profession, which in the end means the welfare of the community as well as protecting themselves from unprofitable risks.

ABNORMAL ARRANGEMENT OF BRAIN-CONVOLUTIONS.

In his presidential address before the Section of Psychology of the British Medical Association, W. J. Mickle spoke of the abnormal forms and arrangement of brain-convolutions, and showed how little of value there is known on the subject. The normal brain has hardly been sufficiently studied, so that a standard does not yet exist. Benedikt, in his study of the brains of convicts, claims to have found in them features suggesting resemblance to simian brains, but Bischoff, Binswanger, and other observers have found such characteristics as often in the brains of supposedly honest individuals, and Maudsley wonders "if the stigmata of degeneracy, which the Lombrosian school would have found in Saul, the persecutor of the early Christians, would have vanished when he became Paul the apostle of the Gentiles." If fissures on the surface of the brain are so important in determining the quality of the brain-structure, why may not the convolutions of the intestine, the folds of the skin, the depth and complexity of the rugæ of the stomach be likewise studied with a view of locating the exact position the individual occupies in the evolutionary scale?

Formerly, the *weight* of the brain was held to determine the relative intelligence of the person possessing it; however, when idiots were found with large brains and some bright men with small ones, this theory was dropped, and the thought was given out that superiority consisted in the greater number of convolutions, which allowed a greater amount of gray matter to occupy a definite space. But now we have some criminologists who say that the degenerate brain often shows a most complex system of fissures and convolutions; and that an extra convolution here and there is not at all uncommon. Thus we are finally forced to search the ultimate histologic nerve-cells in the endeavor to find the characteristics of the criminal, insane, idiotic, and mattoid brain; to discover there, if we can, what induces the one to steal, the other to remain upright; what allows the one to become a genius, the other to remain an average man. Having, for instance, once located the center for honesty, we could for the relief of abnormal conditions cut down upon it, remove the growth or relieve the pressure present, and reform our criminals; soldiers could be inoculated with a toxin acting as a stimulant on the murder-center; and prostitutes would have no need of their profession after the appropriate operation on the center for chastity. What is most needed is a carefully determined standard of the normal brain, and until this is obtained we cannot come to any positive conclusions in regard to variations. The vagaries of the faddists of the anatomic school well illustrate the disgusting tendency of many pseudoscientific investigators, who go at every subject with theories and prejudices and dogmatisms as unscientific as any medieval "bigot." The basis of all true science is unprejudiced, uncolored induction from carefully observed facts.

The Judicial Council of the Association of American Medical Colleges has decided that its constitutent members may graduate in 1898, students matriculating in 1895 and attending three full courses of lectures of six months each in three separate years.

EDITORIAL COMMENTS.

The Noise-nuisance.—One of the best arguments we know of against the frequently heard statement that modern nerves are becoming morbidly sensitive is the indifference usually manifested toward the horrible noises and din of city life. Bring a country-bred individual, either man or horse, suddenly upon one of our busy thoroughfares, and the thing he is at once most keenly conscious of is the maddening, deafening jangle and tangle of frightful noises. He hears every one of them at once and in equal degree, and is literally paralyzed by conflicting impulses to escape from them all. The city dweller, on the contrary, simply treats them as if they did not exist, and by a remarkable feat of nervous toleration not only is not annoyed by them, but is actually unconscious of them all, unless they develop unusual or threatening tones, when he notices them at once. Like the street-broken horse he has learned by experience that none of them is going to hurt him, and his brain-centers ignore them. He still hears them, however, as is shown by the fact that he is even quicker than his country cousin to detect among them the wild rattle of a runaway or the fierce gong of the ambulance or fire-engine, which he must look out for at once. And this tolerance assumes even more remarkable forms. Not only is he not disturbed by the noises, but he actually seems to depend upon them and is disturbed by their absence. The man about town often cannot sleep well in the country for the first few nights "for the deadly stillness." Those who live in the near neighborhood of mill-dams, mills, and machinery will wake instantly in the night should the machinery stop, and often complain after moving to other neighborhoods that they "miss the noise." Nevertheless, in spite of the wonderful powers of accommodation of the human nervous system, endurance has its limits and the noise-nuisance is a most disagreeable and injurious factor in our city life. Especially is this true of those noises which are periodical or occasional, and which occur at unseasonable hours of the night or early morning, such as early church-bells, trains, fish-horns, milkmen's bells, and pedlers' shrieks. In many quarters a determined effort is being made to put a stop, so far as possible, to these attacks upon the rest and comfort of the community. This cannot be too highly commended, although in a couple of recent instances the attempt has developed a somewhat amusing situation.

The first is that of an English gentleman, who, after vainly endeavoring to abate by process of law a vain and extremely noisy chanticleer belonging to an attaché of a foreign legation next door to his house, finally adopted the bold means of writing directly to the sovereign of the obdurate official. Whether he used a special-delivery stamp or a registered letter is not stated, but, although he got no reply, the rooster promptly disappeared to the great relief of the complainant's insomnia. The other is the controversy that has sprung up over the action of the Board of Health of an eastern village in requesting the rector of an Episcopal church to discontinue certain chimes which were accustomed to ring at seven o'clock on Sunday morning. As the chimes in question admittedly rang out three tunes of two verses each, followed by a "general peal" about five minutes long, they were certainly well adapted to thoroughly disturb the Sabbath slumbers of the neighborhood, and numerous complaints were made to the board by business-men deprived of their most precious Sabbath privilege, the Sunday-morning sleep. These were backed up by reports of sick persons whose scanty slumbers were rudely broken, until finally the board rose to the emergency and issued the order aforesaid. While they were in the vein they also made demonstrations against the gongs and bells of certain bakers and milkmen, and even appointed a committee to wait upon the superintendent of one of the railways to protest against the whistling, ringing of bells, and blowing off of steam on the part of an unnecessarily obstreperous and self-important freight-train that passed through the village in the early morning hours. Diletantteism in religion and esthetics at once united with general obstreperousness, and such a disturbance was made that the board found it wisest to rescind its order, and the chimes remain in possession of the field—a plain instance of copartnership of church and devil.

The loyal American has been taught for generations the diabolical lesson that to celebrate or to enjoy oneself means to make the most fiendish noises possible. It is amazing the misery that people will cause and endure on the manifest pretence of having "a good time." Few things are more indicative of the deplorable dearth of genuine pleasure than the noise-making mania. Contemplate street-car loads of lunatics, all at once screeching, bawling, howling, drum-beating, horn-blowing, fife-squealing, tearing through a city in the middle of the night. Think of the nervous systems of a million people that will endure that, and think of the police-system that smiles at it! What hope of civilization is there in such a condition of affairs? The health of well people is endangered and the lives of the ill are shortened by a hundred such crimes against sleep and rest. It is time that medical men and medical societies entered upon a combined crusade against the pernicious indifference of the police to the brutalities of the noise-makers. It is useless for individuals as individuals to complain. We who know that only by proper sleep and rest can the human organism carry on the work of modern life should seek to prevent the atrocious cruelties of those who make useless noise, and especially during the night.

Diphtheria in Philadelphia.—The death-rate in this city from diphtheria continues to be as great as ever, and the number of cases this year will not fall far short of the number occurring last year.

For the nine months ending September 1, 1895, the Medical Inspector had reported to him 2213 cases with 726 deaths, a mortality-rate of 32.8 per cent. For the same period last year there were recorded 2402 cases and the death-rate for the whole year was 33 per cent.

The following table shows the number of cases with the deaths for the past five years:

Year.	*Cases.*	*Deaths.*	*Per cent.*
1890	1820	528	29.0
1891	3251	918	28.2
1892	5053	1435	28.3
1893	3149	916	29.0
1894	3159	1047	33.0

From this table we see that there has been but little change in the virulence of diphtheria for the past five years, and that change for the worse.

According to all accounts we should have expected, with the establishment of the bacteriologic laboratory, a greater number of cases of a mild nature, and a consequent diminution in the total death-rate. This has not happened, and the death-rate of 32.8 per cent. for the nine months of 1895 shows how fatal the malady still is.

On the other hand, from all parts of Europe come authentic statements reporting a marked reduction in the death-rate under the use of the antitoxin. The remarkable fact that over 400,000 doses have so far been used without serious effects establishes the innocuousness of the new remedy beyond a doubt. Realizing this fact it seems that the antitoxin is worth a trial, not only in undoubted cases of diphtheria, but in all suspected cases, as all other methods of treatment, in Philadelphia at least, have shown themselves to be of comparatively little service.

Yellow Fever in Cuba.—Poor Cuba has more than one host to contend with. The invasion of the land with Spanish troops has not as yet resulted in much bloodshed, the majority of battles ending with few wounded on either side; but "yellow jack" has been rather busy among the inhabitants. The United States Sanitary Inspector reports that during the month of September 650 deaths occurred in the city of Havana, of which number 126 were caused by yellow fever, and during the week ending October 3d, 90 new cases appeared, with 29 deaths. The majority of these cases are among the military, and the Spanish soldier unaccustomed to the climate falls a prey readily to the malady. This battling with yellow fever is a form of warfare not taught in military colleges and the insurgents are greatly profiting by it. "It's an ill wind blows no one good."

REVIEWS.

Clinical Gynecology, Medical and Surgical, for Students and Practitioners. By Eminent American Teachers. Edited by John M. Keating, M.D., L.L.D., and by Henry C. Coe, M.D., M.R.C.S. Pp. 994. Philadelphia: J. B. Lippincott Company, 1895.

The astonishing growth of gynecology as a special and distinct branch of surgery and medicine is fully exemplified in this handsome and massive volume presented by the eminent editors, the late lamented Dr. John M. Keating and Dr. Henry C. Coe. It is safe to assert that within the past decade and a half no other branch of medical science has made such progress as has that dealing with the diseases peculiar to women, and the technic of abdominal surgery during this period has been entirely revolutionized, mainly through the efforts of the gynecologist. In the present volume, in addition to the editors, such men as the late William Goodell, William H. Baker, Francis H. Davenport, Hunter Robb, Bache McE. Emmet, Barton Cooke Hirst, Matthew D. Mann, William M. Polk, J. Whitridge Williams, Henry T. Byford, Paul F. Mundé, Hermann J. Boldt, William T. Lusk, Chauncey D. Palmer, Charles Jewett, John Polak, Edward E. Montgomery, Dudley P Allen, Louis A. Duhring, and Milton B. Hartzell have brought their best efforts to bear in presenting in a most acceptable form the various subjects allotted to them. That they have succeeded it is hardly necessary to say. It would be invidious to single out any one article or series of articles as being of more than usual merit. All have been written by men who have attained eminence and fame in their chosen branches, and while some of the views advanced cannot be indorsed by all, and while there are others that it would have been better, perhaps, to have entirely omitted from the book, on the whole the volume may be said to fairly represent the status of gynecology in America. However, there is no perfect book, and with its virtues this volume has its defects and blemishes. Together with all other composite books it is open to the criticism of the promulgation of diverse opinions, often diametrically opposed, as well as to waste of space arising from unnecessary repetitions in the various articles from inability on the part of the authors to draw a clearly defined line of demarcation. It is also to be regretted that so much space has been given to a description of the various forms of pessaries, which we cannot admit to be "necessary evils," but which are rapidly growing obsolete, except in a very limited proportion of cases, and which merely represent the transitional stage from inaction to appropriate surgical intervention. The pessary is merely a palliative means, and palliative measures should never be resorted to when operative procedures may be adopted. The pathetic feature connected with the work is the death of one of the editors, Dr. Keating, prior to the publication of the book. His work in gynecology and pediatrics will live after him and will continue to live as long as medicine lasts. A similar melancholy interest attaches to the introductory remarks by Dr. Goodell, the last published writing of one who may be designated as the father of American gynecology. This contribution is characterized by the conservatism that marked the methods of Dr. Goodell for a few years prior to his decease. The work of the publisher has been well done, and the book, in consequence, presents a bright and attractive appearance. The type is good, the illustrations clear and numerous, and the indexing satisfactory.

A Text-Book of Practical Therapeutics; with Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by Drs. G. E. de Schweinitz, Edward Martin, and Barton C. Hirst. New (fifth) edition, thoroughly revised. Octavo, 740 pages. Philadelphia: Lea Brothers & Co., publishers, 1895.

A book that has reached its fifth edition is practically beyond the range of criticism. Though it may have faults, it must yet fulfil a want, or possess neutralizing qualities, in order to commend itself to the favorable consideration of those who need an authoritative expression or a faithful representation upon the subject with which it deals. In addition to the usual revision and emendation, a few paragraphs on the antitoxin-treatment of diphtheria have been incorporated in this new edition. On the other hand, not a word is said as to the similar

method of treating tetanus. Under the subject of asphyxia we are unable to find a reference to rhythmic traction of the tongue. Among the salts of strontium the salicylate has failed to receive mention; nor are ammonium salicylate and cinchonidin salicylate considered. In the treatment of acute opium-poisoning, nothing is said of the use of potassium permanganate. Neither myxedema, nor cretinism, nor thyroid extract is anywhere in the book even named.

CORRESPONDENCE.

NEW YORK LETTER.

New York State Medical Association.

THE twelfth annual meeting of the New York State Medical Association has just been held here under the presidency of Dr. Austin Flint. As usual, a wide variety of subjects has been covered. In a paper entitled

A CLINICAL REPORT ON ORTHOPEDIC SURGERY,

DR. S. E. MILLIKEN, of New York County, described what he believed to be the first instance in which a healthy muscle had been made to do the work of one that was completely paralyzed without interfering in any way with the work of the former. The case was one of long-standing infantile paralysis, which had not been benefited by mechanical treatment, and in which the child, a boy of nine years, seemed doomed to be a cripple all his life. Examination showed that the tibialis anticus muscle was the one chiefly involved, and that consequently flexion of the foot was accomplished through the agency of the extensor proprius pollicis, the extensor longus digitorum, and the peroneus tertius. Accordingly, under ether, the tendons were exposed and flaps taken from the tendons of the tibialis anticus and extensor proprius pollicis. These were then united by fine interrupted sutures of kangaroo-tendon, and the outer sheath of the extensor proprius pollicis sewn to the inner sheath of the tibialis anticus so as to make a new sheath for these newly united tendons. After the foot had been placed in proper position by manual force, a plaster-of-Paris dressing was applied, and was continued for six weeks. The boy had become quite expert on roller skates, and could abduct the foot nearly to the normal limit.

DR. JOHN G. TRUAX, of New York County, proposed the use of alcohol as

A DOMESTIC TEST FOR ALBUMINOUS URINE.

This agent, which can be readily procured at a moment's notice in almost any household, is a convenient reagent for the purpose named, and may be of any strength between 60 and 95 per cent. The test is made by placing the alcohol in a test-tube, or even in a tumbler, and dropping into it some of the urine to be tested. If albumin be present the alcohol would be filled with white streaks as the urine sank down to the bottom of the vessel, or if a large quantity of albumin were present the alcohol would become cloudy. Mucus would also respond to this test, but with this difference, that the cloudiness would be quickly diffused through the alcohol, and not appear in streaks. Dr. Truax said that he considered this test fully as accurate as any of the others usually employed, and even more delicate.

The next paper presented a somewhat novel subject. Its title was

THE CAUSE OF MUCH SICKNESS THAT IS OFTEN OVERLOOKED,

and its author was DR. W. H. ROBB, of Montgomery County. The sanitary condition of two houses, one in the city and the other in the country, was considered, and the conclusion drawn that various cases of illness, *e. g.*, diphtheria and remittent fever, occurring in these two houses during a period of many years, were due to the existence of "dry rot" in the timbers of the cellars. One case of remittent fever had persisted for eighty days when, at the suggestion of Dr. Harris, then secretary of the State Board of Health, who saw the case in consultation, and was disposed to attribute the prolonged illness to the dry rot in the cellar-flooring, the boy was removed to the upper part of the house. The remissions ceased after another day, and convalescence was rapid and uninterrupted from that time on.

DR. HENRY MCM. PAINTER, of New York County, delivered the

ADDRESS ON OBSTETRICS.

It was devoted to a consideration of the many glaring deficiencies in the present method of teaching obstetrics in the various colleges, and to an arraignment of that relic of the past—the didactic lecture. After describing the pitiable plight in which the recent graduate of medicine usually found himself when attending his first cases of labor, attention was called to the carefully graded system of instruction in practical obstetrics which was the foundation-stone of the now widely known work of the Society of the Lying-in Hospital of the City of New York. This institution and the Sloane Maternity Hospital, the speaker said, were the only places in this country where practical obstetrics was regularly and systematically taught.

DR. WILLIAM H. PARK reported some

RECENT STUDIES ON DIPHTHERIA AND PSEUDO-DIPHTHERIA.

He said that as there are now upward of 10,000 reported cases of diphtheria which have been treated with the diphtheria-antitoxin, statistics are of some value. His conclusions were: (1) That the diphtheria-antitoxin has a distinct curative effect in diphtheria; (2) that the results are better when the injections are used early in the disease and when the disease is uncomplicated; (3) that the total quantity required varies from 1000 to 4000 units of Behring's standard, according to the weight of the patient and the severity of the disease; (4) that immunity is conferred by injections of the serum, and that this immunity lasts for four weeks; (5) that it has not been observed that the antitoxin has caused any serious disturbance of the kidneys; and (6) that its only observed injurious action is to produce a temporary diminution in the number of the red blood-corpuscles.

Reference can only be made to some of the many conditions considered by DR. JOHN E. WEEKS, of New York County, in his paper on

THE EMERGENCY-TREATMENT IN ACUTE DISEASES OF AND INJURIES TO THE EYE.

For hordeolum, he recommended the application of moist heat for twenty-four hours or more, and, as soon as pus is present, free puncture. After this, the treatment consists in bathing the part with hot water several times a day. In referring to diseases of the conjunctiva, the warning was uttered that "all acute diseases of the conjunctiva accompanied by a discharge are contagious." In gonorrheal conjunctivitis, it was recommended that the eye should be carefully cleansed with a 3 per cent. solution of boric acid, the lids being everted. The surface of the palpebral conjunctiva should be freely painted with a 1 per cent. solution of silver nitrate, and the eye should be washed as often as is necessary to keep it free from secretion. Cold should be applied to the eye at intervals of two or three hours until the swelling begins to subside. The same general line of treatment is to be followed in cases of ophthalmia neonatorum. Corneal ulcers may sometimes be aborted by a cautious application of pure carbolic acid, carefully limiting its action to the affected spot. To prevent discoloration of the lid after contusions, a light ice-bag or ice-cloths should be applied for the first twenty-four hours, after which time the aim should be to hasten absorption by hot bathing. When the eye has been burned by the entrance of lime, it is well to wash out the eye with milk, or else with oil, and then instil a strong solution of sugar, which renders the lime inert.

Dr. Charles Stedman Bull, of New York County, read the clinical histories of

SOME UNUSUAL CASES OF ORBITAL AND INTRAOCULAR TUMORS, EMPHASIZING THE NECESSITY OF CAREFUL DIFFERENTIAL DIAGNOSIS.

This was followed by a paper by Dr. Heil J. Hepburn, of New York County, detailing the clinical record of two cases, together with some

NOTES ON THE DIAGNOSIS OF INTERSTITIAL CEREBRITIS.

The evening session began with the Address on Medicine, which was delivered by Dr. A. A. Smith, of New York County. It was entitled

THE PRACTICE OF MEDICINE IN THE LIGHT OF BACTERIOLOGIC RESEARCHES.

In summing up the various ways in which bacteriology has influenced medicine, Dr. Smith said that bacteriologic research has made clear many points in the etiology of disease which have been obscure; it has offered a scientific explanation of the communicability of many diseases; it has made diagnosis more definite, and prognosis more accurate; it has explained complications before but little understood; it has revolutionized surgical and obstetric practice; it has prevented the spread of many dangerous epidemics; and it has led to the specific treatment of diphtheria, and possibly also to that of tetanus, as well as to the conferring of a temporary immunity.

Dr. William Carr, of New York County, then read a paper on

EMPYEMA OF THE ANTRUM,

in which he stated the belief that the vast majority of these cases originate from diseased teeth. The treatment recommended by him is an opening into the cavity through an alveolus, preferably at the second molar tooth, and the closing of this opening with sterilized gauze, except when it is desired to wash out the sinus with a weak antiseptic solution. He objected to the use of drainage-tubes, particularly those made of silver, as they corrode very rapidly, and are liable to slip into the antrum.

Dr. Edward B. Dench, of New York County, offered some

GENERAL SUGGESTIONS REGARDING THE DIAGNOSIS AND TREATMENT OF ACUTE AURAL INFLAMMATION.

He called attention to the fact that while in an adult tenderness on moving the auricle, or on pressure in front of the meatus, is almost pathognomonic of inflammation of the external canal, in infancy this sign is a strong indication of inflammation of the middle ear. Early in an attack, the local abstraction of from one to four ounces of blood, with one full dose of morphin, often gives great relief, and checks the inflammatory process; but under no circumstances should more than one dose of an opiate be given. Dry heat, *e. g.*, by means of small salt-bags made of old glove-fingers, is very grateful, and should always be employed in preference to moist heat. The latter is distinctly harmful by its tendency to produce, or rather to favor, tissue-necrosis. If after such treatment the symptoms continue urgent, a free incision should be made with the object of depleting the tissues. If this is done according to the rules of aseptic surgery, it is a safe procedure, even in the hands of the general practitioner.

Dr. George E. McDonald, of Schenectady County, reported a remarkable case in which he had been able during life to diagnosticate the following conditions, and to have them confirmed by autopsy: Acute hepatitis; gallstones; abscess of the liver rupturing into the bronchi; extrauterine pregnancy.

Dr. H. M. Silver, of New York County, read a paper on

FOREIGN BODIES IN THE ESOPHAGUS.

After describing several interesting cases of this kind, he said that when a sharp, jagged body has been swallowed, no attempt should be made to extract or push it down, but it should be at once removed by operation. The use of catheters, small esophageal bougies and the sponge-probang is to be condemned. The best instrument for determining the location of a foreign body in the esophagus is a metallic bulbous bougie, provided with several knobs of different sizes, and with the stem graduated so that the operator can readily determine the exact distance of the body from the upper incisor teeth. When the body is less than thirteen inches from the upper incisor teeth, it should be removed by esophagotomy; if at the cardiac orifice, or just above, by gastrotomy, if possible; if not, then by intrathoracic esophagotomy. It is not necessary to suture the wound in the esophagus, and this should never be done if the esophageal wall is infiltrated, or approaching a condition of gangrene. The external wound should never be completely closed. No food whatever should be given by the mouth for twenty-four hours after the operation, but after this the

patient may be fed entirely by the mouth. Rectal alimentation, it was held, is not to be relied upon, and the use of feeding by esophageal tubes is unnecessary.

DR. CHARLES G. STOCKTON, of Erie County, then reported

A CASE OF CARCINOMA VENTRICULI, WITH THE CONTINUED PRESENCE OF FREE HYDROCHLORIC ACID AND THE ABSENCE OF LACTIC ACID.

DR. MAX EINHORN, of New York County, followed with a paper on

GASTRO SUCCORRHŒA CONTINUA CHRONICA,

a condition in which gastric juice, or a similar fluid, is freely excreted even during the fasting period.

The afternoon session was devoted to the Discussion on Surgery, the special theme being

THE PROGNOSIS OF MALIGNANT TUMORS AS MODIFIED BY THEIR MANAGEMENT.

DR. JOSEPH D. BRYANT, of New York County, in opening the discussion, said that statistics showed that carcinoma is on the increase in this country. Those organs or parts of the body having a special physiologic significance, and the most exposed to the effects of perverted habits, are the ones most frequently affected by malignant disease. The fact that during the first forty-five years of life, the time of greatest vulnerability and activity, there is the least malignant disease, would argue against the theory of malignant infection. In considering the management of these cases, Dr. Bryant said that the local treatment of malignancy should be characterized by prompt discovery and acknowledgment of the presence of a tumor, prompt advice as to treatment, and the prompt removal of the growth and all infected tissues. The diagnosis could be made certain at an early date by microscopic examination of a small portion of the growth removed with a "harpoon;" although an exploratory operation is the only true test of the exact state of affairs. The latest and most radical methods of operating for the removal of malignant disease of the female breast now gave twenty-six per cent. of practical cures—those cases in which no recurrence takes place for three years after the operation. The use of special toxins should be considered as an aid and not as a substitute for the knife.

DR. JOHN W. S. GOULEY, of New York County, spoke of the effect of early detection and prompt ablation of malignant tumors. He said that when both sarcomata and carcinomata are excised in their incipiency, the period of immunity is greatly prolonged. His experience has taught him that the majority of external malignant tumors have developed as benign growths, and have become malignant by a retrogressive process.

DR. EDWARD K. DUNHAM, of New York County, discussed

THE METASTASIS OF TUMORS.

A carcinoma, he said, has no clearly defined boundary, and its infiltration of the surrounding tissues may be looked upon as a sort of metastasis. The time when metastasis occurs bears no relation to the size and age of the primary tumor. As soon as any tumor forms it is liable to metastasis; hence the logic of prompt ablation.

DR. CHARLES PHELPS, of New York County, said that as no one can predict the time when a benign tumor may take on malignancy, the rule should be to promptly remove all accessible tumors.

DR. PARKER SYMS, of New York County, speaking upon the question of

THE KNIFE VERSUS CAUSTICS IN THE REMOVAL OF MALIGNANT DISEASES,

said that in the use of caustics pure guesswork is substituted for the intelligence and skill of the surgeon; that the action of the caustic establishes a direct communication between the diseased mass and the surrounding tissue, thus favoring infection; and that the result is more disfiguring than when the knife is used.

DR. FREDERICK HOLME WIGGIN, of New York County, spoke of

THE IMPORTANCE OF THE COMPLETE REMOVAL OF A MALIGNANT GROWTH AND OF THE RAPID CICATRIZATION OF THE WOUND.

He quoted statistics showing that when the lymphatic glands are not removed with the diseased mass, recurrence takes place in as many as 45 per cent. of the cases, whereas according to Dr. Dennis 25 per cent. of his cases of carcinoma of the breast have remained three years or over without a recurrence of the disease. It should, however, be remembered that it is not enough to remove only those glands that are enlarged and palpably diseased; all the lymphatic glands in the vicinity of the disease should be extirpated.

DR. FREDERIC S. DENNIS, of New York County, said, regarding the constitutional remedies and so-called specifics for malignant disease, that experience has shown that any beneficial action that they possess in certain cases is really due to their action as general tonics. He has seen a few cases in which supposed sarcomata have been rapidly reduced under a course of potassium iodid, but there is a possibility that these tumors were gummata. The spontaneous disappearance of tumors has been observed occasionally, but it is a mere surgical curiosity. It has been assumed by surgeons, when a tumor does not recur within three years after an operation, that the case is cured, for experience has shown that recurrences after this period take place in only 2 per cent. of the cases.

DR. STEPHEN SMITH, of New York County, speaking of recurrent tumors, said that they should be attacked and removed, whenever and wherever practicable.

DR. WILLIAM B. COLEY, being invited to speak of the therapeutic value of toxins in the treatment of malignant disease, said that he had analyzed 100 cases which he had treated during a period of four years with the mixed toxins of erysipelas and the bacillus prodigiosus. No case of pure round cell sarcoma has been cured, and the melanotic sarcomata and osteo-sarcomata are about as obstinate to the treatment. The spindle-cell variety is more amenable, so that in the 66 cases of sarcoma more than half have been improved by the treatment.

DR. AUSTIN FLINT, JR., of New York County, presented a study of some very carefully compiled statistics representing

OBSERVATIONS ON THE MINOR DEGREES OF CONTRACTED PELVIS.

They embraced the carefully kept records of 6000 cases of labor occurring in the tenements. Minor pelvic contractions were found in a little over 10 per cent., and in the majority of these delivery was effected spontaneously and with a good result as regards both mother and child. When the true conjugate was less than three inches operative interference was usually required.

At the evening session the President, Dr. Austin Flint, delivered his address, entitled

THE COMING RÔLE OF THE MEDICAL PROFESSION IN THE SCIENTIFIC TREATMENT OF CRIME AND CRIMINALS.

He maintained that the object of our criminal laws should not be to punish, but to reform the criminal when this is possible, and in any case to protect society. The first important duty is to separate the curable from the incurable criminals, and treat those two great classes differently. In his opinion we should be able to prevent a murderer from repeating his crime without committing a legalized murder—capital punishment should be relegated to the last.

The proceedings of the last day of the meeting of the Association were opened with a paper by Dr. Zera J. Lusk, of Wyoming County, on

A NEW AND ORIGINAL METHOD OF OBTAINING MATERIAL FOR SKIN GRAFTING.

The author said that being called upon to treat a very severe and extensive burn, it had occurred to him to take some of the exfoliated epithelium and apply it to the granulating surface. A piece one inch square was softened and sterilized in warm boric-acid solution, divided into twelve grafts, and applied to the wound. Seven out of the twelve rapidly developed into vigorous islands of skin. The resulting skin was firm and well-nourished, and there was a marked absence of cicatricial contraction.

Space forbids allusion to all the interesting papers that were crowded into the closing hours of the meeting, but mention must be made of one by Dr. Frederick Holme Wiggin, of New York County, on

THE TECHNIC OF MAUNSELL'S METHOD OF INTESTINAL ANASTOMOSIS.

He had sent a letter to Professor Maunsell asking for further details regarding the method, but before his letter reached its destination Professor Maunsell was dead. His widow requested Dr. Wiggin to revise the descriptions of this operation. This was the object of the paper. The statistics of eleven cases in which this operation had been employed were presented, and they showed that nine of these patients had recovered and that two had died, but that the death in neither of these cases could be fairly attributed to any failure of the suture or to the method of applying it. The greatest advantage of Maunsell's method lies in the fact that no special appliances are required, and it is easy and rapid of execution.

Dr. Darwin Colvin, of Wayne County, was elected President of the Association.

THE EMPLOYMENT OF PRISONERS.

To the Editor of The Medical News,

Sir: I have read with pain your editorial, "The Employment of Prisoners," in the October 12th issue. The writer of this editorial is evidently unsympathetic with the labor movement, hostile to socialism, and misinformed in some few points concerned. In each of the four propositions into which this editorial is formally divided there is an opportunity for friendly criticism.

1. This amendment to the constitution is demanded by the laboring classes because the penitentiaries of the State and nearly all the States have gone into the manufacturing business; and, not being obliged to pay wages equal to manufacturers outside the walls, they have been able to undersell all competitors in the market. Manufacturers outside have been obliged to reduce the wages of their men until they were too low to keep up a decent standard of life. In this way, trade after trade has been ruined for free labor can never compete with bond labor. The amendment was not submitted to placate the "labor"-element, but because all intelligent laboring men demanded it. If this amendment was inspired by "socialism," and I truly believe it was, it will not make anyone who understands the subject of prison labor think less of that cult.

2. The State of New York has in its public needs work enough to keep all its prisoners busy, Eugene Smith to the contrary notwithstanding. The fact that all labor for the State which is to be done by outsiders must be done according to the contract system does not prevent the employment of prisoners on any public work. This criticism of the law is before the fact. The Yates law was killed purposely, not by its enforcement, but by its perversion. The laboring classes, so far as they are informed, would abolish all contract labor on public work and have all such work done by direct employment of the several trades.

3. The writer of the editorial assumes that the State cannot under this law give enough work to keep the prisoners busy, that therefore in enacting the law those citizens outside the prison legislate those inside into idleness, and that this latter act is contrary to some high social or ethical principle which I will state in the words of the author, "One class of men may not forbid another class of men to work." I deny the first assumption, and have stated my reasons sufficiently under the previous proposition (2), but I wish to call the writer's attention to the fact that the very essence of the competitive system, for which the editorial writer evidently stands as spokesman, depends upon the right of the capitalist class to forbid the laboring class to work at all, or, if they allow them to work, then to work only at such wages as the capitalists choose to give. There are none more anxious that all should have the opportunity to work than the Socialists, and they demand, too, that those who work shall have the products of their labor for their reward, and that none shall have these things who do not work.

4. To talk of inhumanity in relation to this amendment is absurd. The prisoners will be kept at work not by greedy contractors under the lash and the bayonet, as they are under the contract system, but by men who are not interested in capitalistic production, but in the

health and reformation of the prisoners and in the doing of honest work. It is eminently unfair to assume that this law contemplates the idleness of the prisoner or would result in such a state.

The medical journal may not be considered the best place to discuss this subject, yet every doctor is interested in the question involved. If prison labor goes into the market it beats down the wages of all laboring men. If the wages of the laboring classes are reduced the remuneration of our profession is thereby reduced with still greater rapidity. The medical profession was one of the first trades-unions supported by law; and yet, in these days there are many trades better informed on social movements than our profession is. The spirit, too, of humanity and inclusive fraternity permeates the new trades-union movement more fully and vitally than the same spirit or a similar spirit does our profession. It is a pity that in this first republic the literary proletariat is not in as close touch with the laboring classes as it is in Germany, France, and England. The fact that medical men are so bitter against the "labor movement" as they seem everywhere in the United States to be, and the further fact that they so readily lend themselves to exploitation by railroads, manufacturing companies, and mining companies, greatly to the discredit and financial loss of the profession, these two facts show how completely commercialized the medical profession has become. The gentlemen of the press and the younger generation in the metropolitan universities are rapidly coming to sympathize with the labor-movement even though they do not come in such close personal contact with the people as medical men do, and do not have that financial interest in the betterment of the laboring classes which could influence the most selfish doctor. The press is silent on all that interests the people because the advertisers subsidize our great newspapers. The Board of Education of one of our great cities was lately robbed of $7,000,000, but it was impossible to secure the publication of the fraud in any daily. It is time that the medical profession enlightens itself on the labor movement, which is the reality, and on socialism, which is the ideal of progress and hope and fraternity, and do this before our profession is reduced to pauperism or sycophancy.

I do not hesitate to pronounce the amendment to the Constitution of New York a step forward. The Constitution of the United States and the several States are liberally interpreted to protect property, but very strictly interpreted when they define the rights of humanity. I feel that the editorial is misleading and harmful, and also that it is prejudicial to the labor movement and to socialism, in both of which my hopes and my heart are placed.

BAYARD HOLMES, B.S., M.D.

CHICAGO.

[Dr. Holmes's letter is evidently the sincere expression of his own private judgment, but it contains a statement of surprisingly authenticated facts by which the value of that judgment can be estimated. As a statement of our correspondent's own opinion the letter is interesting, but it does not seem to us to be especially valuable for an elucidation of the question at issue. This important question can only be gauged by a study of figures and facts—not by a mere announcement of doctrine. With much of the contents of Dr. Holmes' letter we can, as a medical journal, have but little, if any, concern. His assumption, however, that the medical profession is not in sympathy with the laboring masses is entirely gratuitous, and, like his other statements, is entirely without accompanying facts to prove it. That he is radically wrong in this assumption we have not a particle of doubt. The medical profession, as a benevolent, progressive, and humane body of men, is probably as closely in sympathy with struggling and suffering humanity as it is possible for any body of men to be; but as an educated and scientific profession it probably views askance the numerous unreasonable and sometimes unjust demands of labor leaders. The medical profession, in other words, can distinguish plainly between the laboring masses on the one hand and socialistic doctrinaires on the other.

The main facts stated in our editorial article on the "Employment of Prisoners" are not confuted by our correspondent. He marshals no facts to disprove them. He merely states his own opinions. The facts upon which we relied are that the amendment to the New York State Constitution is against the spirit of our laws, because it embodies a partisan and discriminating measure in the Constitution; that the policy of it was dictated by the partisan movement now miscalled "socialism;" that in effect a former law, exactly resembling this amendment, resulted in increased disease, insanity, and death among the prisoners, and an increased burden of taxation for the people; that the amendment is unjust, because it is founded on the principle that one class of men may forbid another and helpless class of men to work; and that finally it is inhuman, because it condemns prisoners to solitary confinement without labor, which notoriously means their physical, mental, and moral deterioration. All these facts, so far as we can see, are unanswered in our correspondent's letter; some of the most important of them in fact (as relating to the health and moral welfare of the convicts) are practically ignored.

The facts and figures given by Mr. Eugene Smith and by the Superintendent of State Prisons remain unaffected; they are the statements of experts and authorities who certainly ought to know, and are not merely unsubstantial expressions of personal opinions and prejudices.

These experts say that under this amendment *one per cent.* of the prisoners can do all the work that is available. Also that under the Constitution all public work must be done by contract—"by outsiders," as Dr. Holmes admits. If all public work is to be done by contract by "outsiders," how are the prisoners to obtain any of it, especially when forbidden by this amendment to work? Again, according to Dr. Holmes, the laboring classes would even abolish all contract or competitive labor, and have all public work done by direct employment of the several trades. If this were done, we ask, Where would the prisoners come in for a share, especially as they are debarred by this very amendment from productive labor? All sophistry aside, the spirit and working of this amendment are to enforce idleness upon the prisoners. Their rights and welfare are completely disregarded.

Our correspondent, like too many who enlist in what is miscalled "socialism," entirely ignores some of the higher ethical questions involved. Has the State, any

more than the individual, the right to do evil that good may come? For a possible benefit to a few free artisans has the State a right to do inevitable and much wrong to the convicts? In our judgment there can be but one answer to these questions.—Editor, Medical News.]

INACCURACY IN SCIENTIFIC TERMS.

To the Editor of The Medical News,

Dear Sir: In looking over my summer numbers of your journal the editorial on "Inaccuracy in Scientific Terms" attracted my attention, and it seems to me in behalf of accurate prescription-writing and the King's English in general that the inaccuracies in the editorial should be pointed out.

You say "in a recent State examination the applicants were asked to describe the alkaloid 'strychnia.'" It may be hypercritical to say that this word is obsolete, but as a term for a substance designated by chemists by a slightly different name, the word *strychnia* was made current by the Pharmacopeia, but changed by the terminology of the Pharmacopeia of 1880 to *strychnina*, and careful writers will either use the strict chemic term *strychnin* or the approved pharmaceutic term, *strychnina*.

The fact is that strychnia is a perfectly correct term, though an old one; whilst the term strychnin is not official, and, as I hold, therefore, not correct. Strychnine is just as much an official term of the United States Pharmacopeia as is strychnina. The Pharmacopeia always gives two official names—one in Latin, one in English; the official Latin name is strychnina, the official English name is strychnine. In my opinion, the Latin name should not be used in the text of an article written in English; if it is used it should be put in italics.

The matter is of importance because the termination "ine" is an official one adopted to distinguish alkaloids; whereas the termination "in" indicates that the substance is not an alkaloid; if of a vegetable nature it is probably a glucoside. It seems to me absurd to expect medical men to keep pace with the changes of chemical nomenclature, but certainly in pharmaceutical chemistry the proper nomenclature for the physician is that of the official standard of the country.

Yours truly,

H. C. Wood.

1925 Chestnut St., Phila, September 30, 1895.

[The News, it will be observed by the quotation which Dr. Wood gives, did not say that the word "strychnia" is erroneous, but that as a pharmaceutic term it is obsolete. Dr. Wood correctly observes that in pharmaceutic chemistry the proper nomenclature is that of the official standard. Now the official standard, the United States Pharmacopeia, does not mention the word strychnia, neither in the index nor under the heading "strychnina," consequently, as The News said, the word is obsolete as an official designation of an alkaloid of *nux vomica*. Dr. Wood is possibly not aware that as far as concerns the spelling of scientific terms, "the King's English" does not control in The News office. (See, *e. g.*, The Medical News of June 16, 1894.) The spelling "strychnin" is therefore equivalent to "strychnine," and is recommended by the American Association for the Advancement of Science. No criticism could have been made if the latter word had been used in the question criticised. Space will not permit us to enter upon a discussion of the point raised in regard to the value of the termination as a means of distinction between alkaloids and glucosids. This point has been previously discussed by us. As a matter of fact the distinction is of no practical value, and has been abandoned in the interest of simplicity. Even in the Pharmacopeia the termination "in" is used loosely, since "lupulin" and naphtalin are not glucosids.—Ed., Medical News.]

THE TREATMENT OF TYPHOID FEVER.

To the Editor of The Medical News,

Sir: Every physician who has attempted the treatment of typhoid fever by the Brand system must at times have felt, if not expressed, Dr. Osler's prayer "for a method which may be, while equally life-saving, to put it mildly, less disagreeable." Such, at least, has been my experience in private practice. It was, therefore, a positive joy to me to read Dr. J. Burney Yeo's contribution on the "Management of Fevers, and Particularly of Typhoid or Enteric Fever," published in the June number of *The American Journal of the Medical Sciences*, 1894. Since reading it I have employed no other method, and my experience, like that of Dr. King (Medical News, March 2, 1895), fully substantiates, so far it goes, all the claims made for it by the author. I report seventeen cases so treated without a fatality.

W. H. Patterson.

Reno, Nevada, October 16, 1895.

"LIFE'S" ANTIVIVISECTION-CRUSADE.

To the Editor of The Medical News,

Sir: I write to thank you for the sensible and outspoken letter to *Life*, which is reprinted in the News of last week. Since the appearance, some months ago, of a venomous and malicious antivivisection-cartoon, I have neither bought nor looked at *Life*. For years I had enjoyed its pages, but a journal that insults my best friends insults me, and I shun it as I would a blackguard of the slums. Yours,

William Osler,

Johns Hopkins University,

Baltimore, October 21st.

NEWS ITEMS.

The American Electro-Therapeutic Association held its fifth annual meeting in Toronto, Canada, on September 3, 4, and 5, 1895. Dr. James Thorburn, of Toronto, welcomed the visiting members on behalf of the resident profession. Dr. Charles R. Dickson in an address also welcomed the members.

The President, Dr. A. Lapthorn Smith, of Montreal, then read his address on "Electro-Therapeutics in General Practice." This was followed by the reading of the reports of committees on scientific questions. Then followed the reading of papers:

Further Studies of the Physiologic Effects of the Sinusoidal Current and a Description of a Perfected Apparatus for Producing both a Sinusoidal and a Direct or

Galvanic Current, by Dr. J. H. Kellogg, of Battle Creek, Mich.

The General Therapeutic Effect of the Alternative Current of High Frequency and of High Tension, by Dr. G. Apostoli, of Paris, France.

Alternating Dynamo-Currents in Therapeutics, by Dr. W. J. Herdman, of Ann Arbor, Mich.

Cataphoresis: Non-Conducting Drugs, fluids may be diffused by employing Conducting Electrodes, in solution, by Dr. W. J. Morton, of New York.

Further Successes in the Treatment of Neuralgias by Cocain-Cataphoresis, by Dr. Frederick Peterson, of New York.

Some Comments upon Cataphoresis in Throat and Dental Diseases, with the exhibition of an Improved Galvanic Current-Adapter, by Dr. W. C. Phillips, of New York.

Zinc-Amalgam Cataphoresis, by Dr. G. Betton Massey, of Philadelphia, Pa.

Electricity in the Treatment of Heart-Affections, by Dr. W. F. Robinson, of Albany, N. Y.

Report on the Electrolysis of Cystic Goiters, by Dr. C. R. Dickson, of Toronto, Canada.

Gautier's Method of Electrolysis in Urethral Stricture, by Dr. Robert Newman, of New York.

Electro-Therapy as a Means of Diagnosis in Gynecology, by Dr. Georges Apostoli, of Paris, France.

The Advantages of Electric over Surgical Treatment, by Dr. F. H. Wallace, of Boston, Mass.

Discussion: Gynecology, by Dr. A. H. Goelet; Genito-Urinary, by Dr. R. Newman.

Faradism in Obstetrics, by Dr. R. J. Nunn, of Savannah, Ga.

Ovaritis, and its Treatment by Electricity, by Dr. C. G. Cannaday, of Roanoke, Va.

The Apostoli Treatment of Uterine Fibromata, by Dr. E. R. Corson, of Savannah, Ga.

The Physiologic Action of Periodic Induced Currents in Gynecology, by Dr. A. H. Goelet, of New York.

Notes on the use of the Continuous Current in Arthritis Deformans, by Dr. H. S. Jewett, of Dayton, Ohio.

The Value of the Sinusoidal Current as an Adjunct in the Treatment of the Acute Insanities, by Dr. Robert Safford Newton, of New York.

Some Experiments with Static Electricity in Functional Diseases of the Nervous System, by Dr. Francis P. Bishop, of Washington, D. C.

Current Controller for the Static Induced Current. A New Rheostat, by Dr. W. J. Morton, of New York.

An Interrupted, rather than a Continuous Douche in Franklinization. A New Form of Administration, by Dr. W. J. Morton, of New York.

Hydro Galvanism of the Urethra, by Dr. Robert Newman, of New York.

Division of the Faradic Current to Secure Intermitting Physiologic Tetanus. A new Clock-work Apparatus, by Dr. W. J. Morton, of New York.

New Transformer to Combine the Galvanic and Faradic Currents in a Single Treatment, by Dr. W. J. Morton, of New York.

Electricity Considered in its Relation to Surgical Gynecology, by Dr. O. S. Phelps, of New York.

The following officers were elected for the year 1895–1896, viz.: President, Dr. Robert Newman, of New York City. Vice-Presidents, Dr. Holford Walker, of Toronto, Canada; Dr. D. B. D. Beaver, of Reading, Pa. Treasurer, Dr. R. J. Nunn, of Savannah, Ga. Secretary, Dr. Emil Heuel, of New York City. Executive Council, Dr. W. J. Morton, of New York City; Dr. G. Betton Massey, of Philadelphia, Pa.; Dr. W. J. Herdman, of Ann Arbor, Mich.; Dr. Emil Heuel, of New York City; Dr. Wendell C. Phillips, of New York City.

The President has appointed the following Committees for the year 1895–1896, viz.: Committee on Induction-Coils and Alternators: Dr. A. H. Goelet, Chairman; Dr. G. Betton Massey, Mr. A. E. Kennelly. Committee on Meters: Dr. M. A. Cleaves, Chairman; Dr. O. B. Douglass, Mr. W. J. Jenks. Committee on Static Machines and Condensers: Dr. W. J. Morton, Chairman; Dr. W. J. Herdman, Dr. J. H. Kellogg. Committee on Constant Generators and Controllers: Dr. W. J. Herdman, Chairman; Dr. Robert Newman, Mr. R. G. Brown. Committee on Electrodes: Dr. C. R. Dickson, Chairman; Dr. Lucy Hall-Brown, Dr. E. C. Riggs. Committee on Electric-Light Apparatus for Diagnosis and Therapy: Dr. J. H. Kellogg, Chairman; Dr. E. C. Riggs, Mr. J. J. Carty.

It was decided to hold the next, the sixth annual meeting of the Association in Boston, Mass., in the latter part of September, 1896.

Dr. George A. Mursick died of diabetes, at Nyack, N. Y., at the age of sixty-one years. He was graduated from the College of Physicians and Surgeons in 1860, and in January, 1863, entered the Union army as assistant surgeon. He was promoted to be surgeon in charge of the General Hospital at Duvall's Cliff, Ark., in November, 1864, and became medical purveyor of the Department of Arkansas in April, 1865.

The American Public Health Association is to be congratulated upon the October number of its official *Journal*, which contains an admirable report of the Convention of Bacteriologists recently held in New York under the auspices of the Committee on the Pollution of Water Supplies of the Association.

Dr. Herbert Harlan has been elected Professor of Diseases of the Eye and Ear in the Woman's Medical College of Baltimore, in succession to Dr. Hiram Woods.

The Illinois Medical Journal is a new "monthly journal of medicine and surgery," published at De Kalb, Ill., and edited by Dr. H. E. Dunlop.

Sir Thomas Longmore, an eminent British surgeon, died on September 30th, at the age of seventy-nine years.

A STUDY OF GUNSHOT-WOUNDS WITH REGARD TO THE CAUSATION OF UNCONSCIOUSNESS.

BY J. N. HALL, M.D.,

OF DENVER, COL.;

MEMBER OF THE MEDICO-LEGAL SOCIETY OF NEW YORK.

IN several trials for murder, in which I have been consulted, the question has arisen whether, after a given gunshot-wound, the person wounded could have offered any resistance or committed any aggressive act against the one who had injured him. The utter lack of any literature bearing directly upon this point has led me to write this article, with the hope that it may at least serve as a nucleus about which such information as is obtainable concerning these points may be gathered.

In certain cases the question of the production of such unconsciousness as would preclude any voluntary act upon the part of the person shot is very easily answered. If the brain is extensively disorganized or the cervical cord severed high up, or if the great ganglia of the sympathetic system or the region about the base of the heart are violently disrupted, as by a large missile passing through the chest and abdomen, we would be perfectly safe in stating that unconsciousness, or, we might almost say, death, would result so quickly as to prevent any voluntary act on the part of the injured person. It should be noted, however, that to produce such unconsciousness the extent of the injury below the cervical cord must be enormously greater than in or above that region. Thus in one of my cases a single pellet of shot from a shotgun caused instant death from its passage through the cord at the atlo-axoid articulation, being far more quickly operative in this respect than would the destruction of all of the body below this point have been.

I have many times seen small animals instantly killed by a heavy rifle-ball when the sole injuries were in the abdominal cavity, or the parts posterior to it. In these cases the shock from the extensive tearing of the tissues, exerted through the solar plexus, produced practically instantaneous death. And even in animals of the size of a deer I have seen death as quickly produced when the rifle-ball of large caliber had passed lengthwise through the cavities of the chest and abdomen; although it does not occur, I believe, when only one of these cavities is invaded transversely, unless the base of the heart is involved. This matter we shall consider later. It would seem that the relative amount of damage to the internal organs must be very large for the production of immediate unconsciousness, while, through the action of shock and hemorrhage, such a state may result after an interval from very small wounds.

Although I have had no opportunity of observing a wound by a large missile, in man, involving the whole body lengthwise, analogous to those just mentioned in animals, I anticipate that such injury would produce practically instant death, regardless of lesions of the heart, chiefly because the damage to the sympathetic system would necessarily be so severe. There is obviously much greater opportunity for extensive injury to the internal organs in the case of such a longitudinal wound than in a transverse one, which would commonly invade but one cavity. In fact, many of those wounded transversely, in either of the cavities mentioned, if only the heart, the spinal cord, and the great blood-vessels escape injury, not only do not suffer unconsciousness, but recover, either with or without operative interference, as abundant reports of cases prove.

To the best of my knowledge, no injury to limb or limbs, such as would be possible from any ordinary gunshot-wound (that is, excluding total destruction by missiles from cannon or other ordnance, which injuries do not here concern us), would cause instant unconsciousness, although the severest shock may result from extensive fracture of bone, especially in conjunction with severe hemorrhage. But this would not preclude voluntary action on the part of the person injured for a certain time afterward. In fact, I have seen repeated instances in antelope, elk, and deer, in which extensive gunshot-injuries, approaching utter disorganization of one or more limbs, existed, even including in some cases practically a whole quarter, without apparently interfering very much, for the first few minutes, with the speed of the animal as it endeavored to escape. In fact, the severance of both front legs below the knee, or of both hind ones below the hock, or the complete destruction of any one quarter, so far as the bony parts are concerned, will not prevent the temporary escape of an antelope from the hunter if he be afoot. This common experience proves.

The popular idea seems to be that any bullet-

wound of the heart produces instant death. I have recorded elsewhere[1] several instances in game animals in which long distances were covered after such wounds, and so many cases[2] have been recorded in man of the prolongation of life for many hours, or even of recovery, after being shot through the heart, that it is needless to quote them here. My own experience in the study of cardiac wounds, in game-animals chiefly, for I have seen but few in man, would lead me to the conclusion that transverse wounds through the lower portions of the heart, giving rise to punctures rather than extensive lacerations, do not commonly cause a cessation of life for a time varying from some considerable fraction of a minute to many minutes or even hours, and especially if the puncture be valvular in character, so as to prevent the loss of much blood. If, however, the wound involve the base of the organ, with extensive laceration of the surrounding parts, death is practically instantaneous. It would seem that injury to the muscular walls of the organ is much less efficient in the production of immediate death than destruction of the cardiac nervous mechanism, serious irritation of the latter producing almost instant death from shock.

It is not necessary to quote here in detail the instances, chiefly from the hunting-field, upon which I have based these conclusions, but it may be briefly stated that two wild geese flew, respectively, one-fourth and three-fourths of a mile after being shot through the heart each with a single pellet of BB shot, the base being in each instance uninjured. In several instances antelopes and deer ran several rods after being shot with a rifle-ball in similar manner; while, on the other hand, death was practically instantaneous in several of these animals in which the base of the heart was extensively lacerated.

In one murder-trial, in which I testified, a woman of twenty-two years of age was shot with a 38-caliber revolver, the ball entering at the left acromion process, and ranging downward and inward through the base of the heart. From the position of the body and the circumstantial evidence, it seemed certain, as was stated to the jury, that she had not moved further than to fall back upon the bed after receiving the wound.

But, on the other hand, death *may* result instantly from a wound of the precordial region; or even, according to Erichsen, from the concussion resulting from the discharge of a pistol containing powder alone, if held directly over the heart, as it does occasionally after a blow upon the precordial region. In such a case one could only say that unconsciousness might well have resulted from the injury, and, in the lack of any other discoverable cause of death, that it had almost certainly done so. It is well to state here, however, the fact so commonly recognized by surgeons, that in times of excitement one may receive an injury which will shortly prove fatal, and yet not be aware of it for some time—perhaps even for several minutes. It would appear that the nervous system is so highly tuned at such times that it does not respond to reflex irritations as readily as in the absence of excitement. A case illustrative of this statement will be found under brain-injuries in this article.

It is in regard to injuries involving the brain that the question of the production of immediate unconsciousness assumes the greatest interest. We may state broadly that if the medulla or the great centers at the base of the brain are wounded by a bullet, instant unconsciousness must result; with any other wounds involving the brain-substance it will with very great probability result. But there is a very broad area of uncertainty. Many instances have been recorded in which the entrance of a small bullet into the anterior part of the brain has not prevented the firing of a second shot on the part of the suicide. Personally, I have not observed such a case, however. But, aside from injuries by the smallest missiles in the anterior parts of the brain, we may speak with almost absolute certainty with regard to the production of unconsciousness, for the jar to the brain from the blow of the bullet upon the skull would produce such a result even if the damage to the brain were not sufficient to do so.

Many injuries to the brain from bullets of moderate size and low velocity do not cause more than a temporary loss of consciousness, and the subjects are seen by the surgeon, after the lapse of half an hour or more, apparently sound of mind. These are the cases in which the ball has lost its momentum in passing through the skull, and has consequently done little damage to the brain-substance excepting to make a passage for itself for a short distance into the brain. It is apparently well established that, in the case of the rifle-bullet of high velocity, and especially if fired from the modern military weapons using nitro-powders, and giving an enormous initial velocity to the bullet, the transmission of the force from the displaced particles of brain (and this rule applies to any other of the soft organs as well) to the adjacent parts is such as to disorganize much of the tissue surrounding the original track of the missile. Under these circumstances a much slighter wound would be necessary to produce unconsciousness or death than in the case of a bullet of low velocity, especially if it were light in weight. Thus I have

[1] Scribner's Magazine, October, 1891: "Actions of Wounded Animals." Recreation, February, 1895: "The Vulnerable Spot."

[2] Sanson and Ollivier alone report twenty-nine cases in which patients lived from four to twenty-eight days after wounds of the heart.

recorded elsewhere[1] an instance of instant death in a grizzly bear, an animal certainly as tenacious of life as any we have, from a mere furrow less than a quarter of an inch in depth through the cortex of the brain, without injury of the skull excepting the removal of the bone necessary for the production of this furrow. The jar to the brain from a bullet of great velocity, as in this case, was alone sufficient to injure the organ irreparably. In a similar manner I have known a deer to be killed by the impact of a heavy rifle-ball against one horn, although there was no evidence of fracture of the skull. On the other hand, game animals often escape after such injuries, not directly involving the brain, although temporarily rendered unconscious, as I have observed in several instances, the diagnosis undoubtedly being concussion of the brain.

Slight injury to the brain, and especially if it be unilateral, then, may not produce unconsciousness. It is not very uncommon for a missile from a heavy weapon to strike the skull, and be deflected without the production of such a state. Near the town in which I formerly practised, the town-marshal shot at a negro who resisted arrest, at a distance of only a few feet, with a 44-caliber revolver, striking the culprit on the side of the head. The wound showed that the ball struck the skull and plowed along under the scalp for several inches before emerging, but it did not even knock the negro down, and no unconsciousness followed later. I once examined an express-messenger who had been shot in the occipital region by a weapon of similar size, while seated at his desk in the car. The blow was a very glancing one and did not produce unconsciousness, and probably, as in the case of the negro, because it did not strike with sufficient directness. A direct wound on the skull from such a weapon commonly penetrates, as experience shows. In the Milton Smith case in Denver, the unusually thick skull of a powerful negro was practically disorganized by a bullet from a revolver similar to those already mentioned, the missile having struck at a right angle with the forehead. Still, in those cases in which any bullet of even moderate size has impinged upon the skull, we should commonly look for at least a temporary stunning as a result, as the great majority of such cases would suffer from concussion of the brain. We do not, of course, include mere scalp-wounds in this statement. One must remember how many cases we see in which stunning has resulted from comparatively slight blows upon the cranium, even those given by the fist. Comparing the concentrated and forceful blow of the bullet with the causes so often operative in the production of unconsciousness, it may easily be seen that the bullet must commonly stun the patient if a firm part of the skull be struck.

In one case,[1] in which the ball from a 38-caliber revolver passed into the right side of the neck and thence upward toward the right side of the skull, and in which testimony was introduced to show that the patient was unconscious two minutes after the shot, I declined to say more than that such a wound might have produced this result immediately, there being, in my judgment, insufficient ground for the formation of a positive opinion. Dr. Parkhill had been unable to definitely locate the ball, and it was uncertain, according to his testimony, whether it had struck the base of the skull or not. Even if it had, its force might have been so reduced as to prevent its producing a serious jar to the contents of the cranium. Furthermore, it is well known that a jar of the side of the neck, whether by its influence on the cord, on the pneumogastric nerves, or otherwise, does not seem to be established, not infrequently suspends consciousness for a time, as so often recorded in prize-fights. The evidence in this case finally left no room for doubt on this point. It was shown by the conditions under which the wound in the culprit's neck was inflicted that he could not have caused it himself, and hence it must have been caused by the woman who was found dead in the room with him. As she had received a wound causing instant death, it became apparent that the story of the shooting as given by the man on trial must be true. This was that the woman had first shot him, that he had struggled with her for the possession of the weapon, and that in the struggle it had been discharged, killing her instantly, as was afterward learned, and that after that he knew nothing until he found himself in the hospital.[2] In this case it seems probable that the subject retained consciousness longer than he might otherwise have done, because of the danger of his position.

As bearing somewhat upon the matter we are considering, I will quote here a very interesting case, previously reported, concerning which I was consulted some three years ago. A man on horseback was shot in the neck by one on foot, a single pellet of shot severing the cord at the atlo-axoid articulation. I was asked if he could have retained his grasp upon a knife he was known to have held in his hand at the time of the shooting. There was a suspicion that the knife he carried had been secreted and a larger one substituted, in order to make his killing more justifiable, as the former knife was

[1] Reported in "Gunshot Wounds in their Medico-Legal Relations." International Medico-Legal Congress, Chicago, 1893.

[2] See "Gunshot-wounds, Accidental, Homicidal, or Suicidal," by the author, presented at the Medico-Legal Congress, New York, 1895.

believed to have been only a pocket-knife. He had been the attacking party in the affray. The large weapon was merely laid in the hand, not being grasped by the fingers. As a severance of the cord in this region would instantly relax all voluntary muscles involved, I stated that he could not have retained his grasp upon the handle, and the prisoner confessed that he had substituted the large knife for the small one. He was convicted of manslaughter.

We have dealt chiefly with wounds that *must* produce unconsciousness. It should be stated that other injuries than those considered *may* produce such a state. I should anticipate that the passage of a bullet through the upper dorsal region, and perhaps in most instances through any part of the spinal column above the sacrum, would render the victim unable to offer any resistance to an adversary, although probably not preventing the action of his mind for a time. There is such a vast difference in different men in the amount of vitality exhibited under trying circumstances that it is impossible to formulate any rules for the consideration of such cases. We may, however, summarize the results we have reached as follows (I am under obligations to Dr. J. T. Eskridge for a critical review of the conclusions herewith presented, which he informs me meet with his approbation):

Consciousness must be immediately suspended after gunshot-wounds involving the medulla, the cervical cord above the origin of the phrenic nerve, the great centers at the base of the brain, or the region about the base of the heart, if, in the latter case, the parts are severely lacerated. It will with very great probability be suspended after wounds involving very extensive injury about the solar plexus, or after any injury, by a missile of considerable size, affecting any part of the brain, unless it be the anterior and lateral parts. Temporary unconsciousness at least will probably follow any wound of the brain-substance, or any serious jar to the cervical cord, by a bullet of even moderate size; and temporary stunning or even death often follows the shock from the impact of a bullet against the skull, without gross damage to the brain, and may follow the concussion of the precordial region, caused by the discharge of a weapon in close contact, even though no penetrating wound be produced. In the majority of other injuries from the cause we are considering unconsciousness is secondary to loss of blood, shock, or a combination of these two causes. But in any injury to the spinal column involving the cord, and more especially in the upper portions, although consciousness may be retained, it is not likely that any serious resistance could be offered by the person so injured, excepting that the hands might still be of use in case the lesion were below the upper dorsal region.

NEPHRITIS VIEWED FROM THE STANDPOINT OF INDIVIDUAL CELL-LIFE.

BY W. M. MEMMINGER, M.D., AND W. KNOWLES EVANS, M.D.,
OF CHESTER, PA.

IN spite of the immense array of medical literature of the past and present, and the accumulated experience of the profession, the physician of to-day finds himself constantly confronted with his inability to contend successfully with innumerable physical conditions. This is evidently due to the fact that we recognize and treat disease from the symptomatology of defined organs, as the heart, liver, lungs, stomach, and intestines, and lose sight of the primarily diseased or irritated *organs*, viz., the ultimate protoplasmic particles or cells of which these structures are composed. The study of cell-life proves conclusively that the individual cell is an organ in itself. It must receive its food-materials; it must construct, generate, and eliminate—in short, its functions are as well defined as those of the major organs. These functions the most minute cells are capable of executing thoroughly under normal conditions, *i. e.*, the absence of any form of morbid irritation; but if irritated their functions become perverted. Thus we see that as all tissues of the body are made up of these innumerable minute cell-organs, upon *their health* depends directly the health of the individual.

As these facts are self-evident, we can now apply them to nephritis—that disease which, according to the literature of to-day, is a disease of the *kidney*, followed by various constitutional changes. We shall not discuss the various classifications of nephritis, as they are based solely upon the degree of structural change of the kidney.

The question now arises, Is nephritis or albuminuria primarily a disease of the kidney? We are prepared to state that it is not, and that upon this fact rests all previous failure of treatment. Primarily nephritis is acute or chronic irritation of the cell-organs of the entire body, causing cell-vomiting or the elimination of cell-food, *i. e.*, *albumin*.

We should first understand that disease is irritation. Irritate the lungs and we get the resulting cough and expectoration; irritate the intestines and we get increased discharge; irritate the stomach and we get vomiting. If this is true of the large organs, as the lungs, intestines, and stomach, is it not equally true of the individual cells throughout the entire body? When an irritant is brought in contact with a cell, as occurs through the medium of the circulation in all diseases, we have perversion of function, and a condition similar to that of an irritated stomach—an inability to utilize its furnished materials to promote nutrition, and a throwing off or vomiting of these. In the case of the stomach it is the crude food-materials, while in the cell-

organs it is the peptonoids or albuminoids furnished to them by the stomach—the evidence of their refusal to utilize these being shown by their presence in the urine and all other sources of elimination.

The recognized causes of nephritis are scarlet fever, pregnancy, alcoholism, mental anxiety, all the eruptive fevers, diphtheria, gout, pyemia, acute articular rheumatism, long-continued cystitis, extensive burns of the skin, malaria, chronic dysentery, ulceration of the bowels, habitual exposure to moisture and cold, cantharides, turpentine, oil of mustard, phosphorus, ars nic, silver nitrate, lead, and mercury. Each of these causes is a specific irritant to the individual cell-organs of the *entire body*, as is evidenced by the symptoms produced. For example, in scarlet fever we have the chill, vomiting, irritation of the fauces, high fever, rapid pulse, heat of skin, bright scarlet rash, headache, great restlessness, and delirium. In acute articular rheumatism there is chill, pain, and stiffness of the joints, nausea, vomiting, hyperpyrexia, profuse acid sweats, and scanty high-colored, albuminous urine. Or if we take alcoholism as an example, we find general increase of fibrous or areolar tissue, followed by contraction and destruction of secreting cells, gastric catarrh, anesthesia and hyperesthesia, delirium, acute and chronic mania, and numerous organic inflammatory diseases. In mercurial poisoning these are its local and constitutional effects: its action upon the red corpuscles even in minute doses, its marked effect upon the nervous and digestive systems, the action on the salivary glands, fetid breath, and emaciation.

Given now an irritant producing acute inflammation, the tendency of the latter is to become chronic, and our efforts to prevent this have been directed to treating the symptoms of the affected parts, and we have failed to extend our treatment to the cell-organs, which are irritated throughout the entire system. Just as surely as the tendency of inflammation in major organs, as lungs, stomach, and intestines, etc., is to become chronic without proper treatment, so surely will the individual cell-organ run into chronic inflammation if the primary irritation is not given a part of our care. In acute gastritis we have acute vomiting; in acute cell-irritation we have acute *cell-vomiting*, or acute albuminuria. In chronic gastritis we have chronic vomiting, and chronic cell-irritation produces chronic cell-vomiting, or chronic albuminuria, resulting in chronic nephritis. Acute gastritis becomes chronic because we have failed to soothe and palliate it; acute cell-irritation becomes chronic from the same cause.

Viewed from this standpoint, albumin in the urine is the direct symptom of either acute or chronic general cell-irritation; the hypersensitive condition of cells causes them to repel or throw off their good material. Albuminuria and the changes in the kidneys are but secondary.

If from irritation of the cell-organs we have perverted functions, or throwing off of cell-food, a resulting malnutrition of the cell must occur, and a consequent degeneration of the entire system. This is simply evidenced by the general conditions gradually evolved in nephritis, the proliferation of tissues of low vitality, the multitudinous degenerations, and general anasarca.

A food-substance taken into the stomach, if not accepted by it, is eliminated either by vomiting or by passage through the intestines more or less unchanged, frequently giving rise to destructive changes in the channel of elimination. Food-material likewise taken into the blood, if refused by the cell-organs, must necessarily be eliminated. As the kidney is the principal source of elimination of the products of the blood, it suffers in like manner.

Not only does the kidney suffer from being the avenue of elimination, but the structural changes found to exist in it are due to the presence of tissues of low vitality, constructed of badly nourished cells. Like changes may be found in all portions of the body; the primary enlargement and subsequent contraction of organs and the general sclerosis, the pale, flabby, edematous tissues are in themselves evidences of cell-impoverishment.

Simon, in his recent article on "Functional Albuminuria," or the "Albuminuria of Da Costa" (*New York Medical Journal*, September 14, 1895), after referring to the writers of the day on this subject, says: "After carefully surveying such literature, there can remain no doubt in one's mind that an albuminuria may occur in the absence of organic changes affecting any of the tissues of the body." Now, as the presence of albumin in normal urine must yet be proved, the so-called functional albuminuria is simply the result of general cell-irritation, and although the article referred to is full of evidence of such irritation, the author has failed to recognize it as the cause of the albumin being in the urine without structural changes taking place. He is very right, however, when he states that such a condition may result in chronic interstitial nephritis, with all its structural changes. All that is necessary is to let this primary acute cell-irritation, without structural change, become chronic.

In the treatment of nephritis our first duty is to remove the cause of the general cell-irritation, and, second, to soothe and palliate the irritated cells (as we soothe the irritated cells after a burn or external application of an irritant by bland ointments, oils, etc.).

In regard to general treatment, the promotion of all that tends to good hygienic conditions, the elimination of all forms of mental anxiety, rest, and diet, are all important. Medicinally, opium and

cod-liver oil are our sheet-anchors. Mental anxiety must be avoided, as it is a direct cause of cell-irritation and its resulting albuminuria. To be beneficial rest must be complete, not only bodily rest, but cellular rest. This calm and peaceful sleep will furnish us. By rest we do not mean the absolute "rest-cure" of Weir Mitchell, but the normal rest and sleep of the healthy animal. Sufficient moderate exercise in the open air must be secured for hygienic purposes.

The ordinary "milk-diet" would seem to be the best, as milk is a non-irritating form of food, and so it has proved to be in regard to decreasing the amount of albumin eliminated, but the general condition of the patient suffers because milk is an insufficient food to sustain the normal life of an adult, and contains too much water. Our ordinary foodstuffs are not irritating to cell-life in themselves; but are often made so when prepared in the usual palatable forms. Wholesome meat served rare, plainly prepared without condiments (salt in small quantities alone is allowable), should be taken freely. All the cereals may be used, but care must be exercised to avoid fermentative changes taking place in the stomach, as they may generate acids of an irritating character. Only a few vegetables are permissible, as a number of them generate products of irritation. The white potato we would recommend as the principal vegetable.

A general idea pervading all literature upon this subject is that the taking of nitrogenous foods directly increases the amount of urea in the blood. This is so, but it is not the taking of the nitrogenous foods that increases the urea, but the refusal on the part of the cells to assimilate and utilize the albuminoids furnished to them. Urea we do not consider to be alone the result of tissue-destruction, but also of food-destruction. Thus our efforts to rectify the amount of urea must not end by stopping the supply of nitrogenous foods (which are so important to the sustaining of the general health of our patient), but should also lead to allaying the irritation of the cells so that they may receive the albuminous products.

In regard to drugs, opium is best adapted to our wants, as our object is to allay cell-irritation. Entering directly into the cell-protoplasm, it soothes their hypersensitive condition, and secures the cellular rest that is all-important.

The opium should be given in as small quantities as will meet the indications, and should be continued indefinitely, Scanzoni and Loomis having amply demonstrated the safety and value of morphin, even in the most serious calamity of nephritis, *i. e.*, uremic coma.

At first there may be some resistance on the part of the cells to respond satisfactorily to the drug, as there is on the part of the stomach, but this is overcome by its continuance. Morphin bimeconate is by far the preferable form of exhibiting the drug, as it is the most free from disagreeable effects.

Cod-liver oil is strongly indicated, because in doses suited to the powers of assimilation it improves the condition of the nervous system, causes a rapid increase of urine and perspiration, increases the appetite, improves nutrition, enhances the number of red blood-corpuscles, increases healthy cell-formation, and exerts a general alterative effect. In addition, its phosphorus, iodin, and bromin exist in organic combination capable of being readily appropriated by young cells. In case the stomach does not receive it kindly, we have the ready mode of introducing it into the blood by inunction and gentle massage. This plan should always be used if the stomach refuses the drug. We would strongly urge the avoidance of all irritating drugs, such as the pharmaceutic preparations of iron, the giving of quinin, strychnin, cantharides, digitalis, turpentine, arsenic, etc. Pilocarpin and mechanical purgatives are, however, permissible and of value if serious kidney-destruction has occurred.

EPITHELIOMA OF THE UPPER JAW.

BY FRANK WISTER THOMAS, M.D.,
OF GERMANTOWN, PA.

WHILE carcinomatous affections of the upper jaw, beginning in the antrum, are by no means common, they are yet of sufficiently frequent occurrence to be accurately described in the standard text-books on surgery, and would be easy of recognition by any careful observer, particularly if he were at all familiar with the affection as occurring in other parts of the body; but epithelioma beginning in the mucous membrane of the upper jaw is so rare an occurrence that the ordinary text-book writer has failed adequately to portray it.

In an examination of a number of standard authorities, while descriptions of the disease as occurring in the tongue, on the cheek, in the pharynx, on the palate, and in the larynx were full and accurate, yet in only one work, viz., *Bond's Dental Medicine*, did I find any description that would throw light upon the case about to be described; and this author quotes Mr. Liston and Professor Mütter as both regarding carcinoma of the gums as exceedingly rare. According to his description, a carcinoma in the gum has the distinctive qualities of hardness, acute, lancinating pain, and inequality of surface; although one form may occur, presenting the appearance of a soft, spongy, bleeding fungus, accompanied by great sensitiveness and great pain. Carcinoma of the jaw, according to him, may occur in two forms—the occult and the open; the former generally preceding the latter

and presenting itself in the form of a hard, dense tumor of slow growth, seated in the glandular structure. At first this tumor is nearly insensitive, but subsequently causes sharp, darting pains; and as the disease progresses the skin adheres to the tumor, corrugates or puckers, changes color, and ulcerates.

The resulting ulcer is both painful and irritable; discharges a thin ichor, which is, in the majority of cases, devoid of fetid odor, except in the later stages. Its edges are hard and irregular, "reversed and contorted." The sore manifests no tendency to form healthy granulations, but spreads among the surrounding tissues, which successively harden and ulcerate and become carcinomatous. Lymphatics propagate the disease to the nearest glands, which are found swollen, indurated, and often ulcerated, and the pain is burning and scalding.

Sometimes such an ulceration occurs without the preceding scirrhus. When this is the case, the ulcer presents an even, smooth surface, with little secretion; the open sore rarely yields even to surgical remedies. Its cause is a matter of controversy; its origin is ascribed to a wound or a pinch, but this can only be occasioned when there is a constitutional tendency to the affection. That the disease is a degenerative one is evinced by the fact that it invariably occurs in the declining period of life, like all other forms of the disease; but while other forms have, in rare instances, occurred in youth (the late Professor Gross having observed an encephaloid of the antrum in a child of five years), I find no mention of the form we are considering occurring in early or middle life. Its relation to other degenerative diseases has not been thoroughly investigated. Charcot, however, significantly says, in speaking of the relation of gout to carcinoma in the aged: "I can affirm that, in nodular rheumatism, cancer and cancerous growths are not exceptional affections."

All the writers whom I have consulted speak of the involvement of the neighboring glands, but deny the visceral recurrence of the affection; and they all agree that it induces a cachexia, and destroys the patient by exhaustion before its local ravages have reached a vital spot.

Erichsen claims that such malignant disease of the jaw early manifests itself in swelling of the submaxillary glands, and that this complication sometimes occurs even before ulceration has taken place.

One writer affirms that ulceration is always a secondary process, but that, owing to the painlessness of the initial tumor or wart in epithelioma, the first stage frequently goes unrecognized.

The appended case illustrates many of the points here described, but differs in the essential features of absence of submaxillary swelling and acute pain, and in the very tardy appearance of cachexia.

My patient is a married woman of 87, from a remarkably long-lived family, one brother having recently died at 90. Her family is free from any constitutional taint, excepting gout, which has manifested itself in the patient under consideration by nodular swellings of the joints, a tendency to eczema, acidity of the stomach, and by the frequent appearance of the abnormal excretion of uric acid. Her children manifest the same tendency, and one of them is the subject of extreme nervousness and periodic attacks of hemicrania. A son, now past the prime of life, has been the subject of chorea from youth, and evinces a predisposition to attacks of eczema of a severe form, occurring in the neighborhood of a scar occasioned by a wound received in the late war.

In the spring of 1894 my attention was called to a cavity in the alveolar margin of the left upper maxilla, about the position occupied by the first molar tooth. This cavity had dark edges; it extended about a half-inch in depth, and had all the appearance of an unclosed tooth-socket. It was tender—hardly painful—and annoyed her principally by its tendency to make her seek to put the point of her tongue into it.

Not suspecting any malignancy, the cavity was disinfected and swabbed with a solution of silver nitrate (five grains to the ounce), and in a month's time it was filled, presenting a smooth, granulating surface, with everted edges. As there was no glandular involvement, and no change in color, the disorder was treated as a simple ulcer. For six months little or no change took place; then the granulating surface began to spread. A dentist was called in consultation, but he could make no diagnosis; he however suggested the local use of liquor sodii carbolatis. Spreading gradually continued, but no pain exhibited itself except upon the contact of hard food or broths containing salt. The patient's general health remained good; if anything, she was better than during the spring.

In the early summer of 1895, the disease had involved the mucous membrane on the outer alveolar margin and on the palatal plate, inward to the median line and forward to the second lateral incisor. Drs. Yorkes and Cryer, two specialists in diseases of the jaw, were then called and confirmed a suspicion of an epitheliomatous nature which I had begun to entertain.

In September of the present year growth was more rapid; the breath became very fetid, irregular nodules appeared, and points like stalactites hung from the alveolar buccal junction. A gangrenous slough, a half-inch in diameter, was thrown off from the center of the sore, which let out a discharge of pus and put an end to the fetid odor.

At the present writing, the ulcer has eaten deeply into the jaw, and appears to communicate with the antrum. By keeping it clear with hydrogen dioxid and potassium permanganate, all odor is suppressed. The patient takes two quarts of milk daily, consumes two eggs, and takes beef-peptonoids, with comparatively little discomfort; she retains all her faculties, shows no cachexia, and no tendency to glandular enlargement of the affected side, although

within the past week the gland at the angle of the jaw of the opposite side has been slightly swollen. At the present rate of extension there is grave reason to fear serious local involvement before the cachexia and exhaustion, which the authors describe as so essential a feature of the disease, shall have made its appearance.

The particular points of interest in this case are the association of so distinctly a gouty history with the occurrence of the affection; the strange absence of lancinating pain; the slight tendency to glandular enlargement; the delay in the appearance of cachexia; and the great similarity of the physical appearance and progress of the disease to the ulcerative or open form of epithelioma of the jaw, as described by Bond.

CLINICAL LECTURE.

FOUR CASES OF MIXED OR IRREGULAR FORMS OF MULTIPLE NEURITIS IN WHICH PARAPLEGIA WAS THE MOST PROMINENT SYMPTOM IN THREE, AND A CONDITION SIMULATING HEMIPLEGIA IN THE FOURTH.[1]

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.
NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITAL

LECTURE I.

I wish to call your attention to-day to a series of interesting and rather peculiar cases. Of the first one we have the following history:

CASE I.—John E., aged 27, born in Sweden, living in the United States since 1893 and in Colorado since 1894, was admitted into this hospital February 20, 1895. The family-history so far as he knows is negative. The patient's health in childhood was poor, but he can give us no definite account of his health during this time, further than that he was said to have lacked nerve-force, and he also remembers to have suffered from time to time from considerable pain in the chest. Some weeks before entering the hospital he had a chill, and was troubled with some shortness of breath and fever. On admission into the medical wards of the hospital he was found to be suffering from acute lobar pneumonia and was placed under the care of Dr. McLauthlin. In the early part of April, while he was slowly convalescing from his lung-trouble, he began to complain of pain in the legs below the knees and of a sore feeling in the legs above the knees, but no pain such as he experienced below the knees. The legs felt cold and he was annoyed by a prickling, numb sensation, and a constant, dull, heavy pain. About the 20th of April, or two weeks after he complained of these nervous symptoms, it was observed that he had double foot-drop, with marked wasting of the muscles of the legs below the knees. Tactile sense is said to have been but little impaired at that time except around the feet. The knee-jerks were noticed to be increased, but there was neither bladder-trouble nor bowel-disturbance. Early in May he was transferred to the nervous wards.

The examination, May 4, 1895, showed extreme double foot-drop and inability to flex or extend either foot. The posterior tibial muscles were slightly contracted, so that the feet could not be forcibly dorsally flexed beyond a point at right angles with the tibia; the muscles that flex and extend the knees were fairly strong, and the hip-muscles were unimpaired; the bladder and bowels were unaffected, and there was no paresis or paralysis of any of the trunk or facial muscles. The dynamometer registered R., 116; L., 116. All the arm-muscles seemed to be in a normal condition. The knee-jerks were decidedly increased, and on depressing each patella a rythmic contraction of the rectus femoris group of muscles took place. Ankle-clonus, plantar and tendo-Achillis reflexes were absent. The increased myotatic irritability was so great in the extensors of the knees that on placing the front of his feet against some resisting substance a continuous clonus-movement took place. The cremasteric and abdominal reflexes were present; all of the reflexes of the arms were normal. Tactile sense was apparently nearly normal except on the soles of the feet and on the dorsal surfaces of the toes, where it was not completely abolished, but was greatly lessened. The temperature-sense seemed to be unimpaired except over a small area over the upper and outer portion of each leg just below the knee. All other general sensory phenomena were normal. There was no involvement of the arms or hands, and no impairment of tactile sense around the anal region or over the external genitalia. The special senses showed no deviation from normal. The eye-grounds presented no pathologic appearance except that the left seemed a little hyperemic and showed evidence of slight old neuroretinitis. The patient has never been addicted to the use of alcohol to excess; neither has he been a moderate, steady drinker. Syphilis was denied. The wasting was extreme in the muscles of the feet and legs below the knees.

A large-sized Flemming battery was used in testing the reaction to the faradic current, and the muscles in a nearly normal condition usually responded slowly to an interrupted secondary current when tapped at button numbered 1.

Tibialis anticus: R., 4+2; L., no response to the strongest current.

Peroneus group: R., 4+3¾; L., 4+5½.

Ext. long. digitorum: R., 4+6½; L., no response to the strongest current.

Posterior tibial group: R., 4+3½; L., 4+1.

Rectus femoris: R., 1; L., 1.

All the other thigh-muscles responded normally to this current.

To the galvanic current:

Tibialis anticus: R., K.Cl.C. = 10; A.Cl.C. = 8. L., K.Cl.C. = 20; A.Cl.C. = 15.

Peroneus group: R., K.Cl.C. = 12; A.Cl.C. = 15. L., K.Cl.C. = 15; A.Cl.C. = 20.

Ext. long. digitorum: R., K.Cl.C. = 10; A.Cl.C. = 8. L., K.Cl.C. = 20; A.Cl.C. = 15.

After the patient was transferred to the nervous wards he was kept in bed until a few weeks ago, when he was allowed to be up a portion of the day. The treatment consisted in covering the affected part with flannels, in placing sand-bags at the soles of the feet to prevent con-

[1] Two clinical lectures delivered at the Arapahoe County Hospital, September 14 and 21, 1895.

tractures of the flexor muscles of the ankles and feet; and strychnin, iron, and quinin were given internally. The affected parts have been masséed daily, and a continuous and interrupted galvanic current has been applied to the paralyzed muscles. I shall examine him today before you.

You notice that the right leg below the knee is much larger than the left and presents an edematous appearance. The right ankle-joint seems to be distended with fluid. The left leg below the knee presents a wasted appearance, with some edema in and around the ankle. The reaction of degeneration is said to exist when the muscles lose their normal irritability to the faradic current and respond to the positive pole of the galvanic current as readily, or even more readily, than they do to the negative. The man is now able to slowly flex and extend the feet, but the tibialis anticus, extensor longus digitorum, extensor longus pollicis, and peroneus muscles are extremely weak. The knee-jerk on the right is greatly exaggerated and increased by reinforcement; the left is even more exaggerated than the right and is also increased by reinforcement. No clonus is obtained by depressing the patella. Ankle-clonus and the plantar reflexes are absent; tendo-Achillis jerk is slightly increased. Usually in health very little response is elicited by tapping the stretched tendo-Achillis, but you notice that a sharp response is elicited by striking these tendons in this patient. All the superficial and deep reflexes above the knees are normal and there is no impairment of muscular power except in the parts below the knees. The posterior tibial group of muscles is fairly strong and the anterior tibial group brings the feet at right angles to the tibia, but with little force interposed the power is easily overcome. The left tibialis anticus is stronger than the right. Tactile sense on the right foot is normal except on the sole and on the end of the toes. On the left foot the area of tactile anesthesia is less than on the right, and involves the inner side of the sole of the foot, but on the outer side of the plantar surface the man is able to feel the touch of a camel-hair pencil in motion. There is a little anesthesia around the left ankle. The temperature-sense is not lost, but it is lessened. The feet and legs feel cool. All the affected muscles respond more readily to the faradic current than they did early in May of this year. To the galvanic current the muscles show a better response than at the former examination, but these still exhibit a change both in quality and quantity, so that we have a condition known as the reaction of degeneration in the muscles most affected.

Before considering the next case I wish to call your attention to certain conditions in this. You observe we have, first, motor paralysis; secondly, sensory disturbance; third, trophic changes; and, finally, changes in electric reaction. You also notice that the trouble is bilateral and limited to the legs, assuming a form of paralysis known as paraplegia. When paralysis affects an arm or leg upon one side it is known as hemiplegia; when either one leg or one arm on one side of the body it is known as monoplegia; when the arms and legs are affected on both sides of the body it is known as diplegia. You observe another condition in this patient: his paralysis is limited to the distal portions of the extremities, and, further, a multiplicity of nerves are involved. The sensory disturbance, like the motor, is only found at the distal portions of the extremities.

We shall consider the nature of this case after we have reviewed others.

CASE II.—William R., aged 28, single, a rancher by occupation, born in Ohio, living in Colorado 2 years, was admitted into the hospital July 31, 1895. The family-history is unimportant. The patient enjoyed good health until 2 years ago when pulmonary tuberculosis began to develop, and for this he sought the climate of Colorado. He was feeling well until about the middle of July, of the present year, when he contracted typhoid fever, for which he entered the hospital. About the 9th of August delirium developed and continued for 2 weeks. He had a slight hemorrhage from the bowels 2 days later. His temperature ranged rather high, from 102.5° to 105° F., until August 24th, when he had a severe chill, and the temperature descended to 95°. By the application of heat and the administration of stimulants the temperature soon rose to normal. There was no delirium after August 25th. The pulse-rate has been high, varying from 100 to 150 throughout the disease. About the middle of August the man began to complain of pain in the legs, which it was noticed were exceedingly sensitive. I was asked by Dr. Bothwell, who had charge of the patient, to see him September 3d.

Upon examination I found extreme wasting of the leg-muscles, more marked below than above the knees. The dorsal flexors of the feet were almost completely paralyzed; the plantar flexors were much stronger. Each tibialis anticus muscle was capable of slightly moving the foot, but the left peroneous group was completely paralyzed, and the right nearly so. All other muscles of the legs were fairly strong for one in the man's emaciated condition. As to the reflexes, the right knee-jerk was very slight; the left absent. The plantar reflexes were exaggerated, the tendo-Achillis absent, the cremasteric and abdominal reflexes present. The deep reflexes of the arms were exaggerated. Tactile sense was almost completely lost over the feet, greatly lessened around the ankles, and decidedly impaired up to a point midway between the ankles and the knees. Over the area of tactile anesthesia the man was unable to appreciate considerable differences in temperature. Sensory phenomena around the anal region and over the external genitalia were normal. Objectively all forms of sensation were normal in the hands and arms, but the patient complained of a numb sensation in the right hand and in the little finger of the left hand. There was foot-drop, but no wrist-drop. The toes were exceedingly sensitive to pressure, and the contact of the clothing was annoying. No attempt at examination of the muscles by electricity was made because of the weakened and irritable condition of the patient.

This patient also presented a form of partial paraplegia, motor and sensory disturbance being limited to the distal portions of the extremities, with involvement of a multiplicity of nerves. There were motor, sensory, reflex, trophic, and, undoubtedly, electric changes.

CASE III.—John T., a man 87 years old, born in Pennsylvania, but living in Colorado one year, was admitted into the hospital March 20, 1895. His family history, as far as I am able to learn, is negative. The patient in childhood and youth was healthy, except for an attack of rheumatism at his 15th year. He suffered from typhoid fever 50 years ago, but made a perfect

recovery. His health continued good until 4 years ago, when he injured his right hip by falling from a wagon. He says that he did not consider himself seriously injured at the time, but his hip has troubled him ever since, especially if he stands long on his feet, or gets very tired. During the summer of 1894 an eruption broke out on his face, the parts burned and itched all summer, and in September the symptoms were quite severe. In February, 1895, the eruption began to disappear, but the soles of the feet became so sore that the man could scarcely walk. He had, at this time, a prickling and tingling sensation in both feet and legs up to the knees, which in the right extended to the middle of the thigh. Sometimes his feet seemed to burn; at others they seemed to him to be as cold as ice. These sensations increased to such an extent that he was compelled to take to his bed early in March. On his admission to the hospital, 20 days after having been confined to his bed, he complained of pain in the legs from the hips downward, more marked on the posterior portion of the thighs than on the anterior. He experienced pain in the parts, especially when the legs were extended, and said it was worse in the right than in the left leg. Careful examination at that time, both by the rectum and over the nerves by palpation, revealed no spots of decided tenderness. His chief complaint was of a dull heavy pain in the feet, legs, and hips, and a tingling sensation below the knees. A most careful examination by means of a camel's-hair pencil discovered no loss of sensation, and motion appeared good. Subsequent to this the tingling sensation became a dull heavy feeling in the legs, and it was so distressing that he was compelled to lie in bed and have the affected parts wrapped in warm flannels. It was not until some time in July or August that any loss of sensation was discovered in the feet and legs. Atheroma of all the exposed arteries in the body has been most marked from the time of his admission into the hospital.

A re-examination, September 8, 1895, showed no perceptible loss of power in the feet or legs. The main complaint at present is that his legs below the knees feel numb like sticks, that he has a sensation as though he could not move them, but on attempting to do so he finds that he has the power. Pain radiates from the right hip down to the heel. The knee-jerks are absent, the plantar reflexes are decided, but the tendo-Achillis jerk is absent. The cremasteric and abdominal reflexes are present. Tactile sense is lost from a point midway between the knee and the ankle downward. All other forms of general sensation seem to be about normal. The muscles below the knees are slightly wasted. The right thigh is a little smaller than the left by actual measurement, in several places by about a quarter of an inch. The glands in the right groin are sensitive and more prominent than those in the left. There is no tenderness of the spine, but there is apparent partial ankylosis of the right hip-joint, with some enlargement of the entire joint. It is impossible to determine the exact condition of this joint without etherization, as the adductor muscles of the thigh are so tense.

You notice that this case, while differing in some respects from Cases I and II, has certain characteristic symptoms similar to those found in the first two cases. With the exception of the hip-joint trouble, which is the result of an injury received several years ago, and which is apparently not related to the nerve-affection, the trouble is bilater, symmetric, and limited to the distal portions of the extremities. The sensory phenomena in this case are well pronounced, and the motor are slight.

CASE IV.—I would like to describe another most interesting case. I saw the patient a few days ago in consultation with the surgeon of the Denver and Rio Grande Railroad. The patient was a man about 35 years old, who had lived in Colorado for a number of years, and was employed in the D. & R. G. shops, principally in writing. He had always enjoyed excellent health until a few years ago, when he began to drink alcohol to excess. At first he took from two to three drinks daily. In the morning before breakfast he had his cocktail, and if he felt weak during the day he drank beer, and at night he took two or three "stiff drinks" of whisky to insure sleep. As time went on he found he had to increase his stimulants, as he thought, to keep himself up to his work. This habit of daily drinking continued for about 2 years. Two or three months ago, he found it quite difficult to use his right hand in writing, but did not notice anything wrong with the left. He did observe, however, that he did not walk as firmly as formerly, that he experienced a little difficulty in walking in the dark, and that occasionally numb and tingling sensations were felt in the hands and feet. A few weeks ago, on trying to alight from a car while it was in motion, he was thrown to the ground, falling on his right side, and bruising his right arm and leg. At the time the injury seemed to be slight, but soon after he observed that the right arm and leg were quite weak, and a few days later, on attempting to dress himself one morning, he found he was unable to stand. On examination I found the dorsal flexors of the foot below the knee almost completely paralyzed on the right side, and the flexors were weak. The muscles of the left leg below the knee were weaker than normal, but retained more than twice the strength of those of the right leg. There was partial foot-drop on the right side, but not on the left. The right arm below the elbow was almost completely paralyzed, so that there was partial wrist-drop. On the left side there was no wrist-drop, but the strength in the left arm was considerably impaired below the elbow. Tactile anesthesia was well marked on the bottom and dorsal surfaces of the right foot, and slight on the left foot. On the palmar surface of the left hand and on the dorsal surface of the fingers of this hand there was partial anesthesia. On the right hand tactile anesthesia was well marked, and extended a little above the wrist. The external genitalia and the anal region were uninvolved. Plantar reflexes, tendo-Achillis jerks, and knee-jerks were absent. All the other superficial reflexes were present, but the deep reflexes of the arms were increased. None of the special senses was affected, and the face and tongue were apparently in a normal condition.

This case is also similar in its prominent symptoms to the first three; the paralysis and tactile anesthesia, while most marked on the right side are bilateral, and the trouble is limited to the distal portions of the extremities. We may account for the symptoms being more pronounced on the right side than on the left by the injury which the man received to the right leg and arm some weeks previously, and it is probable that the right hand,

even before the injury, was affected out of proportion to the left, from the fact that he had to use it in writing, and the delicate movements tired the muscles, and, further, the constant use of this hand directed his attention to it more than to the other. However, to the effect of injury to certain nerves supplying groups of muscles in this class of cases, and the apparent unilateral character of the symptoms, I shall refer later in connection with the nature of these affections.

Now let us see if by the process of diagnosis by exclusion we cannot arrive at the probable nature of the trouble from which these four patients are suffering. Pain in the limbs, especially in the muscles and along the nerves, is often mistaken for rheumatism. Rheumatic pains in persons subject to rheumatism may precede or follow serious illnesses. They may be lighted up by injury and are unpleasantly influenced by the use of alcohol, but rheumatism, in the vast majority of cases, when it attacks the extremities, involves the joints, and it is exceedingly rare for the distal portions of the extremities alone to suffer. Rheumatism is not attended with areas of anesthesia, and when muscular weakness and wasting are present, which may occur from the involvement of the joints, there is no reaction of degeneration in the muscles, such as these cases present. The reflexes are not affected in rheumatism, except that at times the deep reflexes are increased. I have seen one case of rheumatism of the legs in which there was complete paralysis of the flexors and extensors of the ankles, but these symptoms were temporary in character, and proved to be due to the inhibitory character of the pain in the legs. Wasting of the muscles, if it occur in rheumatism, is a late symptom, and is always associated with affection of the joints. None of these cases would be mistaken for rheumatism after a careful study of them. Pressure-neuritis may give rise to symptoms somewhat similar to those presented by the cases which we have studied, but in this condition the paralysis is rarely bilateral unless it occurs from pressure in the pelvis or from disease of the vertebræ. When the distal portions of the extremities only are affected and the trouble is bilateral, it will, in the vast majority of instances, be due to other conditions than pressure on the nerves. If pressure should be the cause, the source of the irritation of the nerves in the legs is very easily detected. When the pressure occurs in the pelvis, the symptoms extend up to the seat of the pressure, and if the arms are involved the trunk-muscles will also be affected. There seems then to be no difficulty in excluding pressure-neuritis as the cause of the trouble in these cases. Spinal pachymeningitis may give rise to pain in the legs, shooting or dull, and sometimes the pain is limited to the course of the nerves, but here also the symptoms extend up as high as the seat of the pressure, so that the trouble is never limited to the distal portions of the extremities. In acute ascending paraiysis in which the affection begins in the feet and gradually travels up the legs and involves the muscles of the trunk and arms, there is little danger of mistaking it for an affection in which the trouble is limited entirely to the distal portions of the extremities, besides in acute ascending paralysis the disease runs a rapid course, there is but little anesthesia, if any, and atrophic changes have not time to become manifest in the muscles. Locomotor ataxia, on account of the pain and the ataxic symptoms, may simulate conditions of the kind presented by the cases we are studying, but there is no paralysis until late in the disease; the bladder-symptoms and eye-symptoms are usually pronounced, and there is no marked muscular wasting and true reaction of degeneration. Myelitis may give rise to paralysis that is most pronounced in the distal portions of the extremities, attended with foot-drop and areas of anesthesia around the feet and ankles; but in myelitis, if the symptoms are largely limited to the feet and ankles, the lower portion of the cord is affected, and there will be areas of anesthesia over the external genitalia and around the anal region; besides bladder-symptoms and bowel-trouble would invariably be present. In diphtheric paralysis there is usually a history, though frequently imperfect, of sore throat, but the paralysis always first manifests itself in the palate and muscles of the iris, so that there will be a difficulty in swallowing liquids and a tendency to constant dilation of the pupils. Hysteria is not to be disregarded in any class of cases of nervous disorder, but in this affection, except in cases of many years' duration, there is no marked wasting of the muscles and no electric changes. Further, no anesthetic areas limited to the distal portion of the extremities would be present. In this brief review it seems to me that we are able to exclude everything that would likely give rise to the symptoms that these cases present, except multiple neuritis, but, as my hour has expired, we shall take up and study the nature of multiple neuritis and the individual symptoms presented by these cases at our next clinic, one week from to-day.

(To be continued.)

CLINICAL MEMORANDA.

NOTES OF A GASTROSTOMY.

By H. G. WETHERILL, M.D.,
OF TRENTON, N. J.;
CONSULTING SURGEON TO MERCER HOSPITAL; GYNECOLOGIST TO ST. FRANCIS' HOSPITAL.

The patient whose case I report was a stationer by occupation, and claimed to have been in good health up to about one year ago, when he observed that it was very difficult, and soon became impossible, for him to swallow food. He had subsisted on liquids, which he swallowed with difficulty till one week before operation; and during that week he was sure nothing went into his stomach. Milk and other liquids swallowed in small quantities were promptly returned, mixed with pus and frothy mucus. His bowels had not been moved in weeks, and his urine was scanty and high-colored. Numerous attempts had been made at various times, and by a number of surgeons, to pass a bougie into and through the constriction, and it was thought this had been done; but it seems likely, in the light of subsequent events, that it could hardly have been accomplished.

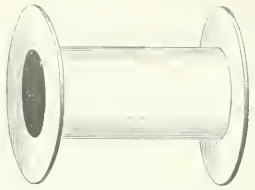
Two strictures were supposed to exist—one about nine inches from the incisor teeth, and one at the point of emergence of the esophagus from the diaphragm or just at the point of junction with the stomach.

When I first saw the man (March 14th) his emaciation and weakness were extreme. He was reduced from 135 pounds in weight to about 85 pounds; his tongue was dry and brown, his breath foul. He coughed a

great deal, and complained much of pain in the right side of the chest.

I passed a feeding-tube (No. 16 American catheter-scale), which met an obstruction nine inches from the

Fig. 1.



incisor teeth; this stricture was easily passed, and without the use of force. The tube was again arrested at fifteen inches, but did not convey the impression of being in the stomach, and a small quantity of milk passed into it soon filled the tube and the space about it, and ceased to flow. On withdrawing the tube the milk was regurgitated. A second attempt was made with a like result, and it was concluded that there was a permeable stricture at nine inches and an impassable one near the stomach.

The family-history of this patient was good, no member of his father's family or that of his mother's having had carcinoma or any strumous disease. He had never had any manifestations of syphilis, though exposed to the disease in early life, and he had a number of strong vigorous, and apparently healthy children. No tumor could be made out, and the cause of the obstruction could only be surmised. For the relief of the urgent need of nutrition, and to prevent starvation, an immediate gastrostomy was advised and accepted. The patient was removed to St. Francis' Hospital and was operated upon the following day, March 15th, after due preparation, rectal feeding being resorted to in the meantime.

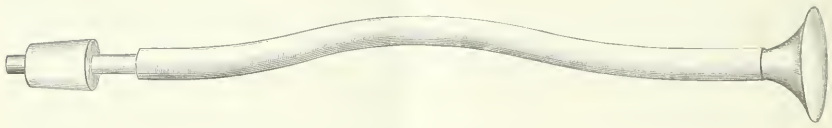
The thin abdominal wall was quickly traversed by an incision three inches long, the left border of the liver presenting at the upper end of the wound. The small and collapsed stomach was found lying against the vertebræ; it was caught, drawn up into the wound, and when a portion had been selected which was comparatively free from bloodvessels, was stitched by a double row of sutures to the parietal peritoneum and muscles. A dressing was quickly applied and the patient put to bed.

His recovery from the ether was prompt, and his condition under the circumstances very good. Rectal feeding was maintained, and on the second day after the operation the stomach was opened, and a glass tube (one-and-one-half inches long) with a flange on each end was carefully introduced.

The dressings were split, carefully placed about the tube, and covered with a piece of rubber to keep them dry. The stomach was then washed out with a little warm water, and a small quantity of milk was introduced and retained by a cork in the external end of the tube.

It soon became evident that the long, unused, and collapsed stomach would not dilate to receive a sufficient quantity of food unless some slight force was used to expand it; so a cork was perforated and a glass tube passed through it, to which was attached a rubber tube with a small funnel at the other end. The first cork was now removed from the tube in the stomach, the perforated cork introduced, and the apparatus brought into use. The force of gravity secured by raising the funnel eighteen or twenty inches was sufficient for the

Fig. 2.



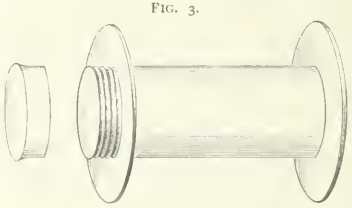
Perforated-cork apparatus.

easy introduction of half a pint of hot milk-punch at a time. By quickly changing the corks again, the food introduced was retained, the pressure from within acting against the inside flange and preventing any leakage by the sides of the tube.

There was nothing for use in such a case to be found in the instrument-makers' catalogues or in the instrument-stores to which I had access; so I had a tube made of hard rubber with a screw-cap, for permanent wear, as it seemed safer than a glass one, *i. e.*, not so liable to be broken.

This was introduced, but it was not so satisfactory as was hoped, because the screw-cap could not be easily and

Fig. 3.



quickly put on, and there was much loss of stomach-contents and soiling of dressings. The screw-cap when in place was flatter and less in the way than the cork.

The patient gained in strength and spirits at once after substantial food was taken. His bowels began to move regularly, and his urine was much increased in quantity.

It became evident that there was a spasmodic element

about the constriction of the esophagus that had been relieved by rest, as the man could now swallow small portions of beer or water; yet milk given through the tube regurgitated by the mouth at times. Strong hopes were entertained that the stricture could be passed from below and distended by the Cutter rosary bougie and the string-saw when he had gained sufficient strength to warrant the attempt.

These hopes were delusive, as his improvement was temporary. In two weeks his failing strength and energy were nearly exhausted, and on April 4th (twenty-one days after the operation) he died, notwithstanding the fact that he had taken fair quantities of food which had seemed to be easily digested and assimilated. The reason for this became apparent at the autopsy.

The body was found to be very much emaciated. The stomach was firmly adherent to the abdominal wall, there having been no peritonitis. The liver was enlarged and displaced downward and to the right. The gall-bladder was distended, and its fundus was within an inch of the symphysis pubis. The right border of the liver reached well below the crest of the ilium. The other abdominal organs seemed normal.

On opening the chest a great deal of inflammatory thickening was found about the lower end of the esophagus. The right lung was adherent, and the right pleural cavity contained about a pint of thick, bloody, and offensive pus. The lower lobe of the right lung was infiltrated with pus, and was the seat of croupous inflammation. It was hepatized and thoroughly consolidated. The apex of each lung contained cicatrices of old tuberculous lesions. On the right side there had been considerable destruction of tissue (cavity). A stricture of the esophphagus was found one inch below the bifurcation of the trachea, with an ulcerated opening or false passage leading into the right pleural cavity.

About this were sinuses containing pus. The stricture involved only about one-and-one-quarter inches of the esophagus, and was the result of an ulcer, probably of specific origin. It was very evident that the condition of things in the right lung and pleura was due to the communication with the esophagus. The cause of death was pneumonia, sepsis, and asthenia.

The study of this case in the retrospect develops many interesting points, and reinforces the good old teaching as to the exercise of great care in the use of the esophageal bougie; for there can be little doubt that the false passage into the pleural cavity was made by the passage of a bougie. Subsequent inquiry of the family fixed the time when this accident very probably had taken place. In August, 1894, a bougie of large size was passed with difficulty. The operation was painful at the time, and was followed by a free flow of blood, by pain in the right side, with chills, fever, and confinement to bed; cough and expectoration supervened and remained till death.

Esophageal bougies have been thrust into abscesses, anuerysms, the pericardial and pleural cavities, as well as into the mediastinal spaces; so that the utmost gentleness must be exercised in their use.

That this condition in the chest was not diagnosticated before death was due to the fact that I had seen the patient only the day before the operation, and then the imminent starvation was the matter of greatest importance, demanding immediate attention, and his condition was such that no thorough physical examination could be made.

The dreadful condition of the lower lobe of the right lung and the pleural cavity, the former being riddled with pus-pockets and the latter full of pus and of portions of food which had been swallowed or introduced by the tube, made it a marvel that the man had survived so long a time. Beside this, little food could have gone into his stomach, as the stricture was so tight as to be almost impenetrable.

The question whether milk and other food which had been introduced into the pleural cavity might have been partially absorbed, and so prolonged life, was considered; but it seems hardly probable that any considerable quantity could be thus taken up by tissues so inflamed and disorganized.

Could this gastrostomy have been done before the esophagus was perforated, there can be but little doubt that the patient's life could have been saved, the stricture being passed from below and subsequently dilated, after which the closure of the new mouth into the stomach would have been an easy and natural sequel.

TACHYCARDIA ASSOCIATED WITH FUNCTIONAL AND ORGANIC MURMURS AND DISTURBED NERVOUS MECHANISM.

By THOMAS LUTHER COLEY, A.B., M.D.,
of Philadelphia.

William McC., aged 19, white, a clerk by occupation, first came under observation on July 16th. Two days before (on the 14th, which was a very warm day), he had been playing baseball and was seized with a violent attack of palpitation, accompanied by great dyspnea. Both of his parents are well; one grandparent is alive at 85; the others all died after 70. The patient has one brother who is a hale, hearty boy of 16. One brother died of diphtheria at 2 years, another of hydrocephalus at 3 months. William has always been a weak, sickly child whom his parents had despaired of raising. He has had measles, chicken-pox, whooping-cough, and pneumonia of a severe type some 8 winters ago. He is of an extremely nervous temperament. For 5 years he has had attacks of palpitation of varying severity brought about by the slightest nervous shock, even at times by straining at stool. None of these attacks has been of long duration, and most usually but momentary. One, however, was very severe in December, 1892. At that time the attack lasted uninterruptedly for 4 weeks, but was lighter than the present one. The pulse when first counted was 195. A few moments afterward it had fallen to 165. He said that the slightest noise in the street or in the house, the slightest commotion, the visits of expected friends, even the opening of his door, all tended to aggravate the symptoms.

The patient was very thin and extremely emaciated. The mucous membranes were pale, the conjunctivæ pearly, and the skin ashen. A blood-count made at this time showed 55 per cent. of hemoglobin and two-and-one-half million red corpuscles. The chest was very much malformed and markedly rachitic, the costal

angles being considerably increased. The left side was much more prominent than the right; the apex-beat was greatly displaced downward and to the left. It was very diffuse and centered at the seventh rib in the mid-clavicular line. There was much epigastric and precordial pulsation and visible pulsation in the jugulars. The chest, while emaciated and somewhat flattened on the right side, was of good depth, antero-posteriorly, and the movements of respiration were well marked. There was no edema under the eyes or in the hands and feet, nor had any existed to the patient's knowledge. The tumultous pulsation was transmitted strongly to the palpating hand and moved it forcibly. The lungs were normal, with slightly increased expiration. On auscultation the rhythm of the heart was found to be greatly disturbed; but so great was the rapidity of its action that no functional or organic murmurs could at this time be detected. An ascribed cause of this condition, that of abortive systole, conveys the idea of the sound of this terrific overaction.

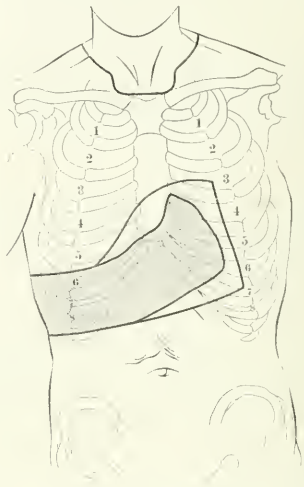
The patient was placed at absolute rest in a darkened room and upon milk-diet and stimulants. Calomel was prescribed in divided doses to keep the stools soluble. The bromids were ordered in 20-gr. doses t.d., and increased to 30 gr. An ice-bag was also applied to the chest. Strychnin was given in doses of $\frac{1}{20}$ gr. every 4 hours. Digitalis was also tried in 15-drop doses of the tincture; but the result of this treatment was unsatisfactory. The bromids were discontinued at the first signs of disturbing the stomach. Fowler's solution was next prescribed in ascending doses and morphin given, $\frac{1}{8}$ gr., every 3 hours. The morphin, which was also tried in $\frac{1}{4}$-gr. doses hypodermically, gave the patient considerable comfort, but the pulse did not fall below 165. The boy continued to grow weaker, his appetite failed entirely, and symptoms of jaundice appeared, which was unfavorably regarded as due to passive portal congestion, but this was happily relieved by calomel. For 6 weeks the patient continued in this condition, with the heart pulsating from 195 to 165 per minute, but not going lower.

Finally tincture of cannabis indica in 5-minim doses, with tincture of aconite in 2-minim doses, was tried with success. After a very few doses had been taken great improvement was noted, and soon the pulse fell to 60. Earlier in the case a slight degree of pyrexia (100°) had been observed, and a simple mixture with drop-doses of tincture of aconite had relieved it, but this did not affect the heart's action; the action of the cannabis indica, combined with aconite, proved, however, very satisfactory.

Auscultation performed after this remarkable drop in the heart's rapidity led to the astonishing fact that, while no murmurs could be detected at any time during the attack, now they were plainly audible. This is another case of the sort reported by Brunton,[1] in which a basic murmur, well heard when the heart was beating quietly, disappeared when its action became very much greater.

There was present in the case under consideration a very pronounced mitral systolic murmur, well transmitted to the inferior angle of the scapula. The aortic second sound was markedly accentuated. There was a soft, blowing, systolic, pulmonary murmur, with a snapping, ringing second sound. Both sounds at the ensiform were valvular and forcible. The heart was very irregular in its action; both sounds were plainly heard in the carotids. In the veins at the root of the neck, most distinct upon the right side, hemic murmurs were heard, accompanied by a continuous thrill and a venous hum.

The percussion-outlines, as shown in the accompanying illustration, indicate great hypertrophy and dilatation of both ventricles, the marked deformity of the left side referred to supporting the evidence of percussion.



Showing superficial and deep cardiac and hepatic percussion-dulness.

The causes that tend to produce palpitation may be enumerated as follows: (1) Anemia; (2) pyrexia; (3) exophthalmic goiter; (4) organic heart-disease; (5) pure neuroses; (6) reflex influences, such as gastric disturbances, tapeworm, etc.; (7) shock; (8) rheumatoid arthritis; (9) the use of tea, coffee, tobacco, etc.; (10) central nervous disease, causing pressure on the pneumogastrics, such as basal tumors, etc.; (11) nephritis, especially late in the cirrhotic form (Brunton). Of these there were eliminated in this case the pyrexia, of which but a very slight degree was present, and that not continuously, the shock, rheumatoid arthritis, reflex influences, pressure upon the pneumogastrics, the effects of tobacco, tea, and coffee, none of which had been used. The patient's youth and careful examination of the urine, which proved normal, leaves nephritis out of the question. The thyroid was not enlarged, no exophthalmos was present, nor von Graefe's or Stellwag's signs.

We have left then to discuss anemia, pure neuroses, and organic heart-disease. Of these the anemia accounts so readily for the symptoms and for the cardiac neurosis that it seems best to regard it as the cause of

[1] Lancet, November 27, 1875.

the conditions associated undoubtedly with the neurotic tendency.

The blood in anemic conditions is usually regarded as deficient, both in quantity and quality, and the hemoglobin of the red blood-corpuscles is decreased; also the albuminoid constituents of the blood-plasma.

"This impoverishment," says Fowler (*On the Origin of Anemic Murmurs*) "is felt in every tissue and organ of the body, and the sum-total of the phenomena thus evoked constitutes the anemic condition."

It is hardly possible to believe that the weakened, dilated heart of anemic conditions is not also accompanied by the grave structural change of fatty degeneration of the heart's muscle. The degree of hypertrophy found associated with the dilatation of anemia and due to overaction must necessarily be limited, for the weakened heart-structure cannot produce very great hypertrophy.

The destructive changes in the nervous mechanism of the heart follow upon these other changes, notably in the quantity and quality of the blood, and there are produced the nervous effects of tachycardia and such associated symptoms of the purely neurotic type of palpitation.

It is not always a simple matter to differentiate between a functional and an organic cardiac murmur. No excessive dilatation of the organ could long exist without producing valvular deficiencies. In this case the soft, systolic, pulmonary murmur seems to be typical of the condition of grave anemia. The accentuated aortic second sound indicates the dilatation and hypertrophy of the left ventricle.

The systolic mitral murmur is clearly heard at the inferior angle of the scapula, in which position a purely functional murmur is not (?) heard. The right heart, while evidently greatly dilated, fortunately does not reveal the evidences of tricuspid regurgitation.

To summarize, the patient suffers from palpitation of the heart from functional, organic, and nervous causes. The anemia, however, seems clearly responsible for the severity of the condition.

The patient continues to take strychnin and Fowler's solution, and has greatly improved. He has been able to resume work, and his appetite and digestion are good. The disturbed cardiac mechanism still causes him the occasional return of spells of palpitation, but these have not been of a severe character.

The prognosis in such a case cannot be very favorable, but it is gratifying to note the increase of red blood-corpuscles to 3,100,000 and of hemoglobin to 60 per cent. at the last blood-count (October 4th), and that the patient has gained 9 pounds in weight.

MEDICAL PROGRESS.

Congenital Absence of the Rectum.—Woodhouse (*Lancet*, No. 3760, p. 733) relates the case of a thin, weakly woman, thirty years old, with a tuberculous family history, who came under observation three days after the birth of her first child—a male. The infant had been constantly sick since six hours after birth, when the mother first nursed him, and although abundant urine had been passed, the bowels had not acted. The child was thin and puny, cried repeatedly, and was evidently in great pain. The abdomen was much distended and tympanitic. The anus was absent, nor was there any evidence of its presence in the normal situation, beyond a slight depression close to the median raphé. There was no impulse or bulging in the perineum when the child cried. It was decided to at once make an attempt to relieve the child and establish patency of the rectum, which it was thought would probably be within a short distance of the surface. The little patient was anesthetized with chloroform and an incision an inch long made in the middle line in the normal situation of the anus, cutting upward and backward, and keeping close to the sacrum. From time to time the little finger was introduced into the wound, but nothing indicative of gut could be felt, even at the depth of 1¾ inches. Inguinal colotomy was abandoned on account of the exhausted condition of the patient, and the wound was dressed with boric powder and salicylated wool. Death took place five hours after the operation. On post-mortem examination the intestines were found greatly distended, but otherwise normal, until a point was reached close to the brim of the pelvis in the left iliac fossa, where the sigmoid flexure abruptly terminated in a cul-de-sac. The peritoneum was intact and showed no signs of inflammation. All the other pelvic organs were normal. The pelvis itself was smaller than usual and the tuberosities of the ischia much closer together.

A Diagnostic Sign of Aneurysm of the Heart.—Embley (*Australian Medical Journal*, vol. xvii, No. 8, p. 361) has reported the case of a well-nourished man, sixty years old, a watchmaker, of sedentary though temperate habits, who presented loss of power in the right upper extremity. The apex-beat of the heart was in the nipple-line, while the area of cardiac percussion-dulness extended considerably to the left. The heart-sounds were with difficulty audible in consequence of their low pitch and of the thickness of the chest-walls, but especially because of the presence of a musical sound quite distinct from the normal sounds. This sound was high-pitched, humming, continuous throughout the entire cardiac cycle, rising in systole and falling in diastole, audible from apex to base, but loudest at the apex. There was complaint of pain and numbness in the left arm, with pain and hyperesthesia in the cardiac region. Later there was dyspnea on exertion, pain and numbness in both arms, flatulence, anorexia, sleeplessness, and more marked precordial pain and hyperesthesia. The abnormal humming persisted. Death took place suddenly. Upon post-mortem examination the pericardium was found distended with thirteen ounces of blood-clot, and in the posterior wall of the left ventricle was a small, ragged opening from an aneurysmal dilatation. The heart was covered by a thick deposit of fat; its muscular substance was soft and affected by fatty degeneration; the left ventricle was hypertrophied. The valves appeared competent. The vessels were atheromatous.

The Bacteriologic Diagnosis of Diphtheria.—When ordinary facilities for bacteriologic investigation are not available in the diagnosis of diphtheria, Wright and Semple (*British Medical Journal*, No. 1815, p. 907) recommend for the preparation of a satisfactory culture-medium the use of a small quantity—say half a tea-

spoonful—of antitoxic serum, or, if this be not at hand, white of egg, which is introduced into a small, wide-mouthed bottle. The latter is placed in a horizontal position and its contents coagulated over steam. Any water of condensation is poured off, and the culture-medium is permitted to cool. The inoculation is made by passing lightly over the surface of the medium a stout wire or glass rod which has been brought in contact with the diphtheric throat. The stopper is to be replaced and the bottle is to be kept as nearly as possible at blood-temperature. If this is not attainable the temperature of an inside pocket will generally suffice. The microscopic examination may be undertaken after twenty-four hours have elapsed. The material for examination is obtained by lightly scraping the surface of the culture-medium with a platinum wire.

Successful Removal of a Brain-tumor.—In the Section for Surgery of the recent Congress of German Naturalists and Physicians, ROTH (*Deutsche medicin. Wochenschr.*, 1895, No. 40, Suppl. No. 25, p. 168) reported the case of a man, 60 years old, who had presented a typical clinical picture of focal epilepsy. On trephining the skull a soft tumor was found in the cortex, invading the fissures and in places adherent to the pia mater. The growth was removed principally by blunt dissection. Careful examination proved the formation to be a parithelioma arising from the parithelium of the vessels. Immediately after the operation the arm of the affected right side was totally paralyzed; the right leg and the lower portion of the right side of the face were markedly paretic; paraphasia was considerable. In a short time, however, progressive improvement set in. The paresis of the face and leg disappeared, then gradually the paraphasia. Bodily and mental strength increased. The attacks of headache formerly present were not repeated, and the convulsions remained in abeyance. The paresis of the right arm disappeared very slowly.

Poisoning by Stale Eggs.—CAMERON (*Dublin Medical Journal*, October, 1895, p. 311) has reported the occurrence of vomiting and purging in 74 nuns and girl-pupils in the boarding-school attached to a convent in Limerick, following a dinner at which mutton and a custard composed of eggs, milk, corn-flour, and sugar were eaten. The corn-flour was suspected to contain arsenic, but analysis showed it to be free from poison of any kind, and to be of good quality. The sugar also proved to be pure. No other constituents of the meal could be obtained. The vomit and the stools were intensely green from the presence of biliary matter, but careful analysis failed to disclose the presence of ordinary poison. The viscera of two patients that had succumbed also were examined, but no poison was found. Ptomaines were found present, but in small quantity. The milk used had been boiled, and the meat was above suspicion. The eggs, however, were not fresh, and one presented a reddish-brown color, and was thought to be bad. Some of the custard, given to pigs, induced severe diarrhea. Reference is made to an earlier case of poisoning by stale eggs.

A Culture-medium for Diphtheria-bacilli.—TOCHTERMANN (*Centralblatt für innere Medicin*, 1895, No. 40, p. 961) recommends the following formula for the preparation of a culture-medium for diphtheria-bacilli, having several practical advantages over the media in current employ: To a 2 per cent. watery solution of agar-agar are added 1 per cent. of peptone, ½ per cent. of sodium chlorid, and from 0.3 to 0.5 per cent. of glucose, and the whole is filtered, then boiled for from one-quarter to one-half hour with calves' blood-serum in equal parts or three parts of serum to two of agar-agar-solution. The filtrate is received in a flask and sterilized by exposure to the vapor of steam for from an hour to an hour-and-a-half on three successive days. No precautions need be taken to insure sterility of the blood, which is permitted to stand for twenty-four hours and the supernatant serum then poured off. The presence of a small number of red blood-corpuscles in the serum is of no moment, as the filtrate is clear after boiling. The inoculation may be made upon the surface of the hardened medium.

Polyesthesia and Macroesthesia.—STCHERBAK and IVANOFF (*Archives de Méd. Experim. et d'Anat. Path.*, 1895, No. 5, p. 657) have reported a case of polyneuritis and hysteria presenting curious sensory manifestations in the distribution of the right median nerve. A body touched or held with the thumb and the adjoining two fingers felt larger than it was actually (macroesthesia), and at the same time it seemed as if several bodies of the same kind were felt (polyesthesia). At different times varying sizes and numbers were appreciated. The phenomena could not be elicited elsewhere than in the region named. Its advent had been preceded by severe pains, paresthesia, and trophic changes, particularly in the distribution of the right median nerve. The paresthesia continued in association with the polyesthesia and macroesthesia, and disappeared with them. There was also impairment of both tactile and muscular sensibility in the affected area.

THERAPEUTIC NOTES.

The Diuretic Action of the Salts of Lithium.—As the result of an experimental investigation, which was confirmed by clinical observation, MENDELSOHN (*Deutsche medicin. Wochenschr.*, 1895, No. 41, p. 673) has found that while all of the salts of lithium possess diuretic properties the most active in this direction is the citrate, which possesses the additional advantages of solubility and comparative freedom from unpleasantness of taste. Next in activity is the acetate. It is further pointed out that chemic solvents of uric acid are not necessarily useful agents in the treatment of gout or the uric-acid diathesis.

For Hematuria.—

℞.—Ext. physostigmatis alcohol . gr. ⅙.
Quininæ sulphatis . . . gr. ¾.
Ergotinæ . . . . . gr. jss.—M.

Philadelphia.

SATURDAY, NOVEMBER 2, 1895.

THE PATHOLOGY AND THE TREATMENT OF GOUT.

While the clinical picture of gout in its varied manifestations has been clearly made out and its treatment has been placed upon a fairly secure basis, a good deal of doubt and uncertainty surround its intimate pathology, and this the near future promises soon to dispel. In an interesting address delivered recently before the Berlin Society for Internal Medicine, Klemperer (*Deutsche medicinische Wochenschrift*, 1895, No. 40, p. 653) reviewed the main phases through which this subject has passed, and presented evidence showing that none of the views hitherto propounded is entirely adequate or satisfactory. In addition he recited the results of some original investigations which, while not solving the problem, bring it closer to a solution and shed new light on an obscure subject.

Garrod maintained that gout is due to increased formation and diminished elimination of uric acid; when an excess has accumulated in the blood it is deposited in the tissues, in which it gives rise to inflammation and necrosis. Recent investigations have, however, thrown doubt upon the accuracy of the results of Garrod's analyses. Nevertheless Ebstein admits the probability of an excessive production of uric acid, with accumulation in the blood; the circulating fluid, thus surcharged, causes local inflammation followed by necrosis, and in the necrotic tissues uric acid is deposited. v. Noorden has arrived at the conclusion that the gouty condition is independent of the presence of uric acid in the blood; the tissue-necrosis that occurs he ascribes to the activity of a hypothetic ferment, and he believes that the uric acid deposited locally is formed at the necrotic focus.

To determine the relation between the presence of uric acid in the blood and tissue-necrosis, Klemperer made a study of a number of individuals, including three persons in health, a case of leukemia, one of pneumonia, two of interstitial nephritis (one compensated and one uremic), and four of gout (three during a paroxysm and one uremic). In all of the cases of gout, as well as in the case of leukemia, and in both cases of nephritis, comparatively large quantities of uric acid were found in the blood. To ascertain whether this result is due to increased production or to diminished elimination the urine was studied in eight cases of gout, placed under like conditions. In two the daily amount of uric acid found in the urine was between 0.4 and 0.5 gram; in five between 0.5 and 1 gram; and in one between 1 and 1.2 grams. No relation existed between the amount of uric acid present in the urine and the character of the disease.

It has been shown that the ingestion of thymus gland of the calf by healthy persons is followed by increased excretion of uric acid, and a similar increase was also found to take place in gouty persons. From all the facts it appears that there is no retention of uric acid in gout as long as the function of the kidneys is not materially interfered with and that the presence of considerable amounts of this substance in the blood cannot be attributed to diminished elimination, but must be ascribed to increased production. The presence of similar amounts of uric acid in the blood of others than gouty patients, however, shows that this factor does not constitute the essential element in the causation of the gouty condition.

Klemperer has found further that slight and insignificant differences exist in the solubility of uric acid in the blood-serum of gouty patients as compared with that of other patients and also of healthy persons, the solvent power of the serum in all being considerable—in fact, more than sufficient to dispose of the large amounts of uric acid present. He

is, therefore, forced to the conclusion that the deposit of uric acid in the necrotic areas of gouty persons is not due to its insolubility in the blood, but is to be explained by the fact that such tissues possess a greater chemic affinity for uric acid than does the blood. Experimental observations showed also that while the blood underwent some diminution of alkalinity during the gouty paroxysm, this was not more than occurs under other conditions, and certainly not sufficient to account for the crystallizing out of uric acid.

In view of all the evidence, the conclusion is reached that in the gouty certain unknown substances lead to inflammatory and necrotic processes in various tissues, and the necrotic tissues possess the property of attracting from the blood uric acid when present in considerable amount. These substances frequently develop from hereditary influences; sedentary pursuits and high living favor their formation; and two poisons in particular—alcohol and lead—predispose to their activity. It has hitherto been supposed that intoxication with lead paves the way for the development of gout by lessening the excretion of uric acid, but it has been shown that lead-poisoning does not have this effect; it may be that the lead present in the blood enhances the necrotic effect of the gouty poison.

The practical deduction from what has gone before is that successful treatment must depend not upon increased solvent power of the blood upon uric acid, but upon the correction and the prevention of the necrotic process by increased oxidation and increased elimination. The attainment of these ends is largely reached through the employment of established measures whose use is sanctioned by the empiricism of centuries. These include increased physical activity, warm or hot baths, free ingestion of milk and of water, preferably alkaline, the avoidance of meat in excess, particularly red meat, and of fats, alcohol, and other carbohydrates. Finally, thymus gland may be administered to increase elimination of uric acid.

KEATS, THE APOTHECARY-POET.

INTO the Academy of the Immortals, that small and select body, few members of the profession of medicine have ever been admitted. In English literature we have furnished two or three to the charmed circle that surrounds Shakespeare; but, by common consent, one sits close beside the Master, the young apothecary, Keats, the centenary of whose birth all lovers of poetry have celebrated this week. Born in 1795, at the sign of the "Swan & Hoop," Moorgate Pavement, London, son of the head 'ostler, the circumstances of his birth and of his early years were by no means favorable to the cultivation of the Muses. Fortunately, at school, the influence of Charles Cowden Clarke turned the thoughts of the pugnacious lad from boxing to poetry, and before he had reached his fifteenth year Keats was an ardent student of the Elizabethans, and his fate was sealed. In 1810 he was apprenticed to Mr. Hammond, a surgeon at Edmonton. In the lithographed copies of the indentures of that date the number of specific negatives indicate the character of the apprentice to whom cards and dice, taverns and playhouses, fornication and matrimony, are equally interdicted. We know but little of the days of Keats' apprenticeship. A brother-student has left on record that "he was an idle, loafing fellow, always writing poetry." In 1814 pupil and master quarrelled, and, by mutual consent, the contract was broken. It would appear from the following sentence in one of Keats' letters that not words alone passed between them: "I dare say you have altered also—our bodies every seven years are completely fresh materiel'd. Seven years ago it was not this hand that directed itself against Hammond." Keats attended the United Hospitals of St. Thomas' and Guy's for two years, 1814–1816, and in the latter became dresser to Mr. Lucas. On July 25, 1816, he passed the examination for License of the Apothecaries' Hall, then, as now, the lowest qualification in England.

A medical student capable of writing such a sonnet as the celebrated one "*On first looking into Chapman's Homer*" was not likely to settle down as junior partner in some suburban or city practice. While at Guy's, Keats had made the acquaintance of Leigh Hunt and other literary men, some of whom recognized the quality of his mettle. So far as is known he never practised medicine, but for four years lived, as he says, "an odd sort of life, here and there—no anchor." He had many warm friends, and his letters to them and to his brothers show great depth of feeling, and often a critical faculty of singular delicacy in one so young.

In 1817 he issued a small collection of poems, and in 1818 the more ambitious *Endymion*, which was mercilessly hammered by the reviews. An article in the *Quarterly* was for long thought to have

hastened his death, but the basis for this widespread belief is chiefly the jaunty lines from "Don Juan:"

> "'Tis strange the mind, that very fiery particle,
> Should let itself be snuffed out by an article."

In 1818, and again in 1819, he buried a brother with pulmonary tuberculosis, of which disease his mother had died. In February, 1820, he had a hemorrhage from the lungs after exposure, and from this date he began a hopeless struggle against rapidly advancing tuberculosis. In 1820 Keats issued *Lamia, Isabella, and Other Poems*, the volume which contains his greatest treasures. In September he sailed for Italy with his friend, Severn, an artist. During the months of January and February he was in Rome, attended by Dr. (afterward Sir James) Clark, and nursed with unremitting care by Severn, whose account of Keats' illness is one of the most touching descriptions in literature.

Racked by a hopeless passion, and consumed by an insatiable disease as the end drew near, when the "shadow of white death" was o'er him, he asked to have inscribed on his tomb the line, *Here lies one whose name was writ in water*. But the world has judged differently, and has taken the verdict of the man whose heart was so soon to rest beside him, and whose *Adonais* is an everlasting tribute to his memory.

EDITORIAL COMMENTS.

A "Shake-up" in the New York City Hospitals.—Ever since the recent request from the Commissioners of Charities and Correction for the resignations of all the members of the staff of the Harlem Hospital, there has been a feeling of uneasiness among those connected with several of the hospitals under the control of the Commissioners. Only last week, one of the former staff of the Harlem Hospital declared before the New York State Medical Association that he understood this process of ousting, or "reorganization," as it is considerately termed, was to be extended to the other hospitals. His prediction was soon verified. A few days ago the Commissioners of Charities abolished the consulting and medical boards of all the hospitals under their control, with the exception of Bellevue Hospital, in which the new system of making appointments has been in operation since 1882. The result of this radical step has been the creation of one-hundred-and-twenty vacancies in the hospitals. Many of these physicians have given faithful and gratuitous service for many years, only to find themselves unceremoniously removed, without any charges having been made against them, and with not even a conventional "thank you" for what they have done. There is small wonder, therefore, that such a sweeping measure should call forth a burst of indignation from the medical profession, and it has already found expression in resolutions adopted by the New York County Medical Association, in which it is declared that this action of the Charities Commissioners is not only unjustifiable, but is, in fact, a slur upon the hospital-physicians who have so freely given of their time and skill.

According to the resolutions adopted by the Commissioners, the College of Physicians and Surgeons, the University Medical College, the Bellevue Hospital College, and the Fourth Division of Bellevue Hospital are requested each to make a certain number of nominations to the visiting staff of each of the other hospitals, and the consulting staff of Bellevue Hospital, created in a similar manner, is to act as a consulting board for these other hospitals. It is openly charged that the Commissioners have been induced by the medical board of Bellevue Hospital to take this action because that hospital found itself short of clinical material. Some of the physicians who feel especially aggrieved at the action of the Commissioners do not hesitate to assert that, in addition to affording these colleges an opportunity to secure more clinical material, this new system gives a little more political power to the President of the Charities Commission.

But the chief objection made, and one which can hardly be gainsaid, is that under the new *régime* the appointments to the visiting staffs of these hospitals will be made solely from the three large medical colleges already mentioned. The Commissioners, on the other hand, defend their action by stating that, as the system had worked well in Bellevue Hospital for a number of years past, they were anxious to improve the other hospitals by adopting the same system in them all. They also say that the measure is intended to remove the appointments entirely from political influence. Undoubtedly, to remove the appointments beyond the reach of politics would mean a great improvement in the service of the hospitals, but, if we mistake not, there is a good deal of politics in certain medical circles, and a "trust" composed of three powerful medical colleges, controlling a large and valuable patronage, is more than likely to be so tainted. It certainly does not seem right or just that these medical men, many of whom have conscientiously served these hospitals, and have given their best years to the work, should be thus peremptorily ordered to stand aside and make room for whomever it may please the colleges to put in their places. The Commissioners say that it will be found, when the appointments are announced, that many of the former incumbents have been retained. So far, so good; but how about those who are dropped without a charge against them, without a hearing, and with no means of redress? If these hospital-positions carry with them a great deal of prestige—and it cannot be denied but that they do—can such arbitrary removal fail to work a gross injustice to those who have not sufficient influence with the colleges to secure their reinstatement?

School-children and Food.—The Board of Education of New York City refers to parents the question, Whether one hour's recess for school-children is too short or not? A member of the Board thought that too little time was allowed the children to digest their food, and that, as a consequence, dyspepsia resulted. The teachers, on the other hand, maintain that the extra half-hour recess that it is proposed to give the children would only be spent in play, that the meals would be eaten as hastily as ever,

and that nothing would be gained; the parents of the children have, therefore, been asked to state their views on the subject in writing to the Board.

A heavy dinner eaten hastily, violent exercise immediately after, and then the school-task, is surely not conducive to sound digestion, but lengthening the recess will hardly bring about the desired result. The higher schools and many private schools accomplish all that is necessary in one session, and why cannot the other divisions do the same? A light luncheon during the forenoon would be sufficient to appease hunger in even the youngest child, and then after a second meal at home at two o'clock the rest of the afternoon could be devoted to play or such other studies as now come in the evening, the heaviest meal occurring at six o'clock. Many persons are at present concerning themselves with the matter of supplying school-children with proper lunches, and the New England Kitchen has done much in this direction in the city of Boston; but why not go a step further and serve a hygienic luncheon to all the children in the school-room at public expense, thus giving them an acceptable object-lesson on the subject of foods, their preparation and value, and teaching them ordinary table-manners. But more than this, what a blessing these meals would be to the thousands of little children who now come to school practically with empty stomachs. This would be charity? Yes, but it would have none of its evils and all of its benefits, as it would be regarded in the same light as free school-books are now, a right shared in by all without distinction of class.

All children are wards of the State, the richest as well as the poorest, the honest as well as the delinquent, and it is the State's business to see that they receive a healthful education as well as a helpful one. It is the duty of the State to do this because it is a matter of self-protection and more needed than the building of warships or the equipment of armies; the one, in fact, often makes the other unnecessary. A proper education, we maintain, is dependent on proper body-nutrition; this question of feeding has more to do with the intellect, and with morals, too, than most philosophies account for, and some day our pedagogues will be as much concerned about the building of brain-structure as they are now in the adornments of intellectual trappings. The feebly nourished brain-cell becomes warped and bent under its burdens and gives way, just as the starved bones do under the weight of the body, The fault is not so much in the weight, but in the weakness of the structures. When all children will have plenty of exercise and plenty of healthful food, then only can we expect to have a race of healthy, well-educated, noble-minded beings. Any objection to free school-luncheons on the ground that the measure is socialistic or paternalistic seems to us unwarranted and puerile.

We believe in compulsory education, but studying is working, and the State does wrong when it compels a child to work on an empty stomach or if insufficiently fed. On the other hand, it derives from the wise education of every individual a benefit that cannot be valued in dollars and cents, and should do all in its power to foster such education.

Faith-healing and the Pulpit.—There is no question that the scientific and rational spirit is abroad in the land and is getting "abroader" every day. It has long been a matter of deep regret to our profession and to scientists generally that the one great survival of the credulity of the savage stage of our development, the faith-healing delusion, was almost unanimously endorsed and supported not only by the clergy, but also by the great mass of evangelical opinion. It is true there were many honorable exceptions and that a considerable portion of the more thoughtful orthodox element displayed no enthusiasm over or even approval of these "modern miracles," but even their lips were largely sealed by such texts as "With God all things are possible," "The prayer of faith shall heal the sick," etc., and they hardly dared to deny the, at least possible, divineness of these manifestations. As a result they have become extraordinarily prevalent of late not only among the ignorant peasantry of Europe, where they occasion little surprise, but also all over this enlightened Republic of ours, whose intelligence and freedom from superstition has long been one of our proudest boasts. No small proportion of our "revivalists" have gradually come to claim "the gift of healing," and scarcely a town or neighborhood can be found through the Middle and Western States which has not been visited by one or more "faith-healers" within the last few years.

But like all other evils, this one has brought its remedy with it, and signs of a healthy reaction within the church itself are now plainly to be seen. The protest was started some years ago by the brilliant and eloquent Methodist divine, Rev. J. M. Buckley, of New York, and less prominently by a number of other ministers, and the good sense of the churches has now become aroused to such a degree that a considerable part of both pulpit and pen not only refrain from approving, but even openly denounce, all such displays as unchristian as well as irrational and based upon either ignorance or deceit. An interesting illustration of this change of opinion has just been furnished by an incident reported from a group of towns in Iowa. A certain Mrs. Woodsworth has been holding a "series of meetings" in 5 of these villages, with the result that many miraculous cures are reported from each place. To the great credit of the ministers of the district, most of them, instead of keeping Gamaliel's counsel as hitherto, "lest haply ye be found *even* to fight against God," have come out openly in disapproval not only of these "cures" in particular, but of the faith-cure in general. In Lake City one divine preached against the delusion from the pulpit, was answered by a more credulous brother from his pulpit, and from that they betook themselves to the papers, and the whole community was set by the ears. So bitter did the dispute become that as a last resort both parties agreed to appeal to the decision of that uncrowned pope of modern evangelicism, Dwight L. Moody. Greatly to the surprise of the "faithful" party to the dispute he promptly decided against the evangelist, declaring that he "took no stock in faith-cure or modern miracles."

We cannot but rejoice that we are no longer to combat this delusion single-handed and welcome heartily our new allies. May we not hope that they may be led a step further in the same direction and come to recognize the unwisdom of permitting their names to appear on the testimonial pages of other equally marvellous and even less genuine "cures" wrought by the latest commercial panacea or quack nostrum.

A Brave Medical Man.—That was a brave act by a medical man, Charles Toller, by name, who during a gale off the coast of England risked his life in the effort to save another. As related by the *British Medical Journal*, a man, the sole survivor of the crew of a schooner that had foundered, supported by a life-belt had managed to struggle on to the rocks and lost consciousness. As it was impossible to reach the man from below, Dr. Toller, with a life-line fastened under his arms, descended from a shelving portion of the cliff to the spot where the sailor lay and instituted measures of resuscitation. Efforts to haul the sailor up the cliff, as well as an attempt to reach the spot in an open boat, were unsuccessful, but as the tide changed a boat succeeded in reaching and rescuing the man, who unfortunately died of exhaustion.

Remarkable Impertinence is shown in a circular that is being sent by an advertising firm to physicians, offering prizes of pictures and books for lists of names of patients suffering from a certain class of diseases. The expressed object of the advertiser is to send directly to these patients "literature," the object of which is, we should suppose, readily enough understood. We often marvel in political life to see the egregious stupidity ascribed to the poor dupes of schemers, but we can only wonder more if there is any considerable number of medical gudgeons so poor in understanding as to rise to a bait like this.

REVIEWS.

System of Surgery. Edited by Frederic S. Dennis, M.D., Professor of the Principles and Practice of Surgery, Bellevue Hospital Medical College, etc., assisted by John S. Billings, M.D., LL.D. Edin. and Harv., D.C.L. Oxon., Deputy Surgeon-General U. S. A. Vol. ii. Minor, Plastic, and Military Surgery; Diseases of the Bones; Orthopedic Surgery; Aneurism; Surgery of the Arteries, Veins, and Lymphatics; Diseases and Injuries of the Head; Surgery of the Spine; Surgery of the Nerves. Profusely illustrated. 8vo. Pp. 926. Philadelphia: Lea Brothers & Co., 1895.

The second volume of this important work opens with an abundantly illustrated article on "Minor Surgery" by Dr. H. R. Wharton, of Philadelphia The subject is very fully treated—with a degree of detail, indeed, in marked contrast to the style maintained in most of the other articles. Some matters are introduced here which we presume will come up again and be far more thoroughly discussed elsewhere. Thus we can hardly suppose that electrotherapy, cystoscopy, and urethroscopy are to be finally dismissed with the mere mention here given them. And we think it would have been better either to omit all reference to the exploring-needle, or to state that its use has been very properly abandoned by most surgeons.

The second article, by Dr. G. R. Fowler, of Brooklyn, deals with "Plastic Surgery." It is very sound and comprehensive.

Next follows an essay by Lieutenant-Colonel Forwood, Deputy Surgeon-General U. S. A., on "Military Surgery and the Care of the Wounded on the Battlefield." For medical officers of the Army this is, of course, not intended; and while it will doubtless be of interest to many civilians, the space allotted to it—twenty-eight pages—is insufficient for it to be of practical value.

The article on "Diseases of the Bones," by Professor Senn, of Chicago, is very good, as is also that by Dr. V. P. Gibney, of New York, on "Orthopedic Surgery."

Professor L. A. Stimson, of New York, contributes a very interesting discussion of aneurysms in general, supplemented by a description of the disease as affecting special vessels by Dr. Percival R. Boulton, of the same city.

"Arteritis and the Surgery of the Veins" form the subject of a brief article by the editor, Professor Dennis.

Professor F. H. Gerrish, of Portland, Me., gives an essay on the "Surgery of the Lymphatic System." We should have been glad if he had made fuller textual explanation of his admirable diagrammatic illustrations of the anatomy of the lymphatic glands, or "nodes," as he prefers to call them.

The next article is by Professor Roswell Park, of Buffalo, on "Diseases and Injuries of the Head." It covers 289 pages, and is by far the most original and important chapter in this volume, embodying the latest developments of the subject. The author has drawn largely upon personal observations, for which he has had abundant opportunity; and, while freely quoting foreign authorities, has extended ample recognition to the labors of his own countrymen.

"The Surgery of the Spine" has been allotted to Professor Keen, of Philadelphia, and is very ably set forth.

The volume concludes with an interesting and well-written essay upon "Surgery of the Nerves," by Professor John B. Roberts, of Philadelphia.

As a whole, this second instalment maintains the standard of the first part of the work. The articles are written by men whose practical experience entitles them to speak *ex cathedrâ*, and they have performed their task with credit to themselves. We are well aware that the changes that have been introduced in the methods of instruction in medicine have modified in a great degree the requirements of students and recent graduates in regard to text-books; and it may be that the present work is more nearly adapted to this purpose than it would have been a decade ago. Physicians of some years' standing, who have kept abreast of the advances in science, will find its perusal interesting and profitable. The mechanical execution of the book is such as to make it very agreeable to the reader.

Practical Dietetics, with Special Reference to Diet in Disease. By W. Gilman Thompson, M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine in the University of the City of New York; Visiting Physician to the Presbyterian and Bellevue Hospitals. Octavo, pp. 80. New York: D. Appleton & Co. 1895.

This valuable work on Dietetics has been prepared, according to the author, in order to furnish a "textbook in which the practitioner of medicine may find detailed the appropriate diet for each disease which is at all influenced by right feeding." The volume, however, is more than a dietary manual, as a glimpse at the contents will show.

Since Pavy's work on "Food and Dietetics" no treatise on the same subject of any importance has appeared, and this volume is therefore especially welcome, as it embodies all the newer researches in alimentation. In the opening chapters of Part I the elementary composition of foods and their force-production and economic value are considered.

The classes of foods are then taken up in turn. Milk receives full treatment, all the newer ideas in regard to the alteration of this food-product by microorganisms, the methods of sterilization and preservation, and the various forms of modified milk being considered at length; forty-two pages being devoted to the last subject alone.

Part II is devoted to the consideration of stimulants, beverages, and condiments. Part III is concerned with the preparation of food and cooking, the quantity of food required by the normal body, and the results of starvation and an improper dietary. In this connection the latest researches are made use of. The foods for special conditions, such as age, race, sex, climate, and season, are treated of in Part IV.

Part V considers the digestion of food and the conditions that especially affect it, such as mental emotion, exercise, and sleep. Artificial digestion, elimination of food-waste, and abnormal digestion are subjects likewise treated of in this part.

Valuable as the foregoing pages are, the chief purpose of the book is found in the chapters that follow. In Part VI "Diseases Caused by Dietetic Errors" are fully considered and the various contaminations of food are spoken of. A description of methods used in feeding the sick is contained in Part VII.

"Diet in Disease" is the heading of Part VIII, and here pathology and symptomatology are largely entered into; the author evidently could not forego the opportunity of presenting his ideas on clinical medicine. Seventy-five pages are devoted to the management of diseases of the alimentary canal; all of the more important chemic tests for the gastric secretion are here detailed. The various forms of diarrhea of infancy, constipation, and chronic and acute dyspepsia are ably handled.

Under the heading of "Diseases Especially Influenced by Diet," obesity, with the special forms of treatment, the rheumatic diathesis, gout, and diabetes mellitus, are dealt with at length. Diabetes has thirty pages devoted to it, and the various theories of the causation of this disease are briefly considered.

Part IX contains hospital, army, and prison diets, diets useful in occupations and in athletic training; and the food of infants, young children, and school-children is also considered.

In an appendix are found various receipts for preparing food for invalids.

Altogether we believe this work to be one of the most valuable of recent publications, in that it meets a real need and combines in one volume and in logical relation all that is of worth on the subject.

—

EYESIGHT AND SCHOOL-LIFE. By SIMEON SNELL. Bristol, Eng.: John Wright & Co.

THIS admirable monograph on preventive ophthalmology is most welcome. There has long been a field for just such literature. When the principles here laid down have become the property of physicians and teachers everywhere, then, and then only, can we banish the German specter, myopia. We are fast becoming a race of students. The author warns against the ocular evils that wait upon this intellectual evolution. He brings to his work extended experience, wide research, and a knowledge of the whole domain of ocular hygiene that lend to his statements authority. The style is direct, yet easy and pleasing. The volume is so written that it is equally interesting to the layman, the general physician, and the specialist. We wish that Dr. Snell's monograph might be found on the desk of every doctor and educator.

—

TWENTIETH-CENTURY PRACTICE; AN INTERNATIONAL ENCYCLOPEDIA OF MODERN MEDICAL SCIENCE BY LEADING AUTHORITIES OF EUROPE AND AMERICA. Edited by THOMAS L. STEDMAN, M.D. In twenty volumes. Volume iii. Occupation-Diseases, Drug-Habits, and Poisons. 8vo, pp. viii, 639. New York: William Wood & Co., 1895.

THE third volume of this noteworthy undertaking contains an article of 137 pages on Alcoholism and Drug-Habits, by Norman Kerr, of London; one of 36 pages on Shock and Collapse, by George F. Shrady, of New York; one of 23 pages on Seasickness, one of 34 pages on Heatstroke, and one of 19 pages on Frostbite, by Albert H. Gihon, of the U. S. Navy; one of 31 pages on Mountain-sickness, by George von Liebig, of Munich; one of 15 pages on Osteomalacia, by W. T. Councilman, of Boston; one of 186 pages on the Diseases of Occupations, by James Hendrie Lloyd, of Philadelphia; one of 92 pages on Poisoning, by Beaumont Small, of Ottawa; and one of 30 pages on Poisoning from Lead, Arsenic, Zinc, Copper, Mercury, Silver, and Phosphorus, by James Stewart, of Montreal. This is a notable collection of names, and it may be said that the articles as a whole are fairly representative in character and comprehensive in scope. Lack of space forbids a detailed analysis of the individual articles, and we can make reference to but a few points that seem to justify special comment. In the first place, the article dealing with metallic poisoning, by Dr. Stewart, is rendered almost superfluous by the previous consideration of all the forms of poisoning therein discussed, except that of silver, in the article on The Diseases of Occupations, by Dr. Lloyd, The latter article is an elaborate monograph, which might have been somewhat abbreviated by the omission of an interesting, though perhaps unessential, digest of the laws bearing upon the employment of women and children in the United States. This valuable article deals principally with a description of those injurious effects of diseases that are direct, characteristic, and indisputable. These diseases are considered in three classes, according as their effects are due respectively to injurious substances, such as lead and the various metals; to injurious environment, such as cold, heat, compressed air, and the like; and to injurious exercise, including the occupation-neuroses. We have already referred at considerable length (see THE NEWS, September 14, 1895, p. 301) to the views of Dr. Kerr on the subject of inebriety. All in all, the volume is a most acceptable one. The type is large, the impression clean and clear, and the paper

substantial. A little more care in proof-reading would have prevented the misprint of 237 for 287 in the Table of Contents, would in two places on page 28 not have permitted *special* atrophic paralyses to stand for *spinal* atrophic paralyses, and would not have allowed *MacCormac*, in the article on Shock, to be several times spelled *MacCormack*.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 1, 1895.

EDWARD D. FISHER, M.D., PRESIDENT.

NEURITIS OF THE BRACHIAL PLEXUS AS A SEQUEL OF PNEUMONIA.

DR. W. M. LESZYNSKY presented a man of 36, who five months ago had suffered from an attack of neuritis, involving the brachial plexus upon both sides. This condition had developed during convalescence from acute pneumonia. There was no history of traumatism or exposure to cold, nor was there any evidence of alcoholism, syphilis, or rheumatism. Dr. Leszynski looked upon the pneumonic infection as the direct cause of the neuritis. He said that at present there was a pronounced and typical paralysis of the left serratus magnus, and also some atrophy of the deltoid and supraspinatus. Upon the right side there was well-marked atrophy of the deltoid, with absolute anesthesia in the cutaneous distribution of the circumflex nerve, and complete loss of faradic irritability. There was also some atrophy of the supraspinatus.

HEREDITARY CEREBELLAR ATAXIA.

DR. JOSEPH COLLINS presented a patient illustrating so-called hereditary cerebellar ataxia. The patient, a boy of 11, was the second of two children. Both his parents were still living, and, aside from a marked tuberculous history on the paternal side of the family, no hereditary taint could be traced. The child had never had spasms, and had passed through the ordinary infectious diseases of childhood. He began to talk and walk, and the teeth developed, at the customary time. The mother said he had never been able to walk or talk like other children. He was always "stiff in his joints," "easy to fall," etc.; he never climbed and played like other children, though he tried to do so. When four years old it was noticed that he was becoming very near-sighted, and glasses were applied, and had been worn since that time. In February, 1894, after returning from an outing with his father, he vomited a large quantity of liquid, and later, clotted blood. A few days before this he had had a fall down a flight of stairs, and to this fall the parents attributed his illness. He had been attending school since his fifth year, and had been repeatedly sent home on account of inability to make any advance. A year ago he had been returned from school permanently. For a year or more there had been periods in which his mother said he could not use the left side of the body, and at such times the arm and leg had become very unsteady and his speech more unintelligible. Great difficulty had been experienced in keeping him warm, especially in the winter. The speaker said that mentally the boy was peevish, irritable, and irascible. He was affectionate, fond of animals and pictures, and, while he could be led, he could not be dominated. When seen on July 21, 1895, it was noticed that he was tall for his years, that his face looked very old, his skin looked and felt dry, and the flesh felt pultaceous. The right side of the face was better innervated than the left. There was very slight grip in the hands. The knee-jerks were exaggerated, especially on the right; the elbow-jerk was lively; there was moderate ankle-clonus. The gait was shambling and reeling; the head was bent forward and the boy walked as if intoxicated; he stood fairly well with his feet wide apart; Romberg's sign was not present. The genital organs were extremely undeveloped. The child's manner of rising from the recumbent posture resembled that of one suffering from progressive muscular dystrophy, except that he did not "crawl up the legs." There was no real nystagmus, but the fixation-power of the eyes was not good, and the eyeballs twitched and there was slight weakness of the external ocular muscles. There was progressive myopia, but Dr. W. A. Holden, who examined the eyes, stated that no real change could be made out in the background. The speech was ataxic, explosive, and sometimes quite jerky. It was almost impossible for the boy to go up and down stairs. Ataxia of the upper extremities was very marked. Mentally he was very defective, particularly in his associative faculties.

The speaker said that this case, although not a pure one, would tend to corroborate the view taken of these cases by Nonne, to whom more than to anyone else credit was due for calling intelligent attention to them. Marie, who discussed Nonne's cases and other cases, suggested the name hereditary cerebellar ataxia. He took for granted a factor which apparently was not necessarily constant, viz., heredity, unless we use the terms hereditary and familiary interchangeably. The sister of this boy, who died in her second year, was affected in the same way, for the parents give a very clear description of her condition. Another element stated by Marie to be constant was optic atrophy, yet in some cases recently reported, and in Fraser's case, the first case to be substantiated by autopsy, this symptom was absent. The condition has been more commonly observed in patients older than the one just presented. In fact, adolescence is the period in which it is usually recognized. It was hardly necessary to refer to the apparent relationship between Friedreich's disease and this condition.

CYSTIC TUMOR OF THE BRAIN.

DR. L. STIEGLITZ presented a young woman whom he had exhibited to the Society in January, 1893, after she had been operated upon in June, 1892, for a cystic tumor of the brain, situated in the right arm-center.[1]

The cystic tumor was subcortical, about 1½ in. deep, and its walls had been found perfectly smooth. About an ounce of straw-colored, serous fluid had escaped from the cyst at the operation. In discussing the case at the time it was clearly shown that the cyst could not have been of vascular or of parasitic origin, and it was the conclusion that a glioma was at the bottom of the trouble, and on that account a recurrence of the growth had been feared. During the following two years the

[1] Amer. Journ. Med. Sci., June, 1893.

patient had done very well, and had recovered the use of her arm sufficiently to attend to her housework, but had been subject to more or less frequent focal epileptic seizures involving the left hand or the entire left arm and side of the face. During this period she had also had about five general convulsions, which had set in with the same focal symptoms. In March of this year the patient had begun to complain of headaches, the power in her left hand had again perceptibly diminished, and the focal seizures had occurred more frequent than ever —from one to three times a day. Dr. Koller, who had examined her eyes frequently, found for the first time a beginning cloudiness and swelling of the disc. A recurrence of the original neoplasm or a refilling of the old cyst was suspected, and Dr. Gerster performed a second operation upon the patient in April of this year. Upon exposure of the brain a very small maroon-colored mass about the size of a filbert was found at the point where the cyst had been. This mass was removed, and as it evidently infiltrated the surrounding brain-tissue a broad ring of the latter was excised. The patient made a good recovery. She had two severe general convulsions when the dressings were first removed, but had been free from all seizures ever since—a period of six months. Her arm was at first completely paralyzed, but she had now recovered its use to a certain extent, the only marked paralysis left pertaining to the index-finger, which could not be fully extended, and to the thumb, which could be flexed, extended, abducted, and adducted only very imperfectly. Tactile sensibility was less acute in the paralyzed limb than on the other side. There was marked disturbance of the muscular sense, the patient being very uncertain about passive movements in her finger-joints, especially in those of the thumb and index-finger. The deep reflexes of the arm and the knee-jerk were greatly exaggerated on the affected side. Curiously enough, they were also distinctly exaggerated on the healthy side, though to a far less degree. The microscopic examination of the excised tumor was very interesting. The old cyst-wall was found collapsed, and originating from a point in this wall a small spindle-cell sarcoma was found. This could be seen in the specimen. Sections through the ring of brain-tissue removed showed the new growth to be of a very malignant and complex type. From its character at different points it would have to be termed a melano-glio-angio-spindle-cell fibro-sarcoma. The brain-tissue was infiltrated, and no doubt sooner or later the patient would have a recurrence of the growth.

The case showed that cystic tumors of the brain were not as innocent in character as many would believe, and on that account the excision of the cyst-wall would be advisable in all cases of the kind. If this were not possible at the first operation, it could easily be done at a subsequent operation, a few months later, when the wall would be found compressed into a small, solid mass.

DR. B. SACHS expressed the belief that the original cyst might very well have been of hemorrhagic origin.

THE PRESIDENT said that the clinical history of the case prior to the first operation would throw light upon that question.

DR. STIEGLITZ said that in order to save time he had omitted the details of the original history. The patient had been perfectly well up to December, 1891, when she had been suddenly taken with twitching in her right thumb and forefinger. The twitching had spread rapidly up the arm to the face, and had ended in a general convulsion. In December the patient had had three or four more general convulsions of the same character, but none after this time. She had been subject, however, to frequent focal seizures confined to the right hand. When first seen in December there had been no loss of power in the arm, The weakness in the arm had developed the following March, and had gradually increased until, in June, the time of the first operation, it had become very marked. In spite of the absence of all general cerebral symptoms, the diagnosis of progressive, destructive focal disease, probably a tumor, had been made. The slow and late development of the paralysis after the onset of the symptoms of cortical irritation positively excluded any vascular lesion.

AMYOTROPHIC LATERAL SCLEROSIS.

DR. WILLIAM HIRSCH presented a case of amyotrophic lateral sclerosis which had developed in a patient who had formerly had anterior poliomyelitis. M. D., 45, gave a negative history as regards syphilis and heredity. About three years ago he noticed a stiffness and weakness in his left leg, which gradually became worse. After some time the right leg also became affected. He soon became unable to use his legs in working his sewing-machine (being a tailor), and his gait became so impaired that he was not able to stand or walk for any length of time. When he came under treatment, four weeks ago, he had complained of nothing else, and there were no sensory symptoms or disturbance of bladder or rectum. The examination showed an atrophy of some of the muscles of the trunk and the upper extremities. The right deltoid, the supraspinatus, and especially the thenar eminence on the right hand showed fairly marked atrophy. There was fibrillation in the muscles of the trunk and shoulder, increased by tapping them with the percussion-hammer. There was also diminished electric excitability, and in some muscles the reaction of degeneration was present. There was no atrophy of the muscles of the lower extremities, and the electric reaction was perfectly normal in these parts. The tendon-reflexes of the lower extremities were considerably increased; the knee-jerks were extremely exaggerated; and there was bilateral ankle-clonus. The last very frequently came on spontaneously, to the great annoyance of the patient. Sensation was perfectly normal in all parts of the body, and the senses of pain and temperature were unimpaired. There were no abnormal conditions in the function of the cranial nerves, with the exception that the tongue was slightly atrophied, and there was a marked masseter-reflex. Speech was in no way affected. There was no nystagmus, and the ophthalmoscopic examination showed perfectly normal conditions.

This was evidently a typical case of amyotrophic lateral sclerosis, and the man was brought here because of a possible relation between the present disease and the old affection.

An examination now showed very marked atrophy of the muscles of the left shoulder and upper arm, but the patient did not think it worthy of mention, as he said it had existed as long as he could remember. This appearance, together with the history, showed that he had

had in childhood an attack of infantile paralysis. This brought up the interesting question—Does there exist any relation between the present disease and the anterior poliomyelitis, and if so, what is the nature of this relation? Dr. Hirsch said that Ballet and Dutil were the first to enter upon a discussion of this subject. They pointed out that an infantile spinal paralysis might give rise in later life to various affections of the spinal cord, but that they were all limited to the gray matter of the anterior horns. The irritation of the cord by the old lesion enfeebled, they said, the medulla, and made it a *locus minoris resistentiæ*, which, on any occasion, might become subject to further disease. Charcot expressed the view that there existed in some individuals a certain disposition, a kind of hereditary vulnerability of the ganglion-cells of the anterior horns, which at one period of life might give rise to acute anterior poliomyelitis, and at another to progressive muscular atrophy, so that in fact both diseases would form different periods of one and the same pathologic process. In some cases of infantile spinal paralysis, Charcot said, the old scar produced by the inflammatory process in the gray matter of the anterior horns, formed a latent, but permanent, inflammatory focus, which, at any time, might light up afresh, and cause a new set of symptoms. A similar view, the speaker said, was held by Strümpell who, on the theory of the infectious origin of anterior poliomyelitis, compared the scar in the anterior horns to an old tuberculous focus which was capable of setting up a new inflammation at any time. So far as he knew, the case presented differed from all others recorded in literature in that the later disease was not limited to the anterior horns of the gray substance, but that other parts of the cord were also involved, *i. e.*, both lateral pyramidal tracts. He would not attempt to decide which of the theories applied to this case, but it could be proved with absolute certainty by the history of the clinical symptoms that the pathologic process of the present disease started from the place where the old scar of the anterior poliomyelitis was located. This lesion lay apparently in the left horn of the cervical region of the cord. As the man first noticed weakness and stiffness of the left leg, the process must have approached first the left pyramidal tract which lay next to the scar. Then, after the affection of the right horn, which showed itself in atrophy of the muscles of the right upper extremity, the pathologic process spread over to the right pyramidal tract, causing a spastic condition in the right leg. Whatever the theory regarding the nature of the relation between the two diseases, there could be no doubt that there existed such a relation between infantile spinal paralysis and various spinal diseases of later life. Further observation and study of similar cases might throw more light upon this subject, as well as upon the etiology and nature of the diseases in question.

A REPORT OF A SERIES OF CASES OF MULTIPLE NEURITIS IN INFANTS IN THE CITY OF BRIDGEPORT, CONNECTICUT.

Dr. Graeme M. Hammond read a paper in which he reported a series of cases of multiple neuritis in infants in the city of Bridgeport, Conn. There were ten cases in all, the patients ranging from 4½ months to 4½ years in age. In all but two cases there were distinct premonitory symptoms of headache, vomiting, fever. Following this there was a gradual and progressive paralysis, usually beginning in the feet, and extending to the upper extremities, and in some instances, involving the muscles of the trunk, and in two cases, the muscles of deglutition. Accompanying the paralysis there was pain, both spontaneous and on passive motion, and the nerve-trunks were very sensitive to pressure. The area of pain and tenderness accompanied the extension of the paralysis. The reflexes were abolished, and the electric reactions of degeneration were well marked. Two of the cases exhibited symptoms of spinal meningitis, in addition to the neuritis. One case, the youngest, 4½ months old, died after an illness lasting one month. The muscles of deglutition became paralyzed, and the child died from exhaustion. In the other cases recovery began in from four to six weeks, but was not completed until from three to four months. No similar cases were discovered in neighboring towns. After referring to the epidemics of anterior poliomyelitis which have in the past been reported, both in Europe and in America, the reader concluded by accepting the theory of their microbic origin, and expressed the belief that these cases of neuritis were due to a similar cause.

The author expressed his indebtedness to Dr. John C. Lynch, Dr. Samuel M. Carlick, and Dr. J. W. Wright, of Bridgeport, for the reports of cases and for their courtesy in affording him the opportunities for personal examinations.

CORRESPONDENCE.

THE COLLEGE-GRADUATE IN MEDICAL SCHOOLS.

To the Editor of The Medical News,

Sir: Can the college-graduate properly take advanced standing in a medical school requiring four years' attendance on lectures? Most medical schools have answered in the affirmative, and admit to the second year's work graduates of literary and scientific colleges who have pursued certain biologic studies. The University of Michigan goes further and admits to the third year in the medical department the graduates of its own literary department who have pursued a prescribed course of study.

The preliminary studies required of the college-graduate by the University of Pennsylvania are General Biology, Comparative Anatomy, Botany, Chemistry, Physics, Histology, Human Anatomy, Physiology, Zoology, and Embryology. The University of Michigan (medical department) devotes the two first years *wholly* to laboratory-teaching, and the third and fourth years to practical medicine and surgery. The branches taught the first year are General and Organic Chemistry, General Anatomy, Bacteriology, Physics, and Histology. During the second year the subjects are Regional and Surgical Anatomy, Anatomy of Nervous System, Hygiene, Embryology, Physiology, Physiologic Chemistry, Histology, and Electro-therapeutics.

The preliminary subjects required at the University of Pennsylvania are now taught in all first-class colleges. If human anatomy cannot be practically taught at a rural college, this branch can readily be made up when

the student enters the medical school. The question next arises, Can ordinary colleges do a second year's work, such as is mapped out by Michigan University, if the amount of laboratory-work there required is desirable? The answer given is that, with the present rate of development in the smaller colleges maintained for a few years, they will generally be equipped to do this amount of work. If this work is desirable, *it can be done better in the biologic department of a non-medical school* than elsewhere. Whoever has passed through a medical college knows how difficult it is for the student to concentrate his efforts on subjects which he thinks do not directly bear on medicine. Thus he cannot, and does not, study chemistry as he studies anatomy or materia medica. But in a non-medical college chemistry is pursued without any such difficulty as is experienced in a medical school. The cost of living is generally less in the small towns where literary colleges are situated than in the large cities. There is also much less to attract the attention of students from their studies. The disadvantage which is seen is that the study of practical medicine is postponed for two years, and the course is shortened by that much time. However, it would be no more difficult to maintain a preliminary medical school to do two years' work in such places as Meadville, Lancaster, Easton, Bethlehem, and other smaller towns, than at Burlington, Vt., Hanover, N. H., and, as was done in the past, at numerous villages and small towns.

Is it desirable to do this work in the literary college? I believe that it is desirable to have as many cultured and educated medical men as possible. I think this offers one solution of a problem which confronts educators to-day. The preliminary requirements of the classic and scientific college are greater now than they were a generation ago, by fully two years. The medical courses have been advanced from two years to four years. Fully four more years of time are now required to take a collegiate course, and then a professional course at a university, than was required a generation ago. Many young men are cutting the Gordian knot by entering the universities at once on leaving the high school. The universities, on their part, seem to offer little opposition to the entrance of these untrained and unprepared men.

While the work here outlined is recommended to literary and scientific institutions, it is hoped that it will not be undertaken until there is secured sufficient means to properly equip a biologic department. One science-professor, with text-books, will not be sufficient. There must be several well-equipped teachers and laboratories well provided with apparatus, models, charts, and dry and wet preparations. It is the function of the college to provide these for the community in which it exists.

Respectfully yours,

GEO. G. GROFF,

LEWISBURG, PA. Bucknell University.

SURGICAL SHOCK AS A CAUSE OF DEATH IN WOMEN.

To the Editor of THE MEDICAL NEWS,

SIR: In the issue of THE MEDICAL NEWS of September 7th there appeared an editorial note upon the question of "Surgical Shock as a Cause of Death in Women." The writer discusses the question as to whether women are more liable to surgical shock than men, as from the year 1890 to 1894 there have been reported to the Philadelphia Board of Health 63 deaths from shock in males and 173 deaths from shock in females. He also refers to the very decided increase in deaths from shock from year to year, there having been only 12 deaths in females from shock in 1890, as against 54 deaths in 1894. These figures certainly are deserving of attention, but I am quite sure that their explanation lies not in any supposed greater liability to death from shock in women as compared with men. I would offer the explanation that these deaths are in a large measure the result of abdominal sections upon women, done by men who have not had a proper training in this field of work. It will be found on investigation, I believe, that these operations have been performed either by general surgeons, whose training has been entirely general and who have not been taught by a proper apprenticeship the difficulties and dangers of abdominal and pelvic surgery, or by the family-physician having an itching "to do a section." I am quite sure that an inquiry addressed to the eight or ten best-known gynecologists and abdominal surgeons in Philadelphia would elicit the fact that in the 5 years in question, all told, they have not reported more than 15 or 20 deaths from shock, although they have undoubtedly performed nine-tenths of the abdominal operations upon women. Deaths from shock in women, after abdominal and pelvic operations, as a broad statement, are so many unnecessary deaths, and represent deaths from hemorrhage or from greatly prolonged operations. Of course, the exceptions are the patients operated upon *in extremis*, and these operations are seldom attempted except by the more courageous of well-trained gynecologists.

It is never pleasant to speak disparagingly of others, but I feel convinced that the foregoing explanation offers the solution of the cause of the great increase of deaths from shock among women. The same evidence can be derived from hospitals in which a few trained gynecologists operate and where many general surgeons and family-physicians also do abdominal operations. This question came up for discussion in the Philadelphia Obstetrical Society, with reference to a hospital in which one of the members of the Society reported extraordinarily good results. When his attention was called to the fact that the official report of the institution gave a mortality about ten times greater than that which he had reported, his explanation was that which I have already given. The hospital itself has a large staff, many of whom did abdominal operations, and, in addition, any physician could take a patient there and operate upon her, so that the number of operators was extremely large. This mortality from shock is one of the fruits of the doctrine, which has had many advocates both as to principle and practice within the past few years, that a special gynecologic training is unnecessary as a preliminary to the practice of abdominal surgery in women.

Very respectfully yours,

CHARLES P. NOBLE, M.D.

PHILADELPHIA, 1637 NORTH BROAD STREET.

Dr. Joseph C. Gilbert, a well-known physician of Chestnut Hill, died on October 26th, at the age of 63 years. He was an assistant surgeon during the Civil War.

HARE'S "THERAPEUTICS."

A Correction.

To the Editor of THE MEDICAL NEWS,

SIR: I am glad that my book on *Therapeutics* is, in the opinion of your reviewer (see MEDICAL NEWS, October 26, 1895), "beyond the range of criticism," because it has reached a fifth edition in five years, but I am sorry that in his desire to criticise he has made a statement which is untrue in regard to acute poisoning by opium. He says that nothing is said of the use of potassium permanganate in acute opium-poisoning, but if you will examine the book you will find it is named as the first antidote to be employed, under the head of "Acute Opium-poisoning."

The book is not intended to be a dispensatory, and descriptions of some of the unusual remedies you name were not inserted in the text because the introduction of the fads of a few clinicians, which, by the by, are either not even mentioned or not commended by the dispensatories, would rob the volume of the usefulness which it seems to possess to the practical doctor.

Yours truly,

H. A. HARE.

PHILADELPHIA, October 25, 1895.

[We regret that the statement made in the review of Dr. Hare's *Therapeutics*, that "in the treatment of acute opium-poisoning nothing is said of the use of potassium permanganate," may give rise to a false impression. Although this omission has been permitted on p. 732 in the Index of Diseases and Remedies, we find, since our attention has been called to the matter, that reference is made on p. 277 to the use of the permanganate in the treatment of acute opium-poisoning, while on p. 291, under the head of "Potassium Permanganate," the statement is made that this agent "is the best antidote in poisoning by morphin and that caused by many other vegetable alkaloids."

The antitoxin-treatment of tetanus, rhythmic traction of the tongue, and the use of strontium salicylate, ammonium salicylate, and cinchonidin salicylate, and of thyroid extract, can scarcely be considered either "unusual remedies" or "fads."—ED. MEDICAL NEWS.]

THE MEANING OF THE WORD "TEUTONIC."

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of October 12th I noticed an editorial comment on my paper "On the Growth of United States Naval Cadets." I regret to say that the term "Teutonic" has been misunderstood by the writer of this commentary.

Webster, edition 1872, gives the following definition: "Teutonic, of or pertaining to the Teutons, or people of ancient Germany; of or pertaining to the ancient Germans in general and to their descendants, among whom are included the Dutch and all who are of Anglo-Saxon ancestry; sometimes, also, in a wider sense, including the Scandinavians; pertaining to anyone or to the family of the languages of these people." Now, the modern North German as well as the South German is a decidedly mixed type, very few of the characteristic racial features of the Teuton remaining in his general make-up. Instances of reversion to this ancestral Teutonic type occur perhaps more frequently in America than elsewhere for good anthropologic reasons; and anthropologists know that such instances occur also in England and Ireland, where they are by no means rare.

This whole question, however, does not form the important part of my paper, and is merely a matter of casual remark.

Thanking you for your otherwise favorable comment, I am, Yours very truly,

HENRY G. BEYER.

U. S. NAVAL ACADEMY, ANNAPOLIS, MD.

NEWS ITEMS.

The Revival of the Index Medicus.—The following subscriptions for the *Index Medicus* have been received by Dr. Billings up to October 24, 1895, in addition to those already announced in previous issues of THE NEWS:

Boston, Mass.
Dr. E. G. Cutter,
Boston Medical Library Ass'n.,
Boston Soc. for Med. Improvment,
State Board of Health, Mass.
Bristol, England.
Bristol Medical Library.
Brooklyn, N. Y.
Pratt Institute.
Buffalo, N. Y.
Dr. John Parmenter,
Dr. Roswell Park,
Med. Dept., Univ. of Buffalo.
Cleveland, O.
Dr. Hunter Robb.
Grand Rapids, Mich.
Medical Library Association.
Nashville, Tenn.
Dr. Richard Douglas.
New Haven, Conn.
State Board of Health, Conn.
New York City.
Dr. I. Adler,
Dr. Samuel Alexander,
Dr. L. B. Bangs,
Dr. Francis Delafield,
Dr. C. A. Herter,
Dr. A. Jacobi (2 copies),
Dr. Mary Putnam-Jacobi,
Dr. E. L. Keyes,
Dr. F. P. Kinnicutt,
Dr. Charles McBurney,
Dr. John P. Munn,
New York City (continued.)
Dr. W. K. Otis,
Dr. B. Sachs,
Dr. Reginald H. Sayre,
Dr. John E. Weeks,
German Hospital and Dispensary,
New York State Med. Ass'n.,
Woman's Med. College of New York Infirmary.
Philadelphia, Pa.
Dr. F. X. Dercum,
Dr. J. H. Musser,
Dr. S. D. Risley,
Alumnæ Association of Woman's Medical College,
Philadelphia County Medical Society,
Philadelphia County Pathological Society.
Pittsburg, Pa.
Allegheny County Medical Society.
Providence, R. I.
Dr. M. B. Gornberg.
Richmond, Va.
Dr. G. B. Johnston.
San Diego, Cal.
Dr. Wm. A. Edwards.
Troy, N. Y.
Dr. Wm. Woikyns Seymour.
Washington, D. C.
Medical Society of District of Columbia.

There thus remain some 50 or 60 additional subscriptions to complete the guarantee-fund, which must be done before December 1st in order that the *Index* shall be revived. No physician having the advance of his profession at heart will neglect to support and encourage the consummation of this effort.

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery.—The second quinquennial prize of one-thousand dollars under the will of the late Samuel D. Gross, M.D., will be awarded January 1, 1900.

The conditions annexed by the testator are that the prize "shall be awarded every five years to the writer of the best original essay, not exceeding one-hundred-and-fifty printed pages, octavo in length, illustrative of some subject in surgical pathology or surgical practice,

founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the successful competitor who receives the prize shall publish his essay in book-form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery.

The essays, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, before January 1, 1900.

Each essay must be distinguished by a motto, and accompanied by a sealed envelop bearing the same motto, and containing the name and address of the writer. No envelop will be opened except that which accompanies the successful essay.

The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

The Results of State Medical Examination in Virginia.—The following official figures show the results of the examination of graduates of Pennsylvania medical colleges applying between January, 1885, and October, 1895, to the Medical Examining Board of Virginia for licence to practise medicine in that State:

	Applicants.	Licensed after 1st exam.	Rejected after 1st exam.	Licensed after 2d exam.	Rejected after 2d exam.	Rejected after 3d exam.	Incompetent or withdrew.

ORIGINAL ARTICLES.

A THEORY OF THE CAUSATION OF PERMANENT DEMENTIA.

BY HENRY J. BERKLEY, M.D.,
OF BALTIMORE, MD.

THE silver-chromate method of impregnating the nerve-elements shows, beneath the pial surface of the cerebral cortex, one of the most complicated arrangements of the elements to be found in the cerebrospinal axis. By any manner of silver-staining we find in this region a diversity of impregnation; in some nothing but the cells to the free limits of the dendrons are tinged, while in others the nerve-fibers with their end-apparatus intermingled with but few cellular bodies appear. More rarely both fibers and cells are stained in the same section. The differences appear to depend on some unknown quality in the hardening process. Accordingly, there is in this portion of the brain-surface a most intricate intermingling of the protoplasmic extensions of the peculiar class of nerve-cells of the cortex with fibers and endings of fibers of several degrees of fineness, some of them coming from distant regions, others arising from cells in the immediate vicinity of the pial limit.

A glance at a large number of stained sections reveals that these fibers are of different origin, and by their diameter and other characteristics they may be differentiated into several groups:

(*a*) Fibers of considerable diameter that arise out of the medullary masses at the foot of the cellular layers and pass upward, giving off a few collaterals *en route*, finally terminating in forked free endings, chiefly in the lower and mid-planes of the molecular layer. The origin of these fibers is in great part unknown; probably the majority come from the cells of the opposite hemisphere, the spinal cord, the cerebellum, and the medulla.

(*b*) Fibers that arise from small cells situated in the deeper layers of the cortex, pass upward between the bodies of the pyramidal cells, and eventually terminate, after a series of branchings, in the molecular layer.

(*c*) Fibers of small caliber that come from the Golgi intermediary cells, and only reaching the lowermost limits of the molecular layer end among the thicker portions of the dendrites of the pyramidal cells.

(*d*) Axons from the angular and fusiform cells of the molecular layer that do not as a rule pass beyond the limits of that layer.

(*e*) Collaterals from the descending axons of the pyramidal cells of both larger and smaller varieties that turn upward and terminate, some within the limits of the second layer, others at a higher level.

A research that I made a few years ago[1] with a very fine medullary stain developed the fact that the greatest number of the finer fibers of the cortex were medullated almost to the extremities of the end-terminations, and confirmed the results previously obtained by Flechsig. Furthermore, unmedullated fibers of any length were found to be extremely rare. These conclusions we must still adhere to, as staining with the chrome-silver does not enable one to say definitely whether a fiber is medullated or not, and besides it is highly probable that a thin membranous cover may surround the axis-cylinder after the medullary matter is lost, and that in no instance, except at the free termination, is there actually such a thing as a naked axis-cylinder. Therefore, we conclude that the conduction of the nerve-force from cell to termination, and from termination to cellular protoplasm again, is only through the medium of the ending of the nerve-fiber, and that there is no diffusion of the dynamic forces through the cortex, but that the action is a direct one.

The nerve-cells of the cortex that principally occupy our present attention are the so-called psychic cells—the pyramidal cells of both the long and short ascending-process varieties. The cells having short apical processes occupy mainly the uppermost regions of the second lamina, and have almost straight ascending processes penetrating into the molecular layer among the intricate endings of all the varieties of nerve-fibers described as located in this region. The pyramidal cells with long apical processes are situated, generally speaking, on a lower plane than those of the short variety, are of larger size, and are distinguished by the extreme length of the apical process and the richness of its stem and branches in lateral buds.

Both varieties of pyramidal cells are distinguished from other forms of nerve-elements in the cortex by the richness of the lateral protoplasmic buds or gemmulæ. These gemmulæ only begin on the

[1] Medical Record, March 12, 1892.

primordial process beyond where the capsule commences to lose its definiteness under the microscope. The apical gemmulæ are furthermore differentiated from those belonging to the basal dendrites by several inherent characteristics. In the first place, their direction in respect to the protoplasm of the stem is different, the gemmule of the apical process, beginning at the edge of the stem as an almost imperceptible thread, stands out directly at a right angle with the protoplasm, then gradually increasing very slightly in diameter it ends in a rounded button or knob, which is stained intensely black. The gemmulæ at a little distance above the lymph-space are arranged with great regularity, and are shorter and thicker than more distal ones. As the protoplasmic processes lengthen out, the distance between them increases perceptibly, and they assume more of the appearance of a thin twig adherent to the dendrite. At the terminations of the finer dendrons the gemmulæ are more luxuriant, in the sense of being longer, than near the cell-body.

While the lateral buds of the basal processes have practically the same form as those on the apical branches, the closely set rectangular arrangement of the buds is wanting; they are obliquely set, longer, and resemble closely those of the terminal dendrons on the highest portion of the ascending twigs.

Occasionally one may be called upon to distinguish a subvariety of gemmule. Here and there one is met that is longer than its fellows, stouter in its attachment to the protoplasm of the stem, and has a subdivision into two terminal arborizations. Differences in the function of these two varieties, if present, are of course unknown.

The only other variety of cortical cell we are now especially interested in is the angular Golgi cell of the middle layer, whose single axon turns upward toward the molecular lamina, terminating among the extensions of the pyramidal cells in the middle regions after a number of subdivisions.

The disposition of the axons in the middle layers of cells is somewhat different from the same structures in the higher regions. The thick, ascending fibers coming from the medullated masses give off few collaterals in the mid-regions, but pass higher up, where they come into close contact with the terminal twigs of the pyramidal cells. The axons from the intermediary cells, on the other hand, do not pass up so high, and may be seen coursing closely to the protoplasm of the thicker portions of the basal and apical dendrites. Collaterals from the descending axons of the pyramidal cells also return toward the surface, and may be seen to end in terminal varicosities against the protoplasm of the dendrites of other cells. Lastly, a large number of fine threads, coming, mainly, from the thicker fibers, are seen forming nests around the bodies of the pyramidal cells, and by their terminations distribute their dynamic forces directly to the protoplasm of the corpus, and, in especial, the region of the nucleus.

It would thus appear that the nervous stimuli reach the cell in several ways, and that each cell is influenced by a variety of stimuli arising from a number of cells, situated both intrinsic and extrinsic to the convolution. It would also seem that the protoplasmic processes of the neuron conduct impulses downward to the body of the cell, from the fibers terminating upon the dendritic processes. Stimuli may also be carried upward from the basal processes to the cell-body, and, besides, there is the nest of fine terminal fibers surrounding the cell-body proper.

It has seemed to me that the difficulty the dynamic forces, from the nerve-endings of this latter terminal arrangement, have in reaching the cellular protoplasm is very great, as they are obliged to pass through the cell's capsule as well as the fluid in the lymph-sac before being able to excite, dynamically, the cellular protoplasm. On the other hand, the protoplasmic extensions, at least the finer ones, are to all appearances free from covering, or, if covered by any membrane, this must be of exceeding tenuity, and of a character that cannot greatly interfere with the passage of the stimuli from the terminal ending of the nerve-fiber.

Personally, I am inclined to the belief that the dendron is furnished with some retaining membrane of infinitesimal thinness, and imperceptible by any of the ordinary methods of staining, and through which the stems of the gemmulæ pass, to come into contiguity with the free extremities of the nerve-endings, and, accordingly, there is only at these points free protoplasm.

We have, therefore, two possible ways in which the nerve-stimuli from extraneous sources may reach the corpus of the cell: First, the conduction from the primitive and secondary dendrites to the body of the cell; and, secondly, the direct propagation of a stimulus from the surrounding fine fibers to the corpus of the cell. Apparently, from the wide expansion of the dendrons and greater capabilities for the direct reception of a stimulus, it would seem that at this higher level they received a greater proportion of the impulses coming through the numerous sources to the upper portion of the middle and to the molecular layer, and that the terminations around the body of the cell were of secondary importance in the sensorimotor economy.

The question at length arises in what manner do the twigs of the dendrites receive the stimuli from the nerve-fibers. We have already seen that the dendritic twigs have arising out of the lateral aspects of their protoplasm large numbers of thin, pin-like processes, and that around these coil fine

axis-cylinders, usually provided with short rectangular branches ending in small varicosities. These axons ascend with the dendrons toward the pial limit, and are met in the molecular layer by large numbers of terminal branches from a variety of sources. Now the fibers that ascend with the dendrites are fine varicose, and coil very closely around the buds, twisting in and out between them, and eventually terminate in bulbar endings that closely approximate some of the knob-like tips of the gemmules.

To suppose for an instant that naked axis-cylinders are present in considerable numbers in the cortex is to me an impossibility, for we must necessarily suppose in such an event that in the closely packed arrangement of axons and dendrons presented by the outer portion of the pyramidal and in the molecular layer, where fibers and dendrites touch each other in all directions, the stimuli would quite as often be aberrant as direct, and as frequently reach the wrong as the right destination. Naked axis-cylinders are in all likelihood a physiologic impossibility in the cerebrum, for were they numerous we can suppose nothing but a constant overflow of stimuli from one cell to another, and consequent incoördination not only of thought, but also of action.

In what manner, then, do the axons influence the protoplasm of the dendritic twigs and corpora? Strictly and only by the uncovered free-ending coming into close contiguity with the knobs of the gemmulæ of the dendrons, the nerve-impulses being continued through the medium of the gemmulæ to the dendrite, and through it to the body and nucleus of the cell. Around the lateral buds of the dendrons we have often remarked the fine fibers coiling. In the majority of the preparations it is impossible to find more than the thread of the varicose fiber, but in exceptionally successful preparations numbers of the free, knobby and forked terminations may be found to end in close proximity to the gemmulæ of the dendrons; so close, indeed, that it is not easy to determine whether the two touch one another or not. We are inclined to believe that they do not, as in some instances there is a perceptible interval, while in others the slightest overlapping would produce the effect of a direct contact. The construction of the gemmule is peculiar from the fact that the distal portion is much broader than the basal, and well adapted for the reception of an impulse on the broad knob. Contractile movements of the cell are certainly to be considered in the contact, as it may possibly be that at certain times, when the dynamic forces are passing from fiber to cell, the end of the fibre and the gemmule are in direct adaptation, one with the other.

In a considerable number of cases of terminal dementia, or dementia from the effects of alcohol, and from other poisons that act unfavorably upon the protoplasm of the nerve-cell, we have found a disappearance of the gemmulæ, particularly those upon the primitive dendrons of the pyramidal cells. The disappearance of the buds may be only from the finer twigs of the apical dendron, or may extend further downward to the thicker portion, or may even involve the basal dendrites. In any event, the buds disappear from the diseased portions of the dendrites, and in the following manner: A local swelling of the protoplasm of the twig usually, though not invariably, makes its appearance; the gemmulæ lose the intensity of their staining, and finally one by one vanish completely; and the dendrite, in the intervals of the swellings, becomes reduced to a thin thread, or, when the morbid process is far advanced, to a stump.

Now, as already indicated, we have conceived the theory that the function of the gemmulæ is to receive the nervous impressions from the fiber, to transmit them to the protoplasm of the dendron, and thence to the cellular body. Once the gemmules lose their vitality or in any way become diseased, conduction of nerve-impulses is no longer possible,

Fig. 1. Fig. 2.

Fig. 1.—Photograph of a portion of a normal primordial process of a psychic cell of the long apical-process variety, showing very numerous and well-developed gemmulæ along the sides of the stem. From the brain of a well-educated man who was executed for crime, and the autopsy performed immediately after death. Enlarged 560 diameters. (Photo. by Dr. A. G. Hoen.)

Fig. 2.—Photograph of a portion of a primordial process of a psychic cell of the long apical-process variety, showing almost total absence of the gemmulæ along the sides of the stem. From the brain of a case of terminal dementia, the subject dying at the age of fifty-two years. Both specimens were taken as nearly as possible on a similar plane. Enlarged 560 diameters. (Photo. by Dr. A. G. Hoen.)

and the coördination of the cellular elements ceases. Confusion of thought is at first the result; then, as the morbid process grows deeper and more widespread, coördinated thought almost entirely ceases, and a terminal dementia follows as a natural sequence. In this decadence of the mental powers it is unnecessary to suppose that all the nerve-elements, from their complex relations by means of their axons, are necessarily degenerated.

It is not considered for a moment that the cell-body and its surrounding nerve-terminations play an unimportant part in the progress of the deterioration; only, as the dendrites are the more delicate and sensitive to the effect of an injury from the impression of toxic or other disturbances of whatever nature, they suffer first, and afterward the degeneration of the cell-body plays a secondary but equally important part.

While all these changes are taking place in the protoplasmic extensions of the cell, the axon shows little or no change, but the resistance of the axon and its collaterals to destructive influences is very great, and only after the practical death of the cell's corpus—except in cases of actual inflammation of the tissues—can its involvement come into play. Neurons having their processes totally degenerated, and their bodies reduced to stumps, have still as perfect axis-cylinders and collaterals as the normal cell, and with large numbers of such cells we have been able to trace axons from their origin at the basal end of the cell-body down to the medullated masses, and their collaterals to their varicose endings.

To resume, we repeat that the conduction of the nerve-stimuli to the cell-corpus is principally achieved through the medium of the lateral buds or gemmulæ, and that these delicate portions of the cellular protoplasm are the first divisions of the nerve-body to atrophy and disappear in certain diseases of the brain; then, from the loss of direction as well as from the want of originative impulses, incoördination of thought and motion results, and finally a permanent dementia is the consequence of a widespread degenerative process involving large numbers of the cortical neurons.

Our conclusions have been drawn partly from the cerebra of the human being, partly from the cerebra of small animals systematically poisoned by the action of various toxins exerting a destructive influence upon the cerebral nerve-cells.

Dr. N. O. Werder has been elected Professor of the Diseases of Women in the Western Medical College in succession to Dr. W. J. Asdale, resigned.

The Pasteur Institute.—M. Decleus has been elected director and M. Roux subdirector of the Pasteur Institute in Paris.

SOME REMARKS ON ANESTHESIA FROM ETHER AND CHLOROFORM.[1]

BY SAMUEL M. BRICKNER, A.M., M.D.,
OF NEW YORK.

IT is well for us occasionally to pause in the midst of routine practice to inquire whether the methods that have characterized our work are the correct ones, in view of modern light, and whether we can improve upon them to our own satisfaction, and to the welfare of those who see fit to put themselves under our professional guidance and care. I have chosen this subject because it is trite and well-worn, and be cause comparatively few men, in my relations and experience, seem to attribute sufficient importance to the total abolition of consciousness and sensation that we call anesthesia.

Complete narcosis is always dangerous, though the anesthetist be ever so expert, though the patient have been operated upon successfully many times, though the apparatus and material be of the most superior quality, the fear that a sudden fatality may supervene cannot be shaken off. If ether be used as the narcotizing medium, there may occur sudden respiratory paralysis, vomiting with inhalation of the vomitus, or a remote broncho-pneumonia. Should chloroform have the preference, the patient is under danger of syncope or of a parenchymatous hemorrhage from relaxation of the arterioles. Instances are not far to seek of fatal issue in narcosis from both ether and chloroform. Every physician can recall cases in his own experience or in that of his friends. Nor is the outlook any brighter for the other general narcotics. The A. C. E. mixture of Billroth has its record of deaths; and, indeed, from its very composition it is a dangerous anesthetic, for the fluids do not evaporate at equal rates, and the purpose of the alcohol and ether—to stimulate cardiac action after its depression by chloroform—is defeated, since first the ether evaporates, then the chloroform, and finally the alcohol. The patient is, therefore, first under the influence of the ether, and during the latter period of his narcosis almost completely under that of the chloroform.

Of nitrous-oxid gas and ethyl bromid it is scarcely worth while to speak, for the former can be used only for short periods of time, and the latter, though recently again having established a temporary hold, met its death-blow in 1881, shortly after its introduction as an anesthetic, by causing two deaths from unquestioned syncope.

General sensory and motor anesthesia for surgical purposes is so sublime in its conception and gives the profession such an ideal fortification, is such a boon to those who must go under the knife and

[1] Read before the Metropolitan Medical Society, New York, September 24, 1895.

who struggle in travail, that it becomes the sacred duty of all who have taken the Hippocratic oath to mitigate the dangers of narcosis to the man who suffers from a compound fracture and to the woman in the throes of labor. He who does not give his attention to every detail of anesthesia, and still considers himself competent to administer ether or chloroform, is like the surgeon who has never studied anatomy, and of whom Sir Astley Cooper said: "I would not remain in the room with a man who attempted to perform an operation without a knowledge of anatomy; he can but mangle the living if he have not operated on the dead." Knowing his own weakness, and still daring to risk his patient's life, a physician should be considered a fit subject for practice by a "sharpened form of the cephalotome or by that modification of the fillet which is called into use under other circumstances, when fatal coincidences become too frequent."

But it is not alone by the chemistry of the narcotics that death ensues, though we would fain attribute all such deaths to some mysterious action on nerve or cell. There are sins of omission and sins of commission on the part of the surgeon which can be held accountable for some, at least, of these unfortunate fatalities. In the preparation of the patient, for instance, it is not sufficient to tell the nurse or attending friend: "Give him nothing to eat." The surgeon must insist upon it that for *six hours at least* no solid food should pass the stomach, and that *four*—at least *three*—hours must elapse after the ingestion of fluids previous to the administration of an anesthetic. Necessary stimulation may be given by the rectum; it should never be given by the mouth.

An insufficient or careless physical examination may remain a haunting spirit should a patient with an unrecognized aortic insufficiency succumb to chloroform; and although authorities differ, my own experience would lead me to eschew ether in the face of kidney-disease. So, too, a brain-tumor and advanced pulmonary disease are warnings against ether, and arterio-sclerosis makes the administration of chloroform serious, if not actually dangerous. Similarly, nervous exhaustion from any cause acts as a contraindication to ether. Bearing these little facts in mind may save a patient or two; forgetting or neglecting them is little short of criminal.

Sins of commission are harder to condone than mere menial transgressions. What may be said of the method of administering anesthetics in our large hospitals? Would any of us be willing to trust to the surgical or medical judgment of a third-year medical student? Would we put into his hands a curet or a trephine, and bid him proceed with an operation? Would we think of consulting his opinion on a question of sustained or diminished reflexes, or on the relative qualities of heart-action? And yet we do these very things, and more, by putting into the stripling's hands the most delicate part of a surgical procedure. With absolutely no experience he steps from the county-clerk's office into the ether-room, and, with the knowledge only that ether and chloroform abolish consciousness and sensation, proceeds to narcotize some helpless patient. It is an inexcusable as it is a harmful custom—harmful alike to patient and physician. The young doctor is injured because, if not properly instructed, he never learns properly how to administer an anesthetic. The patient's system is saturated with the narcotic until his stertorous breathing is heard far beyond the confines of the operating-room. He recovers from the operation with an ocular conjunctivitis induced by the constant pressure of the anesthetist's index-finger on his cornea; the soreness about the angles of his jaws gives him no love for the man who held them in a vice-like grip. Major accidents are all too common, and the scene is by no means strange of all hands assisting at artificial respiration, and poking hypodermics into cyanosed limbs. Here is a chance for needed reform; for it is a superficial abscess on our body medical, and a few incisive words from medical boards could establish a permanent cure. Let seniors have charge of anesthetics instead of juniors, and compel them to be thoroughly familiar with the physiologic and pathologic actions of the narcotics. The junior can make as good an instrumentarius as the senior, while the added experience of the latter will make him a much safer anesthetist. In addition, let two men preside at the upper end of the operating table, one to watch the pulse, the other to keep his eye fixed on the respiration. Make the young men who are to act as controllers of life and death read some standard work on anesthesia, such as Kappeler or Lyman, and pass a rigid examination before a committee of attending surgeons before the lives of patients are entrusted to their willing but helpless care. The ideal method would be to have a regular anesthetist attached to each hospital, whose duties should be didactic as well as practical, for it would be unjust to deprive hospital-internes of their one great opportunity to learn narcotic administration. It is of the highest importance to the community that men who give anesthetics should understand their duties fundamentally; they cannot learn them properly if the haphazard method of giving ether and chloroform in the hospitals is continued.

It sometimes happens that the abdominal surgeon finds it essential to put his patient in the position known by the name of Trendelenburg. So long as it is absolutely necessary for the successful performance of the operation it may be kept up. But it is dangerous for the patient, and the surgeon must not

forget that after all his patient's life is the highest consideration. The intestines in this position are thrown up against the diaphragm, and the movements of that muscle become much impeded. Respiration becomes shallow, and the patient cyanosed. Three cases in my own experience, operated on in the Trendelenburg position, have gone, with the help of broncho-pneumonia, to those confines where doctors are not needed, and where, if the lamented Autocrat is to be believed, there are few within call.

Of the proper, approved methods of administering ether and chloroform, and of the ordinary precautions before, during, and after an anesthetic, I hesitate to speak, for these are not within my present province, and they should be familiar to every man in the active practice of medicine. I would like to escort you through the labyrinth of detail involved, for it is an interesting and instructive journey, but my time-limit forbids.

I fear I have given a most gloomy prognosis for the poor individual who is compelled to undergo complete anesthesia. Very fortunately, however, the greater number of narcoses by ether and chloroform proceed to complete recovery of consciousness with no more serious sequel than a few hours of vomiting. It is to the relative safety of the two great narcotics, however, that I wish to direct your attention.

Were I obliged to take an anesthetic, and did I place any high value upon my life, I should unhesitatingly choose ether. Carefully administered, with a proper preparation of the patient, and with a pure drug, it is safer than chloroform, because when it does kill, it kills by respiratory paralysis. And a patient whose heart still beats vigorously has a very good hold on life. Moreover, the asphyxia comes about so gradually that only a most careless anesthetist can overlook the threatening symptoms. Cases are on record, indeed, in which ether has caused sudden death; but they are so rare, compared to similar fatalities caused by chloroform, that ether must be looked upon as the safer of the two. Whoever has been unfortunate enough to witness a death from chloroform knows how hopeless all efforts at resuscitation prove. When chloroform kills, it does its work quickly. If it be given in concentrated form the heart may stop first; somewhat diluted, circulation and respiration may be arrested together; much diluted, it is possible for the heart to continue to beat after respiration ceases. There is no gradual cessation of respiration with a slowly appearing cyanosis, as there is in ether-poisoning. Suddenly, the face becomes pale or livid, the lips white or black, the mouth stands open, the pupils are widely dilated, the radial artery is pulseless, the heart has stopped, the patient takes a few short gasps, and the ghastly picture of death is before the astonished and helpless surgeon. I have lived through three such experiences, and they may have prejudiced me; for two of the patients died before anesthesia was established, and both had undergone previous operation. True, the after-effects of chloroform are not usually as dangerous as those of ether, but even the broncho-pneumonia of ether can be prevented if the prophylaxis is well managed by keeping the fauces clear of mucus, and insuring against the inhalation of vomited matter by proper means. Incidentally I am not a believer in the induction of pneumonia through the irritating influence of ether *per se*.

In the United States a death from chloroform is regarded as something avoidable since ether is the national anesthetic. Nor do I believe that this is solely because its narcotic use was discovered here. The American people are too practical to cast aside any good remedy or usage, particularly in a case of such vital importance. On the Continent, however, except in Lyons, France, chloroform is still in high favor, and the number of sudden deaths from its use does not seemingly alarm the surgeons. In the Vienna General Hospital, for instance, out of 2000 annual autopsies, six are regularly ascribed to chloroform, and this number includes only those cases of death by chloroform in which a previous pulmonary or cardiac lesion was not diagnosticated.

A recent private communication from Professor Kolisko, of the pathologic department of the University of Vienna, gives me the assurance that there are cases of sudden *exitus* during chloroform-inhalation which rest upon a condition the previous diagnosis of which can only partially be made. Briefly summarized, a constant condition found is the *habitus lymphaticus*, characterized by a persistent thymus gland, with an increase of its lymphatic tissues, enlarged lymphatic glands, adenoid vegetations and enlarged tonsils. In cases in which these conditions, or any of them, are known, chloroform should certainly be withheld; but since we cannot diagnosticate the presence of a thymus gland, is it not well to remain faithful to ether? Again, there seems to be some fateful connection between hypoplastic bloodvessels and chloroform, for the former are very frequently found at autopsy after chloroform-narcosis. This is useful knowledge in choosing an anesthetic in those cases in which there is a marked difference in size between two corresponding arteries.

Like a comforting courier from the battlefield the news came to us from Germany last winter that even chloroform-anesthesia can be robbed of its dangers. Rosenberg, of Berlin, called attention to the fact that by spraying the nose with a 10 per cent. solution of cocain, the disagreeable effects of chloroform, both before and after, could be abolished, and the narcosis rendered safe thereby. I refrain from entering into a physiologic discussion of the use of cocain in this instance, and will refer you to

Rosenberg's original paper. Suffice it to say that I have tried this method in eight cases (3 of ether, 5 of chloroform), and have been delighted with the ease and rapidity of abolishing consciousness, the absence of coughing and gagging, the agreeable recovery, and the very casual after-results. One of the cases was in a patient exhausted from purulent peritonitis, and the attending surgeon hesitated to open the abdominal cavity. Under the chloroform and cocain-spray it was safely done, and a large quantity of pus was evacuated. The anesthesia lasted twenty-five minutes, with no bad effect upon the patient. The dose of cocain received is almost a minimal dose, and one need, therefore, not to fear personal idiosyncrasy for the drug; and, indeed, it would be far better to experience a temporary annoyance from the use of cocain than to have a patient in that precarious condition in which his slender hold on life depends upon a hypodermic needle and a rectal tube.

Although the printed news of this innovation came from Berlin, I am happy to say that the discoverer of it was Dr. Felix Cohn, one of our members, who used the cocain-spray in his chloroform-operation for submucous resection of the septum as early as 1891, and, though his use of the drug was for hemostatic purposes, he noticed the gentleness of the narcosis.

I wish finally to call attention to a few procedures in cases of suspended respiration and threatened shock. In rhythmic traction of the tongue, as recommended by Laborde, we have a measure of decided value. Personally I know of two cases in which, by its use, the respiratory function was restored after apparent cessation, in one permanently, in one temporarily. It is certainly worthy of extended trial.

The intravenous or intraarterial infusion of a normal saline solution followed by thorough dosage with strychnin has many advocates, and among them myself. It has been said that when a patient quietly submits to the necessary maneuvers, this is a useless measure. But three out of a score or more of cases which I have infused have gone on to recovery, and if we can always save 14 per cent. of apparently hopeless cases we should not abandon our efforts. Finally, let me urge that so long as there is a perceptible heart-beat, let no effort be stopped which may renew the life departing in narcosis from ether or chloroform.

Briefly recapitulated, I would lay stress upon:

1. Careful administration of any narcotic, with minute attention to detail.

2. A reform in the giving of ether and chloroform in hospitals.

3. The avoidance of ether in cases of nervous exhaustion due to brain-tumor, advanced carcinoma, pulmonary or renal disease, or acute affections, such as intestinal obstruction.

4. The avoidance of chloroform in cardiac and arterial disease, when the *habitus lymphaticus* exists, when there are enlarged glands or tonsils, or adenoid vegetations.

5. Ether is safer than chloroform for general use. Ether kills slowly by respiratory paresis; chloroform kills quickly, usually by syncope.

6. The A. C. E. mixture and ethyl bromid are not to be relied on.

7. The spraying of a 10 per cent. solution of cocain into the nose before the administration of ether or chloroform.

8. Unremitting efforts at resuscitation in cases of respiratory cessation. In cardiac syncope little is to be hoped for.

I believe that attention to the details dwelt upon in this paper—though they could be vastly extended—would largely rob general anesthesia of its fears and of its horrors, and that care and caution bestowed upon this part of surgical and obstetric relief will aid in giving this greatest of blessings the unsullied name it deserves.

109 WEST 82D ST.

THE URINE IN NEPHRITIS.[1]

BY JOHN A. LICHTY, M.PH., M.D.,
OF CLIFTON SPRINGS, N. Y.

WHILE the signs and symptoms of nephritis are many and rather definite, yet the true condition of the kidney can only be definitely learned from the condition of the urine. It is not my purpose to enter into an exhaustive description of the urine in nephritis, but simply to emphasize some very necessary points frequently overlooked in the hurried examinations usually made by the busy physician. New books on analysis of the urine are at present appearing every week, and it would seem almost impossible to offer anything new upon such an exhausted subject; yet these are often more theoretic than practical, and fail us at the very points upon which we most need help. Hence it will not, I hope, be considered an imposition upon my part to offer a few remarks upon the urine and its examination in this very important disease. The causes of albuminuria, aside from actual nephritis, are numerous. Physiologists mention some ten or twelve; yet on looking them over carefully, it will be found that the underlying cause is always some irritant that has disturbed the kidney itself or some other part of the urinary tract. The so-called "physiologic albuminuria" must be looked upon with suspicion. Normal urine should give no reaction with the usual tests for albumin. When the usual tests reveal albumin, and it is proved beyond a doubt by the absence of pus that the albumin is not from an

[1] Read before Ontario County Medical Association, October 8, 1895.

inflammation somewhere in the urinary tract, it is a physician's duty to be diligent in searching for the signs and symptoms of nephritis before he dares to assign such anomalous excretion to normal, physiologic function.

In examining the urine, aside from the more common points to be observed, I wish to lay emphasis upon four facts:

1. A continued low specific gravity must be looked upon with grave suspicion, until it can be proved beyond a doubt that the kidneys are normal.

2. In nephritis, especially of the chronic interstitial type, it may happen that at times during the greater part of the disease the urine may contain no albumin that can be detected.

3. Casts may be present in the urine when it is impossible to detect any albumin by the usual tests.

4. Casts are very easily destroyed in the urine either by bacteria or during the process of fermentation, and unless the examination is made within an hour or two after urine has been passed, the failure to find casts does not prove the non-existence of nephritis.

As to the first proposition: The low specific gravity; the normal specific gravity, as is well known, is from 1015 to 1025. When it is lower than 1015, and the quantity is great, it will of course be necessary to consider the possibility of the existence of diabetes insipidus. Concerning this disease very little seems to be known. Its pathology is obscure and its occurrence rare. A diligent search for casts must be made to differentiate between diabetes insipidus and chronic interstitial nephritis in a late stage. In the *University Medical Magazine*, June, 1893, Dr. H. C. Wood, in a lecture upon chronic contracted kidney, reports a case in which the continued low specific gravity was the only point at all suspicious. No albumin was detected, and casts were found only after repeated examinations, but they were positive in their nature. I have since had several cases similar to this one mentioned by Dr. Wood.

CASE I.—Mrs. C. H. S., aged 36, after two attacks of diphtheria, noticed swelling of the feet and shortness of breath. The heart was found normal, the specific gravity of the urine 1010. There was no albumin and no casts at the first examination. The amount of urine in 24 hours was 70 ounces. Later, by means of the centrifuge, I threw down the sediment of a fresh specimen, and found a few hyaline and granular casts. This was verified several times later, and the patient was placed upon a line of treatment that relieved her of the edema of the feet and the dyspnea.

As to the second proposition—that nephritis may exist without casts or albumin being present during part of the disease—Dickinson, in his treatise on albuminuria, mentions this fact. Various explanations are given. The one most plausible, and which I think I have often seen confirmed on the postmortem table, is that frequently only a part of the kidneys is involved, and, this part being almost entirely effaced functionally, the normal part of the kidney carries on the eliminative process. When, however, any severe strain is thrown upon the kidney—as after a heavy meal of albuminous food, after severe exercise, or after a cold—the old, wornout part of the kidney tries to resume its function, but now performs it imperfectly, and casts and albumin are precipitated.

CASE II.—Mr. S. W., aged 55, a druggist, was first seen July 27, 1893, at which time he gave a history of having had edema of the legs ten years before, and having been "cured" of "Bright's disease." He had, however, not been well since. There were symptoms of gastric dyspepsia; the skin was dry and scaly, the pulse rapid, sometimes intermittent; the aortic second sound was accentuated, and the arteries thick. The specific gravity of the urine was 1015; it was pale, but no albumin was present; 56 ounces were passed in 24 hours. Repeated examinations gave the same result; the specific gravity was always low. On July 17, 1894, the patient was seen again, and his physical condition was about the same as the year before. The specific gravity of the urine was 1010; it was acid, pale, with abundant albumin, and many hyaline casts. Just one week previous to this examination the same patient's urine was reported by a physician in whom I have great confidence to contain neither albumin nor casts. On August 24, 1894, the patient died of uremia. No autopsy was held. It is evident in this case that the "Bright's disease" of ten years previous had not been cured, but that the albumin had merely disappeared from the urine, and reappeared just five weeks before death. How often it may have appeared and disappeared during those ten years no one can tell.

The third proposition, that casts may be found when no albumin can be detected, may seem paradoxic from the fact that casts are formed of albuminous material. The test for albumin most commonly used is the heat and nitric-acid test; though Heller's, or the contact-test, is the most delicate practical one. Its delicacy reveals the presence of 0.00025 per cent. of albumin; but in the later stage of interstitial nephritis, when there is usually marked polyuria, a number of casts may be found, and yet not sufficient albumin be present to give an appreciable reaction with the usual test. I have found as many as from three to six hyaline casts under one cover slip in a urine giving no reaction for albumin.

CASE III.—The patient was Mr. C. M., aged 45, single, who four weeks before being seen by me began to notice swelling of the legs and dyspnea.

When first seen his temperature was 95.2°; he was pulseless at the wrist, the respirations were 22, and he had general anasarca. A mitral regurgitant murmur was present. The specific gravity of the urine was 1030; it was acid, and contained no albumin and no sugar, but a number of narrow hyaline casts. Subsequent examinations revealed no albumin. Nine days later the patient died of uremia, and at the autopsy the kidneys were found to be small, contracted, and granular.

Within the past four months I have seen seven cases whose urine contained casts at various times, but never gave a reaction for albumin.

And now as to the necessity of examining urine soon after it has been passed. After urine remains standing for a time, certain microorganisms, such as the bacterium ureæ and micrococcus ureæ, develop within it. These decompose the urea, and ammonium carbonate is set free, which, with the microorganisms named, will disintegrate tube-casts. The usual way of examining urine is to pour it into a conical glass as soon as the specimen is received, and then wait from six to twelve hours for a sediment. But by allowing it to stand so long the casts may be decomposed, especially if the laboratory is warm. To obviate this difficulty I have made use of the Metzger centrifuge, a new instrument for the precipitation of the sediment of urine and sputum, and for the volumetric analysis of red and white blood-corpuscles. With this one can throw down a sediment from a specimen of fresh urine within a few minutes after it has been received, and thus examine the sediment under the microscope at once. It is practically impossible for any casts to escape detection if this method is used.

I cannot leave this subject without making reference to the necessity of an early diagnosis of nephritis. Very rarely is the disease initiated with an acute attack, but, on the other hand, it frequently begins insidiously, and only after the irreparable mischief has been done are the symptoms sufficiently urgent to lead the patient to seek medical advice. Since the treatment of nephritis, so far as restoring the organ to its former healthful condition is concerned, is so decidedly unsuccessful, our greatest progress in this line must be in the way of prophylaxis. This involves the early recognition of any condition of the urine that may tend to produce irritation of the kidneys, or that may show that such irritation has already taken place. It would, therefore, seem advisable for the family-physician to urge upon the community from which his patients come the necessity of having the urine examined at intervals—much as dentists urge their patients to have their teeth examined—and especially to have it examined during and after any severe illness. Such a course would, no doubt, save many people from death due to nephritis.

CLINICAL LECTURE.

FOUR CASES OF MIXED OR IRREGULAR FORMS OF MULTIPLE NEURITIS IN WHICH PARAPLEGIA WAS THE MOST PROMINENT SYMPTOM IN THREE, AND A CONDITION SIMULATING HEMIPLEGIA IN THE FOURTH.

By J. T. ESKRIDGE, M.D.,
of Denver, Col.;
Neurologist to the Arapahoe County and St. Luke's Hospitals.

Lecture II.

(Concluded from page 487.)

We shall resume the consideration of the subject presented by the four patients whose cases we were studying at our last Saturday's clinic. You may remember that we concluded that all the patients were suffering from multiple neuritis of an irregular or mixed type. I had arranged to have a typical chronic case of multiple neuritis before you to-day in a man upon whose case I lectured to you last year. The lecture was published in The Medical News of December 22, 1894. The patient has been staying on the County Farm for a few months, but he has been attracted by the new messiah, Schlatter, and cannot be found to-day. Although the case is chronic, nevertheless the symptoms and much of the history are typical of the ordinary form of multiple neuritis. They are as follows: "D. F., fifty years of age, colored, single, a male laborer, was born in Kentucky, but has been living in Colorado since 1872. As a child he was well and strong, and thinks he did not suffer from any of the diseases incident to early life. When two years old he had an attack of smallpox, and was ill about four months. At his thirtieth year he contracted a chancre. He has never indulged in alcohol to excess. During the last twelve years he has worked in damp places, and frequently contracted colds. Ten years ago the glands of his neck suppurated, and about that time he experienced numb and tingling sensations in the feet and legs below the knees. These sensations would pass away on exercising, but, when at rest, his legs would become stiff and painful. After suffering from these symptoms, which increased for some weeks, he had to quit work for a week; he was then able to resume work, although for some months he was not entirely free from uncomfortable sensations in the legs and feet. Subsequently to this trouble he remained in good health until December, 1893, when, after working in a damp and cold place, he first felt numb and tingling sensations in his toes and in the anterior portion of the soles of the feet. In a few days these sensatons had spread all over the feet, and extended up the legs nearly to the knees. About this time his ankles seemed weak, so that he could not stand without some support. As he expressed it, he "rocked on his feet." Within two weeks from the time the numb and tingling sensations were first experienced in the feet he found his legs were paralyzed from the knees downward. About the time the legs were first paralyzed he felt a burning sensation in his hands, especially in the palms, a numbness in the fingers, and a week or ten days later his arms were paralyzed from the elbows downward.

A few weeks after the paralysis became manifest he was troubled less from burning and numb sensations. From December, 1893, to March, 1894, he was treated for rheumatism. About the latter date a disagreeable tingling sensation, which later assumed a distressing burning character, appeared in the feet, and was worse at night and during cloudy and inclement weather. Similar sensory disturbances soon afterward manifested themselves in the hands, but to a less intense degree. He was admitted into the nervous wards of the Arapahoe County Hospital, August 11, 1894.

"*Examination.* He lies in bed with all the muscles below the knees completely paralyzed. Foot-drop is well marked, with extreme plantar contraction, and toes flexed, the great toe being flexed to the greatest possible degree. By using considerable force I am able to dorsally flex the feet at right angles with the legs. The legs lie straight at the knees, and he can flex and extend the legs at these joints, but the muscular power is slight. Flexion and extension at the hips are fairly good, but the muscles that make these movements are rather weak. Moving the legs and thigh at the knees and hips causes some pain, or a drawing sensation of the calf and posterior thigh-muscles. Extreme wasting has taken place in all the muscles below the knees, and to some extent in the thigh-muscles. The greatest amount of muscular atrophy is found in the interossei of the feet and in the anterior tibial and peroneal groups. The trunk-muscles are nearly normal. Wrist-drop is present, with flexor contraction of the muscles of the hands and wrists; both hands ordinarily lie in the wrist-drop position, yet with considerable effort he is able to extend the hands at the wrists on a line with the forearms, but he cannot extend them beyond this point. Marked atrophy is present in the muscles of the hands, most pronounced in the interossei and in those forming the thenar eminences. The muscles of the forearms are wasted, but to a much less degree than the muscles of the legs below the knees. The muscles of the upper arms are fairly strong, and present but slight wasting; the muscles of the shoulders appear normal; none of the muscles below the knees or elbows responds to the strongest faradic current from a large-sized Flemming battery. All these muscles show reaction of degeneration. The muscles of the neck, face, and larynx are not involved.

"*Sensory Phenomena.* Tactile sense when tested by the contact of a feather is lost on the feet and legs from a point about midway between the ankle-joints and the knee-joints downward; the sense of touch is present down to a point about six inches above the ankle-joints when the feather is in gentle motion; in the right hand and arm the feather in contact is not felt from a point four inches above the wrist-joint downward, and in the left from a point about four inches above the wrist-joint downward, while a feather in motion can be felt over the greater portion of the backs of the hands and wrists, but is not perceived on the dorsal surface of the fingers, the palmar surfaces of the fingers and hands, and the anterior surfaces of the wrists, and the anterior surfaces of the arms from a point about two inches above the wrist-joint downward. Tactile sense is present and nearly normal over all other portions of the body. Pain-sense is present throughout the body, but it is not normally acute in the areas of tactile anesthesia until the skin is pierced. Temperature-sense is lost all over the feet, delayed, uncertain, and lessened over the ankles, and in areas of tactile anesthesia of the legs, and much perverted over the hands, but not lost as in the feet. Localization-sense is greatly disturbed, especially over the feet, as a sensation produced on the leg is referred to the feet, and sometimes to the foot of the opposite side. Pressure-sense is disturbed more in the hands than in the feet. Joint-sense and posture-sense are present and about normal. Muscular sense is absent.

"The knee-jerks, the plantar, cremaster and forearm reflexes are absent; abdominal and iritic reflexes are present. Taste, smell, hearing, and vision are about normal. The internal and external ocular muscles and the opthalmoscopic examination show no abnormalities."

Now let us consider the characteristic symptoms of multiple neuritis; they are bilateral, usually symmetric, generally affect only the distal portions of the extremities, with an involvement of nearly all, if not all, of the nerves of the diseased parts.

Multiple neuritis is due to a poison that affects the nervous system through the circulation, and is in consequence always bilateral in typical cases. In uncomplicated cases the symptoms are symmetric, but various modifying conditions may disturb the symmetry. Alcoholism is a recognized cause of multiple neuritis, yet traumatism, rheumatism, or other local determining influences may destroy the symmetry of the disease by affecting certain nerves more than others. The influence of gout or rheumatism upon the system may cause the development of poisons which may give rise to multiple neuritis, but under these circumstances the well-known tendency of these diseases to affect one portion of the body more than another may destroy the symmetry of the symptoms. While in the vast majority of cases only the distal portions of the extremities are affected, yet the poison may be so active as to involve to a greater or less extent all the nerves of the body, those of the trunk as well as those of the limbs; but even in this case, the distal portions of the legs and arms suffer more than the other portions of the body.

It is probable that the nerves of the distal portions of the extremities are more affected than those of the proximal because the latter are better nourished than the former. It may not be correct to say that the disease is limited to the distal portions of the limbs, as a systemic poison expending itself on the nerves undoubtedly affects the nerves throughout their entire length, but the morbid process is only sufficiently intense to give rise to obtrusive symptoms in the parts in which the metabolic changes are the least active. Assuming this proposition to be correct, the changes in the parts most distant from the heart may be destructive, while those in the nerves nearest the body may be irritative. This would enable us to explain the variability of the deep reflexes, especially the knee-jerks, for we usually find them absent, but in some cases they are simply lessened, while in a few they are exaggerated. In rare cases there is weakness of the sphincters of the bladder and bowels, but in these the spinal cord or the brain is probably affected. While all the nerves of the affected parts are involved, some suffer more than others, such as the musculo-spiral and anterior tibial, nerves that supply the muscles that dor-

sally flex the feet and extend the hands at the wrists; hence foot-drop and wrist-drop are commonly observed in typical cases of multiple neuritis.

The symptoms of the disease, for convenience of study, may be grouped under six headings: motor, sensory, trophic, ataxic, reflex, and electric changes. The motor symptoms are usually well marked, and consist in paresis or paralysis of the muscles below the knees and below the elbows, the dorsal flexors of the feet and extensors of the wrist and hand being most affected, with resulting wrist-drop and foot-drop. In some cases the muscles of the thighs and upper arms are decidedly weak, but rarely paralyzed, the extensors of these parts being more affected than the flexors.

The most marked sensory change is tactile anesthesia on the plantar and dorsal surfaces of the feet, often in the parts around the ankles, and sometimes on the legs to a point about midway between the ankles and knees, and between the wrists and elbows. In a few cases the anesthesia extends up as high as the knees and elbows, or even above these joints. The other general sensory phenomena in the areas of tactile anesthesia are usually perverted, the extent of the perversion varying in degree with the profoundness of the tactile anesthesia. In some cases pain-sense is increased, although tactile anesthesia seems to be complete. The nerves of the most affected parts are often sensitive to pressure. The plantar surfaces of the feet and the palms of the hands are not infrequently the seat of almost constant, severe, and distressing pain. In some cases the pain in these parts is only complained of at night, except on sudden changes of weather, when it may be very annoying both day and night. Tenderness of the muscles is sometimes greater than the tenderness in the nerves, and may persist long into the period of convalescence.

The trophic changes are observed in the muscles, joints, skin, nails, and hair. Microscopically the nerves always show changes of a trophic character. The extent of the trophic alterations depends upon the severity of the inflammation in the nerves. Trophic changes are most obvious in the muscles, which often waste to an extreme degree. Sometimes the affected parts become edematous and the joints are the seat of effusion.

Ataxia is often so pronounced in the legs of persons suffering from multiple neuritis, especially if the person is able to walk, as to suggest sclerosis of the posterior columns of the spinal cord, and not infrequently from this symptom alone the careless observer has mistaken a case of multiple neuritis for one of locomotor ataxia. The fingers and hands are often decidedly ataxic.

The knee-jerks are abolished in the vast majority of instances, but in exceptional cases they are lessened or exaggerated. I am not convinced that an irritative lesion of the nerves supplying the extensors of the thighs will explain the enormous increase of knee-jerks sometimes witnessed in these cases. It is probable that the knee-jerks may be increased by a heightened irritability of the muscles due to inflammation in the connective tissue of the muscles. The only superficial reflexes involved in the vast majority of cases are the plantar. They may be abolished, normal, or increased.

The electric changes in multiple neuritis are usually quite pronounced, and consist of lessened or abolished faradic response in muscles and nerves, failure of the nerve to respond to galvanism; at first increased muscular irritability to the galvanic current, with changes of the normal formula, so that the muscles will respond equally well or better to the positive as to the negative pole. Later the muscular irritability may lessen to the galvanic current or fail to respond to the negative pole except to a current so strong as to be unbearable to the patient.

In some cases of multiple neuritis the motor symptoms are well marked, while sensation is nearly normal and ataxia is scarcely appreciable; in others the sensory symptoms are pronounced and motor power well preserved; and in a third group ataxia is very decided, while sensation and motion seem to be but little impaired; so that we may have motor, sensory, or ataxic forms of multiple neuritis. I have never seen a case in which on careful examination one of these groups of symptoms was well pronounced and both of the others were entirely absent.

While in the vast majority of cases of multiple neuritis the arms and legs are affected, occasionally the poison seems to expend its influence on the nerves of the legs, the arms escaping, if not entirely, to such an extent that the most careful examination fails to reveal any objective symptoms. I am inclined to believe that multiple neuritis of the paraplegic type is much more common in alcoholic subjects than the recorded cases would lead us to infer. I have observed six cases of multiple neuritis of the paraplegic type; four of them have followed typhoid fever. I do not remember having seen multiple neuritis, unless we regard lead-paralysis as being of this nature, limited to the nerves of the hands and arms.

We will now return to the consideration of the cases that we were engaged in studying at the close of our last clinic. You may remember that by a process of diagnosis by exclusion we came to the conclusion that no nervous lesion, except multiple neuritis, would account for the symptoms. Let us review the cases separately, and see if a lesion of the nerves will account for the various symptoms.

The first case was in a young Swede who during convalescence from a prolonged attack of pneumonia, began to suffer from pains and tenderness in the legs below the knees. On examination all the symptoms, except the increase of the knee-jerks and the disease being limited to the legs, were typical of multiple neuritis. Further, all other lesions of the nervous system that would account for many, if not all, the symptoms could be excluded. Multiple neuritis following pneumonia usually occurs during the early part of the convalescence. In a case reported by Dr. Leech, in the *Medical Chronicle*, motor symptoms were well marked in the legs, but absent in the arms; sensory changes, although more pronounced in the legs, were quite distinct in the hands and forearms. In this case the knee-jerks were absent. The knee-jerks are occasionally present and exaggerated, especially in the alcoholic variety. In the *British Medical Journal* of February 18, 1893, Arthur Maude reports a case entitled "Exaggeration of the Tendon-Reflexes in Peripheral Neuritis, following Prolonged Alcoholic Indulgence," and in the same journal for February 25, 1893, D. B. Leech records two somewhat similar cases. I have seen two cases of alcoholic neuritis in which the knee-jerks were increased and in which the sensory and motor symptoms were entirely limited to the legs and feet. Of 90 cases of alcoholic neuritis analyzed in Ross

and Bury's recent work on *Multiple Neuritis*, in 5 the knee-jerks were exaggerated or lively, in 1 they were normal, and in another they were exaggerated at first, and became lost with the progress of the disease. We must not forget that the knee-jerks are probably exaggerated in the very early stage of multiple neuritis. If the knee-jerks become much increased after an attack of diphtheria, it indicates that neuritis will follow.

In the second case of the series that we were engaged in studying last Saturday the nerve-lesion followed a severe and prolonged attack of typhoid fever. The symptoms of this case were paraplegic in character, and one knee-jerk was slight, the other being absent, as is usually the case in this disease. In most of the cases of neuritis that I have observed following typhoid fever the trouble has been confined to a single nerve of a limb or to certain nerves paralyzing groups of muscles and giving rise to irregular areas of anesthesia. The radial nerves in the arms and the musculocutaneous in the legs and sometimes the anterior tibial are those that suffer most frequently in typhoid fever. Individual nerve-inflammation following typhoid is so common as to lead one to suspect that injury by pressure may be a determining cause of the nerve-affection. There are, however, a number of cases of multiple neuritis developed during the convalescent stage of typhoid fever. They are rarely typical cases, but most of them, judging from my experience, are irregular in type, and the nerves of the legs suffer more than those of the arms. When we remember that multiple neuritis of typhoid fever is rarely symmetric it is easy to understand that the knee-jerks may be irregular. It is probable that the typhoid poison has much to do with the development, or the tendency to development, of multiple neuritis, but it is also probable that local causes, such as pressure or slight injuries to individual nerves have a greater influence in affecting some nerves than others.

Our third case was in a man of 87 years, who had suffered from no special disease from whose poison we could expect neuritis to arise; neither had he been addicted to alcohol. With the exception of the trouble being limited to the legs, his symptoms were almost typical of the sensory form of multiple neuritis, and there is no other nervous lesion by which we can account for the anesthesia. The poor nutrition at the time of his admission and the extreme degree of atheroma of all exposed arteries of the body were the only apparent causes of his trouble. After he had been in the hospital for some time his nutrition greatly improved, and is to-day quite good, but the nervous trouble has continued to increase. It is most likely that we have a senile or thrombotic multiple neuritis. A few years ago I had the opportunity of observing, in this hospital, for nearly two years, a typical case of thrombotic multiple neuritis. The patient suffered greatly from subjective sensory disturbance for a considerable time before areas of anesthesia developed, and motor weakness, and finally paralysis, with great wasting of the muscles, did not become manifest until about six months previous to death. Before the fatal end the feet became gangrenous (dry gangrene), and pressure-sores developed over the various portions of the legs and buttocks. A few weeks before death myelitis supervened, with contractures of the legs and involvement of the sphincters of the bladder and bowels. If I remember the history of the case correctly the arms were only slightly affected, and this did not occur until very late in the disease. The microscopic examination showed degeneration of the nerves of the legs, and great thickening of the walls of the arteries, even of the nutrient arteries of the nerves. In no place could a complete obliteration of the caliber of the nutrient arteries be demonstrated, although this condition probably existed. Gowers, in the last edition of his *Manual of Diseases of the Nervous System* calls attention to senile or thrombotic multiple neuritis. It is probable that this condition is much more common than has heretofore been supposed, and many of the cases of subjective sensory disturbance found in persons of advanced life, especially with degeneration of the arteries, may be due to a low form of multiple neuritis of thrombotic origin.

Of the 4 cases 1 was chronic alcoholic multiple neuritis, and was nearly typical in character until the receipt of the injury which gave rise to motor symptoms largely of a hemiplegic type. The case as seen by me, might easily have been mistaken, in the absence of a history, for one of hemiplegia due to a cerebral lesion. The only peculiarity that this case manifested as compared with the ordinary type of multiple neuritis, before the receipt of the injury, was the marked weakness in the muscles of the right hand out of proportion to the left. I did not see the man at this time, and cannot say whether this symptom was simply subjective, or whether it would have been manifest on testing the strength of the muscles of both hands. As the man had to do considerable writing it is probable that the muscles of the right hand and arm in their weakened condition soon tired, simulating a condition of pseudo-writer's cramp, for which I understand he was treated for a time. Had the muscles of the left hand been subjected to the same strain as those of the right it is probable that this hand would have been complained of also. After the injury a careful examination showed bilateral symptoms, especially of a sensory character. These were more marked in the legs than in the arms. While on one side of the body the strength was about half of normal, the leg and arm of the other side were almost completely paralyzed. This case serves to illustrate the condition to which I have called your attention, that we may have a systemic poison, such as alcohol, causing a symmetric multiple neuritis; but the intervention of a determining local cause may result in the affection of certain nerves to a greater extent than others, and thus destroy the symmetry of the symptoms. Multiple neuritis due to a systemic poison is usually a parenchymatous inflammation of the nerves, but when a local cause determines the inflammation the interstitial tissue may be affected, and the parenchyma becomes involved later. After a serious injury the neuritis is likely to be of a diffuse character, affecting both the parenchyma and the connective tissue of the nerves.

The course and duration of the disease vary according to whether the inflammation is acute, subacute, or chronic. In the acute variety the inflammation increases from four to six weeks, remains stationary from two to three weeks, when the morbid process begins to subside, convalescence extending over a period of several months. In the chronic form the duration may vary from one to several years, and in the subacute it extends over periods greater or less in length, intermediate between

the acute and the chronic varieties. The diphtheric form, as a rule, runs the shortest course, convalescence in the majority of cases being pretty well established in a short time, so that the patient is able to walk about by the end of the second or third month from the time the neuritis began to be manifest. The alcoholic form is not infrequently slow in reaching its height. I have seen patients whose disease had been developing from one to two years before it reached its acme. Those forms which follow an acute disease usually run a course of from three to twelve months. It must be remembered that the muscular strength is not regained for several months after the patient is able to return to his duties. The parts that are first affected are usually the most seriously involved and the last to resume their normal condition. The legs usually improve before the hands and arms, but in alcoholic cases, as well as in many others, the order may be reversed. The feet, and sometimes the hands, especially around the nails, remain hyperesthetic long after the spontaneous pain has subsided. Relapses, to which the patient is always liable, greatly lengthen the course of the disease.

The vast majority of cases of multiple neuritis result in recovery. In a few cases the trunk-muscles, including the intercostals, become affected, and, if the diaphragm becomes paralyzed, death takes place from failure of respiration. These are acute and rapid cases which not infrequently end in death from six to ten days or two weeks. Cardiac failure in alcoholic or diphtheric cases sometimes causes sudden death, and, in a few, the patient is worn out by pain. In the thrombotic form gangrene takes place, bed-sores develop, bronchitis finally supervenes, and death is the result. It is probable that in those cases in which bed-sores develop the spinal cord is affected. In alcoholic cases, cardiac, renal, and hepatic complications may lend gravity to the prognosis. Mental failure is a common complication of alcoholic multiple neuritis, but it usually passes away during convalescence. Sometimes there is a simple failure of memory for recent events, but in the typical cases of the alcoholic form the patient becomes delusional and conceives the idea that he goes out each day and takes long walks, although he may be so completely paralyzed that he is unable to stand or even flex or extend the feet.

The treatment in the early stages consists of rest in bed, protecting the extremities from changes in temperature by means of flannels wrung out of hot water, warm daily baths, if they do not inconvenience the patient too much, keeping the bowels open, and giving a febrifuge when there is a rise of temperature. In all cases protecting the parts from sudden changes in temperature is important. So soon as the acute stage has subsided, massage and electricity, and the internal administration of strychnin, arsenic, quinin, and iron are indicated. The nutrition should be maintained throughout the course of the disease by means of good nutritious food, of which animal food should form a large proportion during convalescence; and codliver-oil may be added to the list of nutrients. Relapses may often be prevented by protecting the affected parts from sudden changes in the temperature by means of flannels worn next the skin. In the alcoholic variety especially, total abstinence from alcohol in every form should be insisted upon. Massage should not be resorted to while the muscles and nerves are sensitive, but gentle rubbing of the limbs from the distal portions toward the body is often grateful to the patient early in the disease. It is doubtful how much the galvanic current hastens the resolution of the morbid process in the nerves and muscles, but the nutrition of the latter may be partially maintained, and the extreme atrophy prevented, by causing gentle contractions of the paralyzed muscles until the patient regains voluntary control over them. When the muscles readily respond to the faradic current this may be used, but the current should be no stronger than is necessary to effect gentle contraction of the most affected muscles. In the majority of cases the faradic current will not induce muscular contraction of the extensors of the wrist, and of the anterior tibial and peroneal groups. If all the muscles will not respond to a slowly interrupted faradic current of moderate strength, the interrupted galvanic must be used, taking care not to exhaust the muscles by prolonging the seances to too great length, or by having too vigorous muscular contraction. From three to five minutes is long enough at first for each of the largest groups of muscles. Ordinarily the slight muscular contraction is less likely to do harm, and is capable of doing more good than vigorous movements. Electricity may be applied for this purpose daily or every alternate day. Massage may be employed daily, or in many cases, twice daily; if it is not done too vigorously. By timely and proper attention, troublesome contractures of the flexor muscles of the legs and arms, resulting in the deformity of the feet and hands, may be prevented. This may be done by keeping the feet at right angles to the legs by means of sand-bags placed at the soles of the feet, and by occasionally placing the forearms and hands on padded splints. The muscles that have a tendency to become contractured should be gently stretched each day.

CLINICAL MEMORANDA.

THREE OPERATIONS FOR THE RELIEF OF TRAUMATIC EPILEPSY, TWO OF WHICH WERE COMPLICATED WITH INSANITY.

BY JOHN D. DAVIS, A.B., M.D.,
OF ALLEGHENY CITY, PA.

THE subject of traumatic diseases of the head and brain is particularly important, and the study of both the immediate and remote results of injuries to this important organ is as interesting as it is inexhaustible. There can be no subject of greater interest to surgical science than that which treats of the restoration of a dead mind or the reestablishment of the functions of a dead part. The alterations in the brain-substance produced by injury may involve the intellectual, the sensory, or the motor areas, or impair all of them, the most frequent sequelæ being insanity, hyperesthesia, convulsions, or paralysis. The injury may not be sufficiently severe to interfere with the functions of the brain, but may only apply to the scalp or skull, and yet very distressing reflex influences may be the result at a more or less remote period.

It is the intention of this paper simply to call attention to the results of operative procedure in three cases, and

if possible to point out the great relief that might be given to many who are now only objects of pity. With asepsis and antisepsis understood and practised as it is at the present time, the opening of the skull-cavity is attended with but little danger to life, and with the nerve-centers and brain-functions localized as they are, we should be able to do much good by judicious surgical interference in carefully selected cases. There are numberless cases of insanity, epilepsy, and other distressing nervous ailments due to traumatism that could be relieved and the subjects restored to usefulness who are now a burden to friends or dependent on charity. As I said before, in many instances the cause of the reflex phenomena is resident in the scalp or skull and no harm can result from a skilful attempt to remove the source of irritation. In many instances the moral effect of the operation would be beneficial.

Case I. *Epileptiform convulsions.*—On November 1, 1892, I was consulted by Frederick K., aged 30 years, for epilepsy. His physique was indicative of a robust and healthy constitution. He was a farmer by occupation, born of healthy parents, both living, with no cases of insanity, idiocy, epilepsy, carcinoma, or tuberculosis known in his family or among his relatives. Ten years ago, while erecting a frame building, he fell a distance of 15 feet, striking the back of his head on one of the timbers. The scalp was not lacerated, nor did he consider himself much hurt; yet within an hour he was attacked with a severe convulsion lasting several minutes. From that date he had on an average two convulsions a day. Occasionally he would have intervals of relief for several days, and again have a number of convulsions in a few hours. He was seldom free from headache in the left occipital region and had continuous tinnitus aurium on that side. His intellectual and facial expression was that of an epileptic. He had been under the care of excellent physicians who had exhausted the *Pharmacopeia* in trying to give the man relief. I suggested opening the skull at the seat of injury and exploring for the cause of the trouble, to which suggestion he readily acquiesced. He was soon afterward placed in the Allegheny General Hospital, where all antiseptic precautions were observed, and on November 14, assisted by the late Dr. Joe Dickson and Dr. F. F. Myers, I removed a 1¼ in. button from the left occipital region midway between the external auditory meatus and the external occipital protuberance, cutting the upper margin of the groove of the lateral sinus. The membranes when exposed presented a healthy appearance, as did also the brain-tissue. There was no indication of a cyst or that the brain-substance had been in any way injured. With a dural separator I explored the inner surface of the skull and detected what might be termed an enostosis situated scarcely ⅜ in. from the trephine-opening in the direction of the parietal protuberance. It was small, but readily appreciable. With the rongeur forceps the bone was cut away in that direction. A very perceptible change in the density of the bone was noticed as we approached the enostosis, and when it was reached we found not only the enostosis soft and cheesy in consistency, but that the softening and degeneration had extended to the skull-bone itself. It cut more like dried cheese than bony tissue. After removing all this softened bone (about the size of a nickel) the wound was dressed antiseptically and the patient put to bed.

Convalescence was rapid and devoid of any unfavorable symptom. The temperature never reached 100°, nor the pulse-rate over 80 per minute. The result of the operation was most gratifying. The headache was relieved almost instantly. The tinnitus aurium ceased in a few days and up to the present time, now 2½ years after the operation, the patient has not had a convulsion. He has been engaged at manual labor all this time and has enjoyed perfect health.

Case II. *Epileptiform convulsions complicated with insanity and paralysis.*—John H., aged 34 years, a restaurateur of Chicago, during the dedication of the World's Fair in October, 1892, received a blow with a chair on the right parietal bone. He was rendered unconscious for several hours. After regaining consciousness he suffered with paroxysmal headaches, but it was not until the following January, 1893, that his mind became so deranged that his friends found it necessary to relieve him of the care pertaining to his business. He was then taken to a sanitarium at Lake Geneva for treatment, but his malady progressed, and was augmented by attacks of epileptiform convulsions, which were of frequent occurrence and very severe. In February a gradual loss of power took place in the left arm, which progressed until paralysis of the arm, forearm, and hand was complete. Following this was a partial paralysis of the left leg and thigh, particularly marked in the anterior muscles.

In April, 1893, the man was removed to an insane-asylum, where he was confined until August 1. All this time the symptoms were growing worse. Early in August he was removed to the home of his parents in Allegheny City, Pa., and when I was called to see him, September 1, 1893, his condition was alarming. He was suffering from most excruciating headache confined to the right side of the head. The pain was so great as to elicit agonized cries, and the patient was with difficulty at times restrained from escaping to the street. His convulsions were frequent, as many as one and two occurring every hour. His appetite was destroyed and sleep was impossible, except when produced by heroic doses of morphin. His hallucination consisted principally of a fear of impending evil, loss of family, fortune, reputation, etc.

Medicaments had had a fair trial and failed; so the patient was placed in the Allegheny Hospital, and on September 5, 1893, assisted by Drs. Dickson and Myers, I removed a button 1½ in. in diameter from the right parietal bone over the junction of the upper and middle thirds of the fissure of Rolando. By means of the rongeur forceps this opening was enlarged in an upward and downward direction. There was a very perceptible bulging of the dura mater into the opening and the membrane itself was unusually adherent to the bone. Other than this there was no indication of injury or disease of the membrane. The dura was laid open by a crucial incision. There was an immediate escape of about two drams of thin pus, apparently the contents of a degenerated cyst, although there were no remains of a cyst-wall. The pus-cavity was washed out thoroughly with a weak solution of mercuric chlorid, the wound dressed antiseptically, and the patient put to bed. The immediate result of the operation was better than we anticipated. The headache was relieved, the convulsions ceased, and the mind was restored. This condi-

tion continued and convalescence was uninterrupted until September 16, when I was suddenly called to his bedside and found that all the previous symptoms had returned. I removed the dressings, reopened the scalp-wound, which had united by first intention, and found a reaccumulation of pus. After removing all pyogenic substance and washing out the cavity most thoroughly, I introduced a double drainage-tube and dressed the head as before. A favorable condition was at once apparent; for a week the wound was washed out with a weak, lukewarm solution of mercuric chlorid by means of the double drainage-tube. A hernia cerebri was feared, but fortunately the wound closed without any such occurrence. In six weeks from the time of operation the patient was removed to his home, practically a well man, with the exception of the paralysis. Shortly after this he noticed a return of power in his left leg and arm. This improvement was slow but continuous, and now, almost two years from the date of the operation, he has perfect use of his left leg, and the power in the left arm, in which the paralysis was complete, is restored, with the exception of the deltoid muscle and extensors of the hand, these being yet slightly impaired. He is now filling a clerical position with one of the traction-roads of this city.

CASE III. *Epileptiform convulsions complicated with pronounced melancholia.*—On October 1, 1894, I was consulted by the parents of Miss Minnie E., a young lady of 22 years, who had enjoyed perfect health until the receipt of an injury sixteen months previously. While skating she fell upon the ice, striking the back of her head a violent blow, rendering her unconscious for three hours. When I saw her, her mental condition was such that her friends feared that she would destroy herself or do some violence to the other members of the family. She was very morose and irritable. Headache had been incessant for over a year and was increasing in violence. Pressure at the seat of injury increased the pain very considerably. She was having on an average two epileptiform convulsions daily; her appetite was much impaired; sleep was almost impossible; and there was marked loss of flesh. Her condition was rapidly growing worse, notwithstanding she had had the benefit of the services of the best physicians, with change of climate and surroundings.

The objective symptoms were very obscure and the treatment doubtful, but with the approval of her parents she was placed in the Allegheny General Hospital, and on October 15, 1894, with the assistance of Drs. Dickson and Myers, I trephined at the seat of injury, removing a 1¼ in. button over the middle third of the superior semicircular ridge on the right side of the occipital bone. The skull seemed perceptibly thickened, and bleeding was free from the entire cut surface. This congested condition was particularly marked and the oozing of blood continued for several hours. The dura showed no indication of disease or of having suffered any injury whatever. The intracranial pressure was very great, so much so indeed that the membranes bulged up, almost filling the trephine-opening, and were so tense that the pulsations of the brain were not perceptible to touch. A crucial incision was made in the dura and the surface of the brain examined and then a careful exploration was made in different directions by means of a hypodermic needle for a suspected cyst, but nothing abnormal was discovered. After satisfying ourselves that the marked intracranial pressure was not due to the presence of a cyst or tumor in that particular part of the brain, an attempt was made to approximate the flaps of the dura, but this was found to be impossible, as the brain-tissue bulged into the opening until it was on a level with the external surface of the skull. The wound was dressed antiseptically and a firm compress applied.

The information obtained from the operative procedure as to the source of nervous irritation was thus very small. The only cause apparently discovered was the congested condition and the seeming thickening of the skull or perhaps the abnormal intracranial pressure, and it would have been difficult at the time to have pronounced either pathologic. The young lady made a most satisfactory convalescence, the wound in the scalp uniting by first intention, the temperature never reaching 100° or the pulse-rate above 75 per minute. Our failure to discover at the time of operation any positive or distinct cause of the nervous phenomena did not lessen our gratification at the ultimate result. Three days after the operation the patient declared herself free from headache, and there has been no recurrence of it since. Her mental disturbance rapidly disappeared, and at the present time intellection is as bright and disposition as genial as before the injury. She has gained twenty pounds in weight and her general health is perfect. Up to this time, eight months after the operation, she has never had a convulsion. She is now in the training-school for nurses in the hospital in which she underwent the operation.

The result in this case may be attributed to the removal of the (apparent) causes we found, or to the moral effect produced upon the mind of the patient by the operation. But however it may explained, the fact is patent that the consummation desired, namely, the relief and restoration of the patient to health, was accomplished. I have for the purpose of brevity omitted the technic of the operation as well as a detailed history of the convalescence.

A CASE OF HEADACHE DUE TO ADENOID GROWTHS.

BY HOWARD S. STRAIGHT, A.M., M.D.,
OF CLEVELAND, O.

IN October, 1894, a boy, aged 16 years, consulted me as to a headache from which he had suffered for 3 years. He was a healthy boy and had never been seriously sick. Nothing in his general condition accounted for his headache. His eyes caused him no trouble. He said that he had some catarrh in the nose, and wished to know whether there was any possible connection between the nasal trouble and the headache. His complaint as to his nasal catarrh was in no way unusual. For three years he had suffered severely from headache. As a rule, on rising his head would ache so much that he could not eat any breakfast, and often he would vomit. The headache would continue until about the middle of the forenoon, and then would gradually subside; by noon it would disappear. About once a week he would have a headache so severe that he would have to go to bed and remain for some hours. He had tried all kinds of medicines recommended without any permanent relief.

An examination of his upper air-passages revealed adenoid growths. There was no other abnormal condition present. A removal of the adenoid growths was advised and no promise was made as to possible relief of the headaches by this operation. The growths were scraped out with a Gottstein curet after painting the soft palate and pharynx with a 20 per cent. solution of cocain. After removal of the adenoids the headaches ceased at once, and have never returned. A recent letter of inquiry as to his present condition was answered in accord with the foregoing statement.

Adenoid growths are mentioned in the literature of the subject as a possible cause of headache. The possibility of headache being due to this condition is not considered at any great length in ordinary treatises. Frænkel has discussed the subject at greater length than ordinary, but offers no explanation of the manner in which the growths in exceptional cases produce such a result. Such cases must be rare. This is the only one that has passed under my observation. There was nothing unusual either in the quantity of growths present or in their character. The boy had had the headaches for three years only. The adenoid growths had in all probability been present much longer, and were at one time even larger than when removed. Why they should have given rise to the headaches for three years only is a question. If at the time of the first occurrence of his headaches his general health had been depressed, one could understand why the adenoid growths should have given rise to a new train of symptoms. There was, however, no such history. It is always an interesting question why a local morbid condition, present it may have been for many years and giving rise to no trouble, should all at once become the cause of marked disturbances.

THE HICKOX.

A CASE OF ENLARGED PROSTATE GLAND TREATED BY REMOVAL OF THE TESTICLES, DEATH.

BY JOHN B. ROBERTS, M.D.,
OF PHILADELPHIA.

A MAN, 86 years of age, had suffered at various times for a considerable period with attacks of retention of urine due to enlargement of the prostate gland. Catheterization for a few times usually relieved him; and subsequently he was able to empty his bladder without further treatment. It was not necessary for him to use a catheter between the attacks of retention. During September of this year he had an attack of retention for which he was repeatedly catheterized by Dr. J. C. Knipe, resident physician at the Jewish Hospital, who had the immediate charge of him. When I examined the prostate through the rectum I found that the lateral lobes were not very much enlarged; the hypertrophy was evidently in the so-called middle lobe. Catheterization was rather difficult, and attended with considerable bleeding. The patient was, however, catheterized two or three times a day, and given potassium acetate, ergot, and tonic remedies. His bladder was occasionally washed out with boric-acid solution. The difficulty of introducing the catheter led to our leaving an instrument in the bladder for several days, which gave him much relief. Finally, on October 16th, we removed both testicles, and left a soft-rubber catheter in the bladder to drain off the urine. At the end of two or three days the patient, who had continued to grow weaker, was troubled a good deal with nausea and vomiting, and the permanent catheter was withdrawn, lest it might be the source of retention. He was then catheterized at intervals, though with some difficulty. He died five days after the operation. The wounds were in good condition, as they had been kept sealed with iodoform and collodion. The dribbling of urine over the scrotum was not allowed to contaminate the wounds, as they were frequently washed and the collodion-dressing reapplied. The patient did not die from the effects of the operation, but from the urinary condition. I seriously contemplated making a suprapubic cystotomy instead of removing the testicles, but concluded to do the latter operation, as the patient's condition was fairly good, and it was possible to introduce a catheter through the urethra. I rather regret now that suprapubic cystotomy had not been done and the removal of the testicles delayed until the man's condition had somewhat improved.

MEDICAL PROGRESS.

Successful Removal of a Foreign Body Impacted for Forty-six Days in a Bronchus.—MORGAN (*Lancet*, No. 3761, p. 769) has reported the case of a healthy girl, eight years and nine months old, in which three weeks before coming under observation, whilst sucking a plum-stone which she had previously cracked, a portion of the stone fell back, and, as was supposed, was swallowed. There was immediate complaint of pain in the neck, and a crust of bread was given for its relief. An attempt on the following day to dislodge the stone by inverting the patient was unsuccessful. Subsequently there was pain referred to the right side of the heart. Poultices were applied and constantly renewed, with a view to relieving the pain, and the child was kept in bed for three weeks, during which time she took very little food. She was unable to sit up, but slept well except when troubled by cough, which occurred in paroxysms both by day and by night. The nutrition was fairly well preserved. The left side of the chest was flattened, chiefly over the second and fifth ribs, and the movements of this side of the chest were deficient, the interspaces being sucked in during inspiration. Vocal fremitus was greatly diminished, especially below the level of the third rib. The apex-beat was felt in the fifth interspace, half an inch external to the nipple. The whole of the left side of the chest was dull upon percussion, except over the left of the sternum, and this dulness extended over the whole of the left lung posteriorly. The right side was hyperresonant. On auscultation some breath-sounds were heard under the left clavicle, but were lost about the third interspace, and some feeble breath-sounds were audible behind in the suprascapular region, below which, however, all was dull.

After due consideration it was decided to attempt the removal of the foreign body by operation. Accordingly, nine days after the accident, an incision was made in the median line from the cricoid cartilage down almost to the inter-clavicular notch. The trachea was exposed, and a scalpel passed through between the third and fourth rings from below upward, well below the level of the isthmus. No mucus escaped, but a

small amount of blood that entered the opening was expelled. The patient was inverted, but the obstructing body was not released. A bent wire, with the looped extremity downward, was passed down the left bronchus, but without first discovering any obstacle to its further passage. A double-looped strand of silver wire was then passed, with the result that the object sought was distinctly felt. On each of several attempts muco-purulent secretion was brought away on the instrument, and a small quantity was expelled through the opening after each trial. On attempting to pass the little finger the child became distressed, the veins of the neck becoming distended and turgescent. The child was allowed to partially recover consciousness and the laryngeal reflex was then excited with a feather. The breathing became very spasmodic and violent, but without the effect of expelling the foreign body. A large oval tracheotomy-tube was tied in with tapes, and the incision drawn together above and below, but owing to some distress another tube had to be substituted. For several days there was a good deal of cough and moderate muco-purulent expectoration.

Fifteen days after the operation the child was again anesthetized and inverted; a feather was passed down the trachea, but no effect was produced upon the foreign body. A long probe, slightly bent, was then passed down the left bronchus, and a hard substance was distinctly felt at a distance of about five-and-one-half inches from the lower margin of the tracheotomy-wound. The wound was then held open by retractors, and a long pair of forceps, curved for the last inch of their length, was passed down the left bronchus, but the retractors had to be removed before the foreign body could be grasped and removed. This was found to be nearly half of an irregularly broken plum-stone, which had been impacted with its apex downward. The wound was covered with a guard wet with carbolic lotion, and closed without further complication.

Splenopexis for Wandering Spleen.—Plücker (*Centralblatt für Chirurgie*, 1895, No. 40, p. 906) has reported the case of a woman, twenty-three years old, and married for five years, who had aborted twice, but had borne no living child. For three years there had been complaint of constant abdominal and pelvic pain. There was no vaginal discharge and no hemorrhage. On vaginal examination the uterus was discovered to be retroflexed and somewhat enlarged and fixed; the right ovary was normal and slightly movable, and the tube was not thickened; the left ovary could not be felt, but in its place was a fairly firm, smooth tumor, equal in size to two fists; this mass was movable and filled the true pelvis. Wandering kidney was excluded in the diagnosis. Wandering spleen was thought of, but from the physical signs and the clinical history a benignant tumor of the uterine appendages on the left side, with retroflexion of the uterus, was believed to exist. Upon opening the abdomen in the Trendelenburg posture the tumor was found to be the enlarged and movable spleen. As the diaphragm was unusually high and difficult of access, ventrofixation of the uterus was effected, and a second incision made in the midaxillary line from the costal arch to the crest of the ilium, and another at right angles to this at the level of the tenth rib and parallel with this. Both of these incisions were continued down to the peritoneum. The parietal peritoneum was detached with the hand from the fascia above and below, and an incision made in it just large enough to permit the smallest diameter of the spleen to pass. When this organ had been removed the opening was then closed, and the parietal peritoneum attached to the pedicle of the spleen. The latter was now placed in its usual situation, though outside of the peritoneal sac. It was attached by a ligature to the tenth rib, and below it a pocket was made by bringing together the adjacent fat and connective tissue, and a number of sutures were passed through the surface of the spleen itself. The wound was carefully closed, and the operation proved to be a success.

Successful Removal of the Breech-pin of a Gun from the Orbit.—Wenyon (*British Medical Journal*, No. 1815, p. 907) has reported the case of a man, 31 years old, who was injured by the bursting of a gun. Coming under observation two months later, he presented a cicatrix on the right side of the nose, above which was a sinus, the orifice of which involved the inner canthus of the right eye, and extended downward and inward for about a centimeter. The sight of the right eye was entirely lost, and the anterior surface of the globe was so uniformily red that the cornea could hardly be distinguished from the surrounding conjunctiva. There was no perceptible enlargement or protrusion of the eyeball, and this did not appear to have sustained any mechanical injury or loss of tissue. The sinus gave exit to a continuous discharge of slightly putrid pus, and the patient complained of constant headache and occasional dizziness. The pain was referred to the right frontal and temporal regions, and the skin of this part of the head presented a slight blush, but there was no superficial tenderness. On the introduction of a probe the lower edge of a hard, metallic substance was detected at a depth of about one inch posteriorly from the orifice of the sinus. Several attempts to remove the foreign body through a slightly enlarged opening were unsuccessful. Accordingly, the incision was carried along the side of the nose to the nostril, laying open the right nasal cavity. The foreign body was then seized with a strong pair of forceps, and the complete breech-pin of a gun removed. It measured a little more than three inches in length, and weighed $2\frac{2}{8}$ ounces. It had evidently lain at the back of the orbit, inclined upward and slightly backward from the point of entrance, at an angle of about 45°. The symptoms disappeared with the removal of the body.

Bilateral Gangrenous Stomatitis.—McDonald (*Medical Herald*, vol. xiv, No. 10, p. 478) has reported the case of a girl, 3 years and 2 months old, who, in the course of an undetermined febrile affection, presented a sore mouth and picked out two of her teeth. In the course of a week the cheek had become swollen and was red and shining, and soon the other cheek became similarly affected. In the course of another week the affected parts of the lips and cheeks became blue and dark, and the discoloration spread on either side. Antiseptic lotions and powders seemed to cause a drying-up of the dead tissues, but failed to check the spread of the gangrene. The condition thus progressed for four or five

weeks. The affected area included the cartilage of the nose, the upper and the lower lips, and three-fourths of each cheek. An offensive odor emanated from the child, whose body had become greatly emaciated. Respiration was accelerated, and coma set in and death ensued.

THERAPEUTIC NOTES.

Death from Potassium Permanganate.—THOMSON (*St. Petersburger medicin. Wochenschr.*, 1895, No. 38, p. 329) has reported the case of a man, 22 years old, who was found upon the street with a partially emptied bottle of of potassium permanganate in his pocket, of the contents of which he had taken between four and five drams. Undissolved crystals of the salt were visible at the corners of the mouth. The face was pale and expressive of pain; the eyelids were half-closed; the mouth wide open; the lower lip and the protruding tongue swollen, black in appearance, and covered with dark crusts. Dark streaks passed from the angles of the mouth to the chin. Respiration was difficult, and attended with sounds of stenosis. The pulse was frequent and small. There was considerable muscular relaxation, and speech was almost impossible. An esophageal sound encountered obstruction at the level of the cricoid cartilage. In the course of the manipulations intense dyspnea suddenly manifested itself, for the relief of which tracheotomy became necessary. Upon the supposition that considerable quantities of potassium permanganate had gained entrance into the stomach, in conjunction with the failure to reach this viscus through the esophagus, and in anticipation of the subsequent necessity of feeding, gastrotomy was undertaken in order to effect lavage. The gastric contents responding to tests for potassium permanganate, the irrigation was repeated after an interval of four hours. Respiration, however, continued difficult; the pulse became rapid and feeble, and death occurred amid signs of cardiac paralysis. Upon postmortem examination the lips and the tongue were found edematous. The mucous membrane of the mouth, pharynx, and larynx was eroded. The trachea, the bronchi, and the esophagus were not attacked. The blood in the large vessels was diffluent and cherry-red in color. The heart was of normal size, and presented a number of petechiæ beneath the pericardium. The cardiac veins were distended, the arteries elastic and not dilated. The myocardium was flabby. The left ventricle contained a small amount of blood; the right rather more. The auricles were filled, but not distended. The lungs contained much blood. Blood from the heart and its afferent vessels, the urine, and a piece of the pectoralis major muscle of the left side failed to yield the reactions of potassium permanganate. The conclusion is reached that death did not result from intoxication, but from the corrosive action upon the upper respiratory and digestive tracts, resulting, in conjunction with the necessary operative procedures, in cardiac failure.

Recovery from a Large Dose of Cocain.—At a recent meeting of the Philadelphia County Medical Society, BALL reported the case of a woman, 35 years old, who swallowed with suicidal intent 6 drams of a 5 per cent. solution of cocain, representing 18 grains of cocain. The patient had for 10 years been a sufferer from stricture of the rectum, for the relief of which she was accustomed to apply cocain topically on a pledget of cotton. After the ingestion of the toxic dose dryness of the throat soon appeared, and on attempting to rise from her couch to summon aid the woman felt dizzy and fell to the floor. Raging delirium set in and the patient attempted to throw herself from a balcony to the ground. She talked loudly, incessantly, and incoherently. Physical restraint was necessary and the hypodermic administration of morphin was resisted, although a third of a grain was given by the mouth. The pupils became widely dilated, the pulse hardly perceptible and very frequent. The tongue was from time to time protruded spasmodically and the teeth were gritted together in a tetanoid manner. At one moment the patient was depressed, at another exalted. She frequently rubbed her hands, which she complained of looking dirty. The tongue was much congested and cyanotic and anesthetic. There was no appreciable anesthesia elsewhere. The administration of black coffee and lukewarm water was followed by free emesis. Two hours after the poison had been taken the patient was resting quietly, with the pulse stronger but still frequent. Thirst was extreme and motility greatly impaired. Emission of urine was secured, and strychnin, gr. $\frac{1}{30}$, and champagne were administered. Perspiration set in and pallor gave way to a slight glow. Four hours from the beginning the patient was sleeping soundly and the pulse had fallen to 100 and was much stronger. After a time consciousness returned, but there was no recollection of time and little of previous events. On the following day the patient was weak; her body felt bruised and her limbs heavy and useless. Feces and urine had been passed without difficulty. Appetite was impaired and thirst was still present. The tongue was no longer congested and sensibility had returned. The patient gave a history of having taken an overdose of cocain in the dry state on a previous occasion, when the delirium was acute and was overcome by the use of morphin in large doses.

The Treatment of Diphtheria with the Antitoxin.—HEUBNER (*Deutsche medicin. Wochenschr.*, 1895, No. 42, p. 687) reports the treatment of 117 cases of diphtheria with the antitoxin in addition to those previously reported, making a total of more than 300 cases. Among the 117 there were 12 deaths—10.2 per cent. There were 97 cases of pure diphtheria, with 10 deaths (10.3 per cent.); and 20 cases of complicated diphtheria, with 2 deaths (10 per cent.). Among 220 cases treated from May, 1894, there were 25 deaths—11.4 per cent. There were 174 cases of pure diphtheria, with 15 deaths (8.6 per cent.); and 46 cases of complicated diphtheria, with 10 deaths (21.7 per cent.). Among the 110 uncomplicated cases treated between the first and third days there were but 6 deaths (5.4 per cent.).

Official statistics show that the mortality from diphtheria in the cities of Berlin, Dresden, Leipsic, Munich, and Hamburg during the first half of 1895 was conspicuously lower, both absolutely and relatively, than during any year covered by the records, although the whole number of cases of the disease, in the city of Berlin for instance, was larger and the proportion of cases received into the hospitals was smaller.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Philadelphia.

SATURDAY, NOVEMBER 9, 1895.

MAGIC AND MEDICINE.

Probably most of us would resent the suggestion that there is any further connection between the terms magic and medicine than the identity of their first letters, but, unfortunately for our pride, it goes much further. Historically considered, one is the lineal descendant of the other. The earliest physician was the priest, the shaman, the conjurer, who even to this day in certain tribes bears the suggestive name of "medicine-man," and the curing of diseases constituted no small part of his activities. Indeed, his priestly or magic functions really grew out of his medical ones, and represent a later stage of thought, wherein all misfortunes, bodily and elemental, are alike regarded as due to the activities of evil spirits. The earliest deities of the race were personified discomforts, and some present-day divinities even yet bear traces of this origin. Our magnificent system of modern medicine bears evident signs of its demonistic descent.

It may sound strange, especially in view of recent developments, to assert that not only medicine and religion, but also science and religion, have a common ancestry. Yet such is literally the fact. The primitive priest-physician is called into being for and principally concerned with the removal or relief of discomforts and misfortunes, both individual and racial. His function is alike to bring rain, to avert storms and floods, to secure abundant harvests, to guard against defeat in battle, and to allay fevers, to cure convulsions, to defend against the "evil eye." To aid him in one class of functions he appeals to and studies the only manifestly heavenly bodies visible to him, the stars, and from this blind beginning astronomy, with its descendants, physics, mathematics, and navigation, is born. Many, if not most, of the stars and planets bear to this day the names that were given to them when worshipped as deities and used in the construction of horoscopes and predictions.

To assist him in the individual class of his duties the priest-physician impresses into the service the neighboring plants, herbs, and saline earths, first probably from their offensive taste or symbolic color, and thus arose the beginnings of botany, of chemistry, and their descendant, biology. The names of not a few of our familiar plants, some of which have lost all connection with the materia medica, such as "fever-few," "liver-wort," "sorrel" ("sore-heal"), "bone-set," etc., bear witness to this genealogy.

As the tribe grew, and its institutions with it, these two fields of effort became gradually separated from each other and assigned to different individuals and classes, but they have always displayed a remarkable tendency to become united again, and even to this day have never become entirely separate and distinct. For instance, in the Middle Ages monks were almost the only professed physicians, and such non-clerical physicians as existed relied largely upon charms, exorcisms, entrails, magic salves, and "spiritual" agencies generally in their practice.

In the brightest days of the most brilliant civilization that the world has ever seen the descendants of Esculapius formed a regular priestly caste and offered sacrifices, and these are merely a few of thousands of instances that might be cited to prove the connection between the two professions. Even in the nineteenth century the relation still lingers in the not infrequent claim to the power of healing disease under certain circumstances, yet made by some clergymen of almost every church and creed. As an historic fact it is supported by a simply overwhelming array of authorities from Humboldt and Tyler to Spencer and Draper.

And even if all these matters of record were

swept away and forgotten the medicine of the earlier part of this very century, the domestic medicine of to-day, which is simply the professional therapeutics of a few generations before, nay even our most modern practice itself, bears scattered but unmistakable marks of their actual genesis.

That a considerable part of domestic medicine is evidently of demoniacal origin—in more senses than one—few will care to deny. The striking prominence among "household-remedies" of horribly bitter and nauseous "yarb teas," of cherry-bark, of quassia, of asafetida, the recommendation of such remedies as a roasted mouse eaten whole, snake-broth, drinking urine, hot blood, etc., etc., the confidence imposed in violent purgatives and emetics, are obvious survivals of the magician's principle of administering nauseous messes of every description in the hope of disgusting and driving out the evil spirit that causes the disease. Their whole medicinal value lies in their offensiveness. Such common practices as the charming away of warts, the wearing of iron rings, and the carrying of potatoes or chestnuts in the pocket to "draw out" rheumatism, are also of unmistakable character, and dozens of others might be mentioned.

But it was in the professional practice of fifty or seventy-five years ago that these survivals most abounded. The extraordinary prevalence of bleeding, for instance, was an almost pure relic of barbarism. Although useful under certain circumstances, and most gravely and learnedly defended on far other grounds both at that time and since, its senseless, indiscriminate use was a plain remnant of the shaman idea that there is in the system some spiritual or material *materies morbi* which must be got rid of by the most vigorous means in our power short of actually endangering the patient's life. And, perhaps, our sturdy phlebotomist-ancestors did not always stop short of this danger-line. The universal practice of systematically starving or "reducing" all "sthenic" forms of disease was originally based upon the same idea, although far different and more plausible grounds were avowed for its continuance.

It was scarcely a generation ago that Graves thought it worth while to order carved on his tombstone, "He fed fevers," and we are more than inclined to suspect that the undue prominence of gruels, beef-teas, soups, and "slops" of every description in the sick-room dietary of to-day is a belated survival of or reaction from the same "demon-starving" theory of medicine. The remarkable manner and heroic doses in which calomel and other violent purgatives, tartar emetic, lobelia, and veratrum were administered in season and out of season, were also obvious survivals of a similar idea. A most significant fact in this connection is that almost every one of these once-vaunted methods and drugs has fallen into disuse, if not disgrace, as the shadow of the superstitions that gave them birth have been dispelled. The only exception of note is calomel, which, however, is used to-day in far other doses and for almost totally different purposes.

But surely there are no such traces of lowly origin to be found upon the bright escutcheon of that queen of the arts and sciences, modern medicine. Take up a prescription-blank and say whose image and superscription that is in its upper left-hand corner. On recent blanks it is ingeniously twisted into a rude letter "R," with a stroke across its last flourish, and we teach the wondering tyro that it is a contraction of "*Recipe*," "take." But turn to a blank of twenty years ago or a German or English blank of to-day and it appears as a character widely different from any known letter of the alphabet, and a little further investigation reveals it as nothing more nor less than the zodiacal sign of the god Jupiter, whose blessing is thus invoked upon the succeeding formula—which often needs it badly enough.

This, of course, is a mere fossil imprint upon our escutcheon, of much historic significance, but exercising no influence upon our present thought. But are there no genetic traces that are still alive and actually affect our conceptions of disease and its cure? Take, for instance, that extraordinary and mysterious disease hydrophobia, of which we hear so much and see so extremely little, and which several competent authorities, who have made for years a special study of collecting and analyzing all reported cases of it, declare is largely made up of either tetanus or hysteria, most commonly the latter. The picture at least of this horrifying disease is an evident and striking survival and copy of the old Norse legend of the "were-wulf" and its madness-producing bite. This is also shown by the fact of its being popularly and even semi-professionally believed to be most prevalent during the "dog-days" or months in which the "dog-star," Sirius, is in the ascendant. The "muzzling-ordinances" that our "city fathers" are annually delivered of

in July and August are actually still based on this idea. We cover its nakedness nowadays by the declaration that hot weather predisposes to the disease, in spite of the fact that it is almost unknown in the tropics and can be shown by statistics to be completely independent of the temperature, occurring in even Iceland and Greenland. In fact, it would hardly be too much to say that the geographic distribution of hydrophobia is closely dependent upon that of the "were-wulf" legend.

Has the tendency to regard mere bitterness or distastefulness as a medicinal property entirely died out? Have we not yet in our materia medica a class of "simple bitters," drugs of whose physiologic effects we know absolutely nothing except that they taste bitter and are traditionally reported to have an improving effect upon the appetite? What claim have quassia, gentian, calumba, etc., to a place among our remedies except their abominable taste?

There is another therapeutic belief that is a positively beautiful case of survival still in full force among us. And that is the mineral-water fad. Our favorite prescription for lithemia, for rheumatism, for dyspepsia is, as it was a hundred years ago, "a course of the waters" of some spring, either at first hand or in bottles. The shelves and the cellars of our drug stores, our restaurants, our bars, nay even of our groceries and residences, are fairly loaded with green bottles labelled "Hathorn," "Carlsbad," "Apollinaris," "Hunyadi," etc. Their wonderful virtues—and still more wonderful formulas—are spread upon the advertising pages of all our journals, and there is no scarcity of medical names to back up their pretensions. They differ widely in their chemic composition, but all are beneficial in all sorts of troubles. This leads one to suspect that their most potent remedial principle is that possessed by them all in common—H_2O. Indeed, most of the benefit derived from their use is now attributed by thoughtful observers to their "flushing" effects, and it is significant in this connection that the one water which has by far the largest sale contains simply pure water and enough carbon dioxid to give it sparkle and "snap." Originally it was "the sparkle" which was regarded as the most important part, for, strange as it may seem, the belief in mineral waters can be traced directly to the superstition that springs that bubbled or seethed or spouted were literally inhabited by spirits that caused the ebullition. The "troubling of the waters" in the healing pool of Bethesda, as related in the Gospels, is a familiar illustration. Hence their wonderful potency as remedies, and especially if they were either hot or sulphurous, which proved them to come directly from the nether world.

But probably the most vigorous and striking survival of the demon-theory of disease is our irrepressible tendency to regard disease as a distinct entity of some sort which is to be "treated" or "driven out." We speak of "disease-processes" as if they were something entirely new and foreign to the tissues, instead of mere health-processes gone wrong, life out of place. The mental habit of far too many of us is simply to determine the nature or often merely the name of the disease and then apply the remedies indicated in that disorder. We are still longing for "cures" and "specifics," for antidotes and abortions.

Not a little of the wonderful vogue attained by the germ-theory of disease is due to the high degree in which it gratifies this tendency. It serves to embody or personify disease as it were, and gives us something definite and separate to attack. In early days a demon was the explanation for everything. Now it is a germ.

EDITORIAL COMMENTS.

The Coroner as a Pathologist.—We believe the coroner's office is intended for the investigation of deaths from doubtful causes. Of course, in the vast majority of instances, death is the result of disease, and a physician's certificate is given. But whenever a human life is ended by suicide or accident, by inadvertence or carelessness, or under circumstances giving rise to suspicions of foul play, the coroner holds an inquest—makes a preliminary inquiry—to ascertain where the responsibility lies. And if in the opinion of his jury the loss of life has been due to fault on the part of anyone, that person may be held for the further action of the proper court.

Here, however, it seems to us that the coroner's duty ends. Should two physicians be at variance as to the question whether in a given case the certificate should read "typhoid fever" or "diabetes," we think it would be absurd to ask that the point should be decided in the coroner's office.

But the Coroner of Philadelphia has shown himself to have a higher view of his functions. He is ready to tackle pathologic problems; to assume authority in matters pertaining to this science. Some time ago he announced that in his opinion there was no such thing as heart-failure, and that he should decline to receive any statement from physicians giving this as the cause of sudden death.

A few days ago, a child died with symptoms suggesting hydrophobia, it having been bitten by a dog

some four or five days previously. According to the daily papers "it has always been the custom of the coroner's officials to ignore the existence of hydrophobia, maintaining that the deaths credited to that cause are always from convulsions. . . . In the case of the Jones child, Deputy Coroner Dugan determined to set the matter at rest once for all, and so a live rabbit was inoculated with virus from the supposed hydrophobic victim." As the rabbit did not die, he stated that the child had not had hydrophobia, and that there was no such disease. He ordered that the cause of death should be recorded as "convulsions."

Now this pathologist is perfectly satisfied with a certificate stating that a patient died of "dropsy," whereas every physician knows that dropsy is a mere symptom, and that no one ever dies of it. It would be about as explanatory to ascribe death to "pallor." We are aware that there have been doubts expressed by members of our profession as to the existence of such a disease as hydrophobia; but they have not yet found advocates of such authority as to outweigh the opinions of Pasteur, or to set aside the practice instituted by him.

When the Coroner and his jury have investigated a case and have decided that death was the result of natural causes, we have no objection to make, although we do not think that they represent the highest type of intellectual or scientific development. They have merely declared that they see no evidence of suicide or of fault on the part of some person other than the victim. But when the Coroner undertakes to offer the medical profession instruction in pathology and diagnosis—to tell them what they are to see or not to see in dealing with disease—we cannot recognize his authority. He may or may not believe that the stoppage of a weak heart is the only assignable cause of death in any case; he may hold what views he will as to the true nature of the disorder known as hydrophobia, but he has neither the capacity nor the right to dictate to the physician with regard to things which belong altogether within the latter's province.

There are communities which are well ordered and prosperous, in which the public welfare is maintained and the medical profession stands high, without any coroner at all. There are intelligent people who consider his existence as a relic of barbarism. Perhaps they are right.

Concerning Schlatter.—As we are likely to hear more of Schlatter and similar persons in the future, we think it well to copy from the private letter of an Eastern physician the following portions telling of a visit paid the "healer" last week in Denver:

He stands in the front yard of an unpretentious house in one of the city's suburbs; a common board-fence separates him from the people. They come in single file, kept so by a railing extending about a hundred feet along the fence. The line at this time of my visit (2 P.M.) was nearly two squares long. Some were standing, some sitting upon rude benches, and some upon their own camp-stools. It is said that people come as early as 2 o'clock in the morning. He has been seeing over a thousand a day for weeks past. They come from all classes. They are not, in the main, a religious-looking crowd. Few seemed to me to have the semblance of a religious attitude. Indeed, it is stated that but few of the professed cures are professing Christians. The crowd of sight-seers outside of the line are well-behaved. At no time is there any hilarity. Indeed, the aspect of this aggregation is sober. No policemen are ever needed.

The "healer" is a tall, heavily built man. His features are large and show strength rather than refinement and intellect. His hands are large and strong, and from the size of his shoes I should suppose he would have difficulty in finding a pair to fit him in an ordinary shoe-store. His long hair, parted in the middle and combed roughly back, falls upon his shoulders. It is straight, coarse, and black, mixed with gray. His moustache and whiskers are somewhat curly and of the same color. His nose is somewhat flattened and twisted, as though from an injury. His brow is broad and of considerable height. What attracts one the most is his small, deeply set, restless, bright-blue eyes. His whole form speaks of an earnest, patient continuance in what he conceives to be well-doing.

As a subject approaches him, in turn, he grasps his right hand firmly (sometimes with severe pressure), and, if the subject has brought handkerchiefs with him to be "blessed," he squeezes them in his left hand, often pressing them hard down upon the upper board of the fence. He rarely looks at the subject after taking his hand, his eyes wandering restlessly and seemingly aimlessly about, mostly in a horizontal plane above the subject's head. His brows contract and his lips move slowly, but no words are audible. He gives about 25 seconds to each one, after which he releases his hand, gives him his handkerchief or other article he has "blessed," and indistinctly mutters some word which sounded to me like "tonk" (I was but 5 feet away from and directly in front of him). A friend by my side thought he meant to say "next," but he never looked in the direction of the next, and spoke too indistinctly to be understood by him. Once he took a cripple's both hands in his, while a rather frivolous young man with a weak profile, the antipodes of the healer, but who seemed to be his only assistant inside the fence, toyed with the cripple's cane, testing its iron point in the hard earth, etc. The cane was returned to the man with a bundle of handkerchiefs which had been blessed, and the aforesaid officious young man told him to "lay them on the sore parts," and that washing would not destroy the virtue in them. Once a crippled old man got near to the healer without being in line, and unobserved by the striplings-assistant; the healer attended to him without seeming to notice the break in the rule or to care for it. He goes on with his work, as it were, automatically. He receives no money nor appears to think about it. I saw no money offered during my time of observation.

He wore a rather short coat, likely given him by some friends to replace the common blouse he had been wearing through rain and even snow. He seemed to be honest in his efforts to do good, and not to be seeking for fame. He recognizes no subject, makes no discrimination, asks no questions; indeed, keeps at his work like a man driven to do so by some power beyond his disobeying. If a mother brings a child he takes its hand, does not even scan it to see what its deformity may be, but goes through the 25 seconds of moving lips, restless wandering eyes, and contracted brows, and then drops it, and reaches for its mother's hand and goes through the same process without ascertaining whether she is an invalid or not. Occasionly he yawns, rubs his head or lifts his feet to shift his position, all of which he does in such a manner as not to let the people feel that he is tired. In none of his actions does he seem to bid for even the sympathy of the people. He keeps at his task, slighting no one, never hurrying to get through, never looking along the line to see how many remain to be treated.

When the people pass from him they generally look subdued, sometimes affected to tears.

I saw no marvellous cures on the spot. One woman insisted that her imbecile boy walked better. Many patients say they have been benefited, but rarely show real evidence of it.

To sum up: Evidently this man is possessed with a form of religious monomania. He is doing what his impaired mind tells him is his duty, regardless of his own comfort, and even at the risk of his life. What cures there are come from the mental impression he is able to make upon his subjects.

He is harmless, not a fanatic. He does not present an array of canes, crutches, or other make-believe evidences of his healing-powers. He makes no show at all of healing-power. He simply stands long, weary hours, patiently going through his simple form for all who may come to him. Physically he shows no signs of breaking-down, and as his reputation is on the increase it is probable that many of the halt and maimed and blind will have the opportunity of seeing what he can do for them.

I went away feeling a deep sense of pity for the poor man whose unbalanced mind compels him to undergo such hardships, and I hope that by some means the proper authorities will be enabled to take him in charge and properly care for him. I did not feel the same pity for the people.

Physicians as Poets.—It is always pleasing to find a largeness of mind and sympathy for other things than those that pertain to one's special department of work, and it is particularly so when we find physicians with creative power in the department of general literature. We are all proud of our Holmes's, Doyle's, Weir Mitchell's, and the rest, and are glad by them to illustrate to the world the truth that medicine is no narrowing and belittling sphere of human activity. We are pleased to bring a new proof of this before the profession in the fact of a recent volume of fine verse by a well-known and highly respected physician of Philadelphia, Dr. Edward W. Watson. *To-day and Yesterday* presents, we are sure, a wider range of theme, a broader interest in the great tragedy of human life, a keener perception of and sympathy with the struggle between science, faith, and ethics, than any other first volume of poetry known to us. Here is no piping falsetto or monotone, but a voice with rich and varied range, singing the ever-varying song of humanity's suffering and joy, love and life.

A New Method of Advertising is fast growing in fashion —and it is reprehensible. It consists in the making of cut-and-dried abstracts of their articles, lectures, clinics, etc., by physicians themselves, who then send them to many journals. It is hoped that at least only medical journals are thus supplied. But even if only to them the practice can hardly be excused, because editors should be capable both of choosing articles to epitomize and of making their own abstracts.

REVIEWS.

Medical Diagnosis, with Special Reference to Practical Medicine. A Guide to the Knowledge and Discrimination of Diseases. By J. M. Da Costa, M.D., LL.D., President of the College of Physicians of Philadelphia; Emeritus Professor of Practice of Medicine and of Clinical Medicine at the Jefferson Medical College, Philadelphia; Physician to the Pennsylvania Hospital, etc. Illustrated with engravings on wood. Eighth edition, revised. 8vo, pp. 1104. Philadelphia: J. B. Lippincott Co., 1895.

Da Costa's *Diagnosis* has already a secure place among the classics of medical literature. A new edition, a revision, of such a book affects, therefore, but little the body of the work, which, at most, requires here a little trimming, there a little addition, by reason of the clearing up of matters previously doubtful, and enlargement of view due to increasing knowledge. The descriptions of diseases and their differentiation as contained in this volume may well serve as models of clearness and completeness, and though time may alter our views as to etiology and pathology, not to speak of prognosis and treatment, the clinical pictures so admirably executed will retain a permanent place in the galleries of medical art. The present revision has been extensive and, in some respects, radical. Additions have been made where it was necessary to bring the work into line with the present advanced position of clinical medicine, and a certain amount of matter that has been left behind in the march of events has been replaced by newer and better. The book is thus increased in size nearly one-hundred pages, and the text is illuminated by an added number of well-executed illustrations, a number of which are colored. A judicious position of conservatism has been taken with regard to the newer pathology born of modern bacteriologic investigation, accepting that which has been proved and assuming a waiting and receptive attitude toward that of which the proof is in varying degree yet incomplete. In addition to the Russian translation of the work there exists also an Italian, and a third edition of the German translation is in course of preparation. Despite the many good books that have appeared during the thirty-one years' existence of this one, Da Costa's *Diagnosis* easily remains the best of the kind extant.

A System of Surgery. By Charles B. Ball, M.D., T.C.D., Arthur E. Barker, F.R.C.S., William H. Bennett, F.R.C.S., Anthony A. Bowlby, F.R.C.S., Stanley Boyd, M.B. Lond., W. Watson Cheyne, F.R.C.S., W. Bruce Clarke, M.B. Oxon., H. H. Clutton, M.B. Cantab., H. Percy Dean, M.S. Lond., Andrew Duncan, B.S. Lond., A. Pearce Gould, M.S. Lond., Frederic W. Hewitt, M.D. Cantab., Jonathan Hutchinson, Jr., F.R.C.S., W. Arbuthnot Lane, M.S. Lond., C. B. Lockwood, F.R.C.S., G. H. Makins, F.R.C.S., J. H. Morgan, F.R.C.S., Henry Morris, M.B. Lond., Herbert W. Page, M.C. Cantab., Bernard Pitts, M.C. Cantab., A. Marmaduke Sheild, M.B. Cantab., J. Bland Sutton, F.R.C.S., Frederick Treves, F.R.C.S., Herbert F. Waterhouse, F.R.C.S., G. Sims Woodhead, M.D. Edin. Edited by Frederick Treves, F.R.C.S., Surgeon to and Lecturer on Surgery at the London Hospital; Examiner in Surgery at the University of Cambridge. Vol. I. With two colored plates and 463 illustrations. 8vo, pp. 1152. Philadelphia: Lea Brothers & Co., 1895.

We have here the first volume of a work projected on somewhat the same plan as Holmes' great *System of Surgery*, the third and last English edition of which appeared only twelve years since. Yet in this brief space of time there has been so great a change in surgical theories and methods that even that monument of profound learning, studious research, and practical knowledge cannot now be regarded as setting forth the existing state of the science and art of surgery.

Mr. Treves says in his preface that there has been no attempt on the part of himself and coadjutors to produce a cyclopedia, but that they have sought in every way to make their work useful to the student and prac-

titioner of surgery. He does not propose to dwell upon the actual details of operative procedures, but to set forth the pathology, clinical manifestations, and treatment of the various diseases and injuries that come within the scope of surgery. He further states that there has been no effort to secure an ideal uniformity of opinion, in cases in which the same subject or part of a subject happens to be dealt with by more than one writer holding differing views with regard to it.

Sixteen of the twenty-five authors have taken part in the preparation of this volume.

The opening article is by Mr. Woodhead, on the general subject of Surgical Bacteriology; it is a remarkably clear exposition of the present state of that most important science. Of course this matter figures frequently in the subsequent chapters. Inflammation, Suppuration, Ulceration, Gangrene, Syncope and Shock, Wounds, and Contusions are discussed by Mr. Cheyne; Erysipelas, Pyemia, Tetanus and Tetany, Burns and Scalds, by Mr. Lockwood.

A very brief article by Surgeon-Major Duncan on Military Surgery is devoted almost wholly to gunshot-wounds. The subject is treated in general terms. We believe that many surgeons in civil life have a wider and more familiar acquaintance with injuries of this kind than army medical officers have. The author makes no reference to the recorded experience of our late Civil War.

Mr. Treves himself contrib utes papers on the influence of Constitutional Conditions on Injuries, as well as on Tuberculosis, Hemophilia, and Hysteria.

On the subject of Anesthesia Mr. Hewitt writes ably, but altogether from a London standpoint. We cannot think the complicated inhalers so commonly employed by British surgeons have any advantage over the simple napkin. And we believe the true inwardness of the whole matter is better understood from careful clinical observations than from experiments in the laboratory.

Surgical Diseases due to Microbic Infection and to Parasites are discussed by Mr. Makins, who later writes on Rickets also.

Syphilis (including chancroid), Gonorrhea, and Diseases of the Skin have been assigned Mr. Jonathan Hutchinson, Jr.

A very interesting article on Tumors and a special essay on Diseases of the Jaws have been contributed by Mr. Sutton.

The remainder of the work is devoted to the consideration of diseases and injuries to the several systems: those of the Bloodvessels, including Aneurysm, by Mr. Gould; of the Lymphatics, by Mr. Morgan; of the Nerves, by Mr. Bowlby; of the Bones, by Mr. Boyd and Mr. Clutton; and of the Joints, including Dislocations, by Mr. Sheild and Mr. Barker.

We regret that our limited space forbids a more extended analysis of the articles enumerated. They embody the prevailing principles of the great British school of surgery, set forth by some of its ablest living representatives. Very little reference is made to Continental authorities, hardly any at all to the writings of our own countrymen. A striking feature of the work is the marked spirit of conservatism which pervades its pages. We find no hint in the present volume as to the proposed number of its successors, or the arrangement of the material to be contained in them. But we predict that the completed work will be recognized as a very important addition to surgical literature.

—

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY. AUTHORS AND SUBJECTS. Vol. XVI, W–ZYTHUS. Washington: Government Printing Office, 1895.

ALPHABETICAL LIST OF ABREVIATIONS OF TITLES OF MEDICAL PERIODICALS EMPLOYED IN THE INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY. Vol. I to Vol. XVI, inclusive. Washington: Government Printing Office, 1895.

THESE, the concluding volumes of this splendid work, constitute the capping-stone of a noble monument of enterprise and industry, which does credit alike to the Surgeon-General's Office of the U. S. Army, to its collaborators, principal among whom stands Dr. John S. Billings, and to the American medical profession. In it are contained 12,759 author-titles, representing 4857 volumes and 11,613 pamphlets; besides 8312 sub-titles of separate books and pamphlets, and 13,280 of articles and periodicals. The announcement is made that the manuscript of a second series, including all the titles of books and articles received too late for insertion in the series just ended, has been prepared, and will probably make five printed volumes of the same size and style as those constituting the first series. The appropriation for the first volume of the second series has already been granted by Congress, and the manuscript for the first volume is nearly ready for the press. It is interesting to note that the total 16 volumes of the *Index-Catalogue* contain of author-titles 413,531: 176,364 titles, 85,663 volumes, 151,504 pamphlets; and of sub-titles 679,669: 168,557 book-titles, 511,112 sub-titles; and portraits 4335. Dr. Billings concludes as follows in the letter accompanying his presentation of the 16th volume to the Surgeon-General: "This is probably the last volume of the *Index-Catalogue* which will be issued under my personal supervision, and, in closing the work, I can only say that it has been to me a 'labor of love,' and that I am very thankful that I have been allowed to complete it, so far as the first series is concerned." The medical profession certainly owes Dr. Billings and his collaborators a profound debt of gratitude for this splendid piece ot work.

—

EXERCISE AND FOOD FOR PULMONARY INVALIDS. By CHARLES DENISON, A.M., M.D., Professor of Diseases of the Chest and of Climatology, University of Denver; Ex-President American Climatological Association. Denver: The Chain & Hardy Co., 1895.

"PULMONARY invalid" can hardly be considered a term to delight the lexicographer, but it is not much worse than the French *poitrinaire*. The author's pathology is not accurate, but his therapeutic aim, the invigoration of the patient, is the true one. On the whole, his advice as to food and exercise is sound, but like many modern writers he seems to think that the science of medicine began yesterday, and while his own work is creditable enough he either neglects to acknowledge his indebtedness to those who have suggested it or carelessly makes acknowledgment to the wrong person.

Thus he seems not to know that what he calls the "Howe tube" is the device of Ramadge, though this information is readily accessible, not only in Ramadge's own works, which are perhaps too ancient to be referred to in these progressive times, but in a very recent encyclopedic article. The "manometer" described as the author's device is a useful instrument, and ought to be generally employed, but it should be credited to Waldenburg, who devised and described it twenty years ago under the name of "pneumatometer." In this country Elsberg and others have written of it, giving proper credit to Waldenburg. The author's "Inhaler and Exhaler" is a useful modification of the instrument of an American observer, described some years ago as "Pneumatic Resistance-Valves." His "Emphysema-Jacket" is ingenious, largely original, and seems to be good in theory. We should be glad to know more of its practical utility. The benefits of inhalations of compressed air and of exhalations into rarefied air should be, but are not, mentioned. The author's diet-lists are useful and the brochure as a whole should do good.

Physical and Natural Therapeutics; the Remedial Uses of Atmospheric Pressure, Climate, Heat and Cold, Hydrotherapeutic Measures, Mineral Waters, and Electricity. By George Hayem, M.D., Professor of Clinical Medicine in the Faculty of Medicine of Paris. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With 113 illustrations. Philadelphia: Lea Brothers & Co., 1895.

This is a work of 419 pages, 200 of which are given over to the consideration of electricity. Climate, mineral waters, thermic agents, and atmospheric pressure are some of the other physical and natural agents treated of. The various European climatic resorts are described at length, and in a separate chapter the editor briefly mentions the more important American resorts.

The chapter on Hydrotherapeutics is short and fails to mention the use of lavage for stomach-diseases or the cold bath in pneumonia; the Brand method in typhoid is described in twenty lines added by the editor.

Other important physical agents not considered in the book are massage, gymnastics, and exercise.

The part on electricity is quite complete, containing descriptions of the various apparatus in use, and giving in detail the facts of electro-physics and electro-physiology, as well as the manner of their application in the treatment of disease. This section has been largely added to by the editor, and contains all that is new on the subject.

Modern Medicine and Homeopathy. Two addresses by John B. Roberts, A.M., M.D. Points of Similarity Between Us and Homeopathic Physicians. The Present Attitude of Modern Medicine and Physicians Toward Homeopathy. Philadelphia: The Edwards & Docker Co., 1895.

The author states in his preface that a desire to look at homeopathy without prejudice caused him "to devote several years to the study of books and journals written and edited by homeopathic physicians. Two presidential addresses were written as a result of this investigation. These are now reprinted, in the hope that some members of the medical profession may find in them reasons for abandoning a sectarian name, and that others may see the impropriety and folly of proscribing those whose opinions conflict with their own." As a matter of fact, nobody does "proscribe those whose opinions conflict with his own;" but Dr. Roberts is perfectly sincere in his belief that the interests of science and humanity will be best served and the folly of homeopathy made indubitably evident when physicians cease to draw any distinction between those educated men who term themselves homeopathic physicians but are not, and other educated men who refuse to accept sectarian designation. No one could demonstrate more forcibly than Dr. Roberts has done the essential and irreconcilable differences between scientific, progressive medicine and unscientific, irrational, fossilized sectarian dogma. No one could show more clearly that nearly all of those who term themselves "homeopaths" have ceased to practise homeopathy. The conclusion which he draws from these correct premises is so evidently a *non-sequitur* that it is useless to enter upon criticism.

The Diseases and Deformities of the Fetus: An Attempt Toward a System of Antenatal Pathology. Vol. II. Congenital Diseases of the Subcutaneous Tissue and Skin. By J. W. Ballantyne, M.D., F.R.C.P.E., F.R.S.E. Pp. 264. Edinburgh: Oliver & Boyd, 1895.

It is with pleasure that we greet the second volume of this truly unique and valuable work. Dr. Ballantyne, than whom there is none better able to cope with the intricacies of his difficult subject, has undertaken a task of Herculean proportions, but he has shown himself thoroughly able to carry through what he has begun. The cordial reception that was extended the first volume, two-and-a-half years ago, must be repeated to this, its admirable successor. The subject-matter now considered includes the pathologic states of the cutaneous and subcutaneous tissues of the fetus, and more can be learned from a brief perusal of the pages of this volume than from hours of search through the tomes and magazines of a large medical library. The literature has been thoroughly culled, as the long bibliographic lists attest. The plates and illustrations are interesting and valuable, and the arrangement scientific and satisfactory. The author pays a handsome tribute to the recent work of Unna on the "Histopathologie der Hautkrankheiten," and states his preference for Unna's classification of cutaneous diseases. The book should occupy a place on the book-shelf of every obstetrician.

Text-Book of Operative Surgery. By Dr. Theodor Kocher, Professor of Surgery and Director of the Surgical Clinic in the University of Bern. Translated with special authority of the author from the second revised and enlarged German edition. By Harold J. Stiles, M.B., F.R.C.S. Edin. Royal 8vo, pp. 303. London: Adam and Charles Black, 1895.

This work is essentially a record of the author's experience and of his individual methods chosen as a result thereof, ably translated, by special authority, from

the second enlarged and revised German edition. As compared with the first edition we find the work completely recast, greatly extended, and almost entirely re-illustrated. The plates are triumphs of artistic anatomic representation and a very valuable feature of the composition. The volume must greatly add to Kocher's reputation and raise him nearer to the position of the first surgeon of Europe, and, in view of his enormous experience, will be accepted as a reliable guide by operators.

Many of the technical descriptions have been taken from dictation during operations on the living subject, while others are derived from demonstrations on the cadaver. The illustrations have all been executed directly from these latter operations. Nearly all of the most recent operative procedures are described and depicted in this greatly improved edition. As a whole, the work is superb; a valuable addition to surgical literature; a monument to precision; a splendid reflection of the very best modern operative technic. Preceding the description of special operations are sections devoted to general considerations, anesthesia, treatment of wounds, and direction of incision. The absence of an index is to be regretted. The omission is inexcusable.

Transactions of the Medical Society of the State of Pennsylvania, at its Forty-fifth Annual Session, held at Chambersburg, 1895. Vol. xxvi. Published by the Society. Pp. 504. Philadelphia: The Edwards & Docker Co., printers, 1895.

The Committee of Publication of the Medical Society of the State of Pennsylvania deserves great credit for the very early appearance of this volume, which contains fifty-four papers, not including the various special addresses.

The address of the President, John B. Roberts, is in the form of an essay, entitled "The Present Attitude of Physicians and Modern Medicine Toward Homeopathy." This address ought to be published by the Society for free and general distribution, as it is intended to acquaint the laity with the facts of homeopathic quackery.

The address in hygiene, by H. H. Longsdorff, is a scholarly paper, calling attention to moral deterioration as a cause of racial and national decline.

Among the papers worthy of mention as representing original work, we find the following: "A Contribution to the Study of Deaf-mutism," by Arthur A. Bliss; "Laryngeal Diphtheria," by Edwin Rosenthal; "The Toxin-treatment of Malignant Tumors," by John B. Roberts; "The Ligation of Arteries in Malignant Disease," by John H. Packard; "Movable Kidney," by Charles P. Noble; and "Dangers in the Use of Vaccine-virus," by H. M. Alexander. A list of the regular physicians licensed by the new Board of Examiners up to April 10, 1895, and the Code of Ethics of the American Medical Association are appended.

Transactions of the Medical Society of the State of New York for the Year 1895. Published by the Society.

This volume of 500 pages contains thirty-eight communications, together with reports of officers, and a chronologic list of the members of the Society since its organization in 1807. Excellent illustrations accompany several of the papers. Prince A. Morrow and J. A. Fordyce, in connection with their communications, gave an exhibition of lantern-slides, and some of these are reproduced in the report. The anniversary-address by George H. Fox, entitled "Credulity and Skepticism in Modern Medicine," contains sound sentiments and shows clearly how the medical literature of the day tends to produce skepticism among the members of the profession.

The report of the State Board of Medical Examiners states that the number of physicians locating annually in the State of New York has been reduced one-half since the institution of State examinations; the board is in favor of a full high-school training as a preliminary requisite to matriculation.

On Some Symptoms Which Simulate Disease of the Pelvic Organs in Women, and Their Treatment by Allopiestomyokinetics (Massage) and by Autopiestomyokinetics (Self-movements of Muscles Under Pressure). By A. Rabagliati, M.A., F.R.C.S.Ed. Pp. 77. New York: William Wood & Co., 1895.

In this volume Dr. Rabagliati touches upon some of the many curious manifestations of that deplorable condition, neurasthenia, which unfortunately has become so common in a certain class of women. After a comprehensive study of these puzzling cases, he has at length come to the conclusion that even when the nervous system is at fault the disease does not primarily reside there. He believes that the trouble lies rather in the muscles or muscle-sheaths, and that, along with them, the nerve-sheaths, the periosteum or bone-sheaths, and many of the joints, particularly the false joints, are so frequently affected that the disease of these fibrous tissues is the main immediate element to be considered in the cases presenting themselves for treatment. Hence he has elaborated a system of kinetics, to be carried out by the physician, or by a masseuse under the former's directions and by the patient herself, whereby this fibrous disease may be counteracted. The book is eminently practical, and treats of a subject that is now of great interest. The original illustrations supplement the text in a clear and interesting manner, and have evidently been executed with care.

NEWS ITEMS.

The Southern Surgical and Gynecological Association will hold its eighth annual meeting at the Hotel Shoreham, Washington, D. C., on November 12, 13, and 14, 1895. The following is the program:

Address of Welcome, by H. C. Busey, M.D., Washington, D. C. Response to Address of Welcome, by Louis McLane Tiffany, M.D., President. A Case of Gunshot-Wound of the Brain, Removal of Bullet, Recovery, by W. E. Parker, M.D., New Orleans, La. Personal Experience in the Treatment of Stab-Wounds of the Intestines and Peritoneum, by Bedford Brown, M.D., Alexandria, Va. Report of Five Cases in Abdominal Surgery in which the Murphy Button was Applied, by A. Vander Veer, M.D., Albany, N. Y. Resection and Intestinal Anastomosis, by H. Horace Grant, M.D., Louisville, Ky. Cecal Hernia, with Report of Cases, by

Obituary.—Second-Lieutenant Leonard M. Prince, Second Infantry, United States Army, died at the Presbyterian Hospital, in Chicago, on Friday last, from injuries received at Annapolis in 1892 in one of the annual games formerly played between the cadets of the United States Military Academy and the Naval Academy. In a scrimmage for the ball an unknown player fell on the small of Lieutenant Prince's back with both knees. When the ball was put in play again it was discovered that Prince could not rise, and he was carried off the field. An examination showed that two floating ribs on his left side were broken and internal injuries inflicted. He was sick for some time, but after he had been graduated it was thought all danger from his injuries was past. While exercising in his post-gymnasium at Fort Omaha 8 months ago, however, he again experienced the old pains. He returned to his home in Bloomington, Ill., where the family-physician pronounced his sickness a result of the injuries received in the football game of 1892. During his career as an army-officer Lieutenant Prince was the recognized leader of his regiment in everything pertaining to athletics. He designed the regimental gymnasium at Fort Omaha, and was instructor in athletics. He leaves a widow and a two weeks-old child.—*N. Y. Herald.*

The Revival of the Index Medicus.—We are advised of the following list of subscribers in addition to those previously published:

Dr. I. E. Atkinson, Baltimore.
Dr. Frank Fremont-Smith, Bar Harbor.
Doliber, Goodale & Co., Boston.
Dr. Charles G. Stockton, Buffalo.
Dr. Gustave Fütterer, Chicago.
Dr. Werth, Kiel, Germany.
Philadelphia Neurological Society.
Dr. Adolph Koenig, Pittsburg.
Dr. Samuel H. Friend, Milwaukee.
Dr. J. H. Bryan, Washington.
Medical Society, District of Columbia.
Dr. G. R. Fowler, Brooklyn.
Dr. J. W. Brannan, New York.
Hoagland Physiologic Laboratory, Brooklyn.
Dr. Martin Deschere, New York.

The Tri-state Medical Society of Iowa, Illinois, and Missouri at its last meeting elected the following officers: *President*, Dr. Robert H. Babcock, Chicago; *First Vice-President*, Dr. A. H. Cordier, Kansas City; *Second Vice-President*, Dr. W. A. Todd, Chariton, Iowa; *Treasurer*, Dr. C. S. Chase, Waterloo, Iowa; *Secretary*, Dr. G. W. Cale, St. Louis. The next meeting will be held in Chicago the first Tuesday, Wednesday, and Thursday in April, 1896.

The William F. Jenks Memorial Prize of the College of Physicians of Philadelphia for 1895 has been awarded to Dr. Abram Brothers, of New York, for an essay on "Infant-mortality During Labor, and its Prevention."

The Alvarenga Prize of the College of Physicians of Philadelphia for 1895 has been awarded to Dr. Guy Hinsdale, of Philadelphia, for an essay on "Syringomyelia."

Prof. Edward G. Conklin, of the Northwestern University, has been elected Professor of Comparative Embryology, to succeed the late Dr. John Ryder.

Dr. Franklin Bechtel Gilbert, a retired physician and veteran of the Civil War, died November 4th, at the age of 69 years.

Dr. Edward C. Kirk has been elected Professor of Clinical Dentistry.

Dr. Harrison Allen has been elected Emeritus Professor of Comparative Anatomy in the University of Pennsylvania.

ORIGINAL ARTICLES.

REPORT OF 111 ADDITIONAL CASES OPERATED UPON WITH THE ANASTOMOSIS-BUTTON.

BY J. B. MURPHY, M.D.,

OF CHICAGO;

PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO AND PRESIDENT OF THE MEDICAL STAFF OF COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXIAN BROTHERS' HOSPITAL; PRESIDENT OF THE NATIONAL ASSOCIATION OF RAILWAY SURGEONS; FELLOW OF THE CHICAGO ACADEMY OF MEDICINE, ETC.

THIS paper presents in tabulated form 111 additional cases operated upon with the anastomosis-button since the publication of my article, "Analysis of Cases Operated on with the Aid of the Murphy-Button up to the Present Time." (THE MEDICAL NEWS, February 9, 1895.) These were gathered from a cursory examination of the current medical literature and from correspondence. They do not include a number of cases reported to me verbally at medical meetings and in my intercourse with medical *confrères*, in regard to which I lack data sufficient to make them available for publication. Beside presenting the tabulated list, this paper gives a brief analysis of the various groups and calls attention to some of the more instructive cases, making such deductions as would seem legitimate from the results obtained.

GASTROENTEROSTOMY FOR MALIGNANT DISEASE. *By Lateral Apposition.* This operation has been performed in 61 cases altogether, with 28 deaths. Of the 34 new cases, 7 died from exhaustion and shock, while the result of the operative technic, as far as we can learn from the reports, was perfect. This further emphasizes the position taken in a former paper that gastroenterostomy in extremely emaciated and cachectic patients is not a justifiable or, at least, an expedient procedure. It can hardly be expected to prolong life or materially alleviate the condition of the patient. Six of the whole number died from peritonitis; of these, in Case 24 there was perfect union at the seat of approximation, showing that the infection existed from the time of the operation and was not due to any defect in the method used. In two of these cases there was an imperfect approximation of the two sections of the button; in a third the smallest-sized button was employed and the thickened wall of the stomach could not be retained within its grasp. An explanation of the imperfect closure of the button was given by both operators, viz., that sufficient pressure was not employed. The case reported by Zielewicz, who was so hasty to draw conclusions, was thoroughly analyzed by Dr. Willy Meyer[1] and Alex. C. Wiener.[2] The report of the autopsy did not state that there were any evidences of union in any part of the approximated surfaces, but I cannot believe that with a properly closed button the wall of the small intestine will stand the pressure for several days without atrophy at some points of its circumference; and if the surfaces were in apposition for seven days there should have been union, unless infection existed. The operation by other methods shows that union can occur within forty-eight hours, and in the dog the button has frequently been voided as early as the third day. Moreover, eating half a pound of "leberwurst" at one meal was rather an heroic test for a seven-day union.

In one case of peritonitis death occurred on the eighth day, with carcinomatous growth involving the whole stomach. One death that occurred on the second day was attributed simply to the generally bad condition of the patient, and in still another no cause whatever was stated. One death was due to a continuation of a hemorrhage that had persisted for weeks before the operation.

In four cases the button was found in the stomach. This is not surprising when we consider the enormous gastric dilatation that accompanies pyloric obstruction. The danger from this occurrence I consider slight, as when the stomach regains its tone the button is likely to be forced out through the enlarged opening that has been found in these cases. The tolerance of the stomach to foreign bodies is well demonstrated by occasional reports of autopsies at insane-asylums, and the largest-sized button is not in itself a specially dangerous or toxic substance.[3] In future cases of gastroenterostomy I would advise the use of the oblong button, as its shape would favor its early expulsion. I think the operation should be reserved for cases of non-malignant pyloric obstruction and small annular carcinomata without secondary glandular infection. In the first

RESECTION, END-TO-END APPROXIMATION. (METHOD: MURPHY BUTTON.)

No.	Date.	Publication.	Operator.	Diagnosis.	Operation.	Position	Result.	Cause of death.	Remarks.
93	1894 Feb. 4	Col. Climat., Mar. 15, 1895.	Wooding, B. F., Trinidad, Col.	Bullet-wound.	Resection, 4 inches.	E. E.	D.	Operated 2 days after injury.	Patient collapsed before operation; death 8 hours after operation. Post-mortem, two perforations not detected.
94	Aug. 19	Col. Climat., Mar. 15, 1895.	Parkhill, C., Denver, Col.	Intestinal obstruction	Lateral approximation.	S. S.	D.	Collapse.	Patient in extreme condition when operated; did not rally from collapse. Carcinoma of hepatic flexure of colon; frequent bowel movements after operation.
95	Oct. 17	Col. Climat., Mar. 15, 1895.	Lymao, C. B., Denver, Col.	Crushing injury of abdomen.	Resection, 2 inches.	E. E.	D.	Shock.	Crushing injury involving the left thigh and left side of abdomen; tissues ecchymotic and emphysematous. Abdomen opened in median line; circumscribed abscess between crest of ilium and last ribs communicated with intestine, evidently result of old intestinal ulceration. Peritonitis (general) present at time of operation. Patient died 1 hour after operation. "The operation was hopeless from the start."
96	Aug. 8	Not published.	Murray, T. J., Butte, Mont.	Strangulated hernia.	Resection, 12 inches.	E. E.	R.	.....	Button No. 3 used; voided 12th day. Strangulation existed 6 days. Fecal matter oozed through wall of strangulated bowel.
97	.....	Lancet, London, April 6, 1895.	Barling, J., Birmingham, Eng.	Strangulated hernia, umbilical.	Resection, 5 inches.	E. E.	R.	....	Button No. 4 used, which passed on 24th day. Uneventful recovery.
98*	Nov. 27 1895	Lancet, London, March 9, 1895.	Bush, J. P., Bristol, Eng.	Strangulated hernia.	Resection, 5 inches.	E. E.	R.	.....	Button voided on 37th day. Patient in excellent condition four months after operation.
99	Jan. 10	Gazette Hebdom., March, 1895.	Villard, E., France.	Strangulated hernia, gangrenous.	Resection, 4 inches.	E. E.	R.	... .	Button voided on 14th day. Uneventful recovery.
100	Feb.	Brit. Med. Journal, April 20, 1895.	Morton, Charles Q., Bristol, England.	Intestinal obstruction (malignant).	Lateral approximation.	S. S.	R.	.....	Approximation of side of ileum to side of colon. Button No. 4 used. Not found up to date of publication. Uneventful recovery.
101	Jan. 29	The Lancet (London).	Lane, J. Ernest, London, England.	Strangulated hernia, 4 days.	Resection, 5 inches.	E. E.	R.	. ...	Button removed from rectum on 19th day. Patient had delirium tremens, diarrhea, and infection from gangrene in shock following operation, still made an excellent recovery.
102	Feb. 25	The Lancet (London).	Lane, J. Ernest, London, England.	Strangulated hernia, fem., 7 days.	Resection, 7 inches.	E. E.	D.	Shock, 30 hours.	Patient did not rally after operation. Necropsy: Perfect approximation, some adhesions, no peritonitis.
103	June	Not published.	Beckett, W. W. and Haynes, Fr. C., Los Angeles, Cal.	Strangulated hernia.	Resection, 6 inches.	E. E.	R.	.....	Splendid recovery; button passed on 21st day.
104	Jan. 4	The Lancet (London).	Owen, Edmund, London, England.	Carcinoma of ascending colon.	Resection.	E. E.	D.	.....	Time from operation to death not given; gas escaped from wound. Necropsy: Perforation found on distal side of button, where thin bowel pressed against side of button.
105	1895	Not published.	Wittwer, H. R., Chicago.	Abscess following oöphorectomy, rupture of bowel.	Resection, 3 inches.	E. E.	D.	Peritonitis.	While removing an abscess-sac which ruptured into peritoneal cavity bowel was torn. Death from peritonitis in 48 hours. Anastomosis completed in 13 minutes. Necropsy: Button in position; union perfect, water-tight.
106	1894 Aug. 18	" "	Silver, H. M., New York.	Strangulated femoral hernia.	Resection, 3 inches.	E. E.	R.	.....	Button voided on 8th day; not one disagreeable symptom after operation.
107	1895 April 5	" "	Stewart, J. T., Los Angeles.	Carcinoma of cecum and colon.	Resection, 12 inches.	E. E.	R.	....	Cecum with ascending colon resected; end of ileum joined to end of ascending colon; button voided on 16th day.
108	Jan. 11	" "	Kime, J. W., Fort Dodge, Ia.	Strangulated perforated hernia.	Resection.	E. E.	D.	Shock, 2 hours.	Patient was operated on for strangulated hernia six days previously and gangrenous bowel returned into the abdomen; it perforated in many places, producing a fatal peritonitis, which was present at time of resection.
109	1894 Feb. 3	" "	Vander Veer, A., Albany, N. Y.	Stricture of sigmoid.	Resection, 4 inches.	E. E.	R.	.....	When end of rectum was united to sigmoid I recognized that there was too much pressure of the bowel over crest of sacrum, and that obstruction might result from the pressure. On third day patient presented all the marked symptoms of obstruction of bowel, though gas had been passed per rectum up to that time. Left inguinal enterostomy of small intestine; free discharge; death from exhaustion in 11 days. Necropsy: Ends of intestine found united; button loose in lower portion of rectum. Patient exhausted before operation.
110	1895 Jan. 4	" "	Vander Veer A., Albany, N. Y.	Multilocular ovarian cyst.	Resection, 6 inches.	E. E.	R.	.....	Six inches of ileum imbedded in papillomatous growth; it was resected and ends united with Murphy button, making operation exceedingly simple. Button not found, but on 19th day three evacuations were not examined. This patient made a remarkable recovery after severe nervous symptoms; now in absolute health; gained 20 pounds.

* No. 98 duplicated, same as No. 120.

111	May 30	Not published.	Peck, George S., Youngstown, O.	Fecal fistula, large.	Resection ileum, 4 inches.	E. E.	D.	Septic peritonitis, 28 hrs.	Autopsy revealed a large collection of chocolate-colored fluid in peritoneal cavity. Button in perfect position; no leakage.
112	July 23	" "	Peck, George S., Youngstown, O.	Appendicitis, gangrene.	Resection, 3 inches.	E. E.	R.	.....	Ileum found gangrenous and perforated, requiring resection. Button passed on 13th day.
113	1895	Belgian Surg. Soc	Rouchet, P., Antwerp, Belg.	Gangrenous hernia.	Resection.	E. E.	R.	.....	The number of inches resected was not given in letter.
114	1894 Dec. 6	The Lancet, Lond., May 11, 1895.	Spencer, W. G., London.	Gangrenous hernia.	Resection.	E. E.	D.	Collapse, 12 hrs.	Patient operated on December 2, 1894, for strangulated femoral herbia; Littré; with gangrene of diverticulum. After operation gangrene spread to intestine, and three days later patient vomited coffee-colored fecal matter; this continued until next day, when a second operation was performed. Bowel found gaogrenous and resected. Gangrenous bowel torn during operation; fecal extravasation. Death 12 hours later. Necropsy: Peritoneum dark-red hue covered with yellow lymph, most abundant in right iliac regioo.
115	1895 Feb.	Not published.	McGuire, Stuart, Richmond, Va.	Bullet-wound.	Resection (double).	E. E.	D.	Shock, 18 hours.	In one place of 22 inches there were 11 perforations; resected; end-to-end union. Five feet from this place there were two perforations requiring second resection. Necropsy: No peritonitis; the button held bowel in perfect apposition.
116	Apr 13	" "	McGuire, Stuart, Richmond, Va.	Strangulated hernia, umb.	Resection, 16 inches.	E. E.	R.	.....	Uninterrupted recovery. Button was found in the rectum on 22d day.
117	?	Med. News, April 13, 1895.	Canthorn, F., Portland, Ore.	Tumor of mesentery.	Resection, 48 inches.	E. E.	R.	.....	Patient did very well for two months, when he began to suffer from borborygmus, colicky pains, and diarrhea. This continued for a long time, when he had a perforation of bowel from button. I feel that I should have operated again for the symptoms.
118	? 1895	Not published.	Dunn, J. H., Minneapolis, Minn	Carcinoma caput coli.	S. S. approximation.	E. E.	R.	.....	Fistula at seat of union producing adhesion of adjacent coil, causing retention of button.
119	June 1	" "	Frederick, Buffalo, N.Y.; Cotter, J. C., Meadville, Pa.	Large vaginal intestinal fistula.	Resection.	E. S.	R.	.....	End of bowel liberated from vagina, liberated end sutured. Proximal end joined to side of distal with button. Button found in rectum on 11th day. Perfect recovery.
120	1894 Nov. 17	The Lancet, Lond., April 6, 1895.	Bush, Paul J., Bristol, England.	Strangulated hernia (gangrene).	Resection.	E. E.	R.	.....	Large-sized button. Patient had severe pneumonia following operation. On January 4, 1895, button passed without pain, imbedded in a large mass of feces. Patient under observation for four months; at the end of this time in excellent health.
121	1895 Feb.	Not published.	Hill, William, Bloomington, Ill.	Typhoid-perforation.	Resection, 1 inch.	E. E.	R.	.....	Button voided on 17th day. Perforation occurred in 6th week of recurrent typhoid. So much of wall of bowel involved in ulcer that it could not be sutured. Operation twelve hours after first symptom of perforation. Patient, boy 13 years old. Excellent recovery.
122	.....	Brit. Med. Journal, Feb. 23, 1895.	Banks, W. Mitchell,	Fibrous tumor of ileum.	Resection.	E. E.	D.	Exhaustion, 30 hours.	Patient in poor condition; did not rally from operation; bowel soundly glued together, except at one point a slight leakage; no peritonitis.

class all of the advantages of pylorectomy are obtained with a minimum of danger; in the second, the patient's condition is greatly improved and life is materially prolonged.

Conclusions. 1. Gastroenterostomy should never be performed in extremely cachectic patients. There is nothing to gain and much to lose.

2. The posterior wall of the stomach is the preferable locality for the approximation.

3. Supporting sutures, outside of the button, are not necessary, except for the relief of tension.

4. The peritoneum of the stomach should be scarified at the point of approximation, as union is thus hastened.

PYLORECTOMY. We have reports of 7 pylorectomies, with 5 recoveries and 2 deaths. One patient of Dr. H. R. Wittwer died five days after the operation, which lasted forty minutes. The autopsy showed a perfect approximation and no peritonitis. Death occurred from exhaustion. Malthe seems to attribute his ill-success in one case to imperfect suturing posteriorly with resulting fistula and peritonitis. The patient survived, however, for three weeks.

This operation is one that should be strongly commended in all cases of incipient carcinoma of the pylorus. With this operation the danger is not great, the time occupied being greatly reduced by the use of the button to approximate the duodenum and posterior wall of the stomach.

Dr. A. H. Ferguson, of this city, was the first to operate with the anastomosis button, July 25, 1893; the patient is still living and in excellent health. Diagnosis of carcinoma of the pylorus should be made long before any tumor is palpable in the epigastrium, and the earlier the operation the better the prognosis, immediate and remote.

CHOLECYSTDUODENOSTOMY. Fifty-one cases are reported, with two deaths, one of these on the seventh day from continued hemorrhage from a laceration of the liver produced in separating adhesions. The other death was from peritonitis due to the escape of septic contents of the gall-bladder into the abdominal cavity during the operation. Death occurred on the fourth day.

The indications for this operation are (1) permanent obstruction of the cystic duct, (2) obstruction of the common duct, (3) cases of septic cholecystitis when a long period of continuous drainage is desirable, (4) cases of fistula of the gall-bladder when the patient is becoming emaciated from loss of bile. The later operations have included the simultaneous removal of the gall-stones, though I had not found that allowing the gall-stones to remain and pass with the button interfered in any way with the favorable progress of the case. It has certainly not been my experience that allowing them to remain in the gall-bladder in cholecystenterostomy is the source of danger that certain operators and theorists in gall-tract surgery would have us believe. In cases of long-continued and severe jaundice all prolonged and extensive operations should be avoided, as these patients withstand the depressing effect poorly and frequently succumb to uremia. This is well demonstrated by a comparison of the statistics of the operations of cholecystostomy and cholecystectomy, and it is also further shown by the results obtained in cholecystenterostomy for malignant disease, when we have in addition to cholemia the malignant cachexia. Operations under such existing conditions are practically hopeless. There were 12 operations of this kind, with 10 deaths. In only 2 of these was there a failure of union, and in both the tissues were so friable that the button tore through. The tendency to general subcutaneous and submucous hemorrhage, as well as to bleeding from local lacerations, is very marked. The drainage-tube-button has been used to advantage in cases of contracted gall-bladder in which it was impossible to suture this viscus to the abdominal wall.

INTESTINAL APPROXIMATION. While the anastomosis-button was originally devised for the operation of cholecystenterostomy, for which all admit that it is an ideal apparatus, still its greatest field of practical usefulness has been in the surgery of the intestines. In the analysis of the operations on the intestine, the special pathologic conditions and the general state of the patient at the time of operating must be taken into consideration in order to properly estimate the merits of the surgical procedure. The intrinsic dangers of the lesions in this class of cases will always insure a considerable mortality, certainly until diagnosticians are more accurate in their art and surgeons are more prompt in their action.

The operations on the intestines are here divided into the following classes: (1) Resections of the bowel for gangrene: *a*, for internal obstruction; *b*, for hernia; (2) resection of the bowel for the cure of fecal fistula; (3) resections for internal obstructions other than malignant disease; (4) resections for malignant growths; (5) resections for perforations of the intestine, traumatic or otherwise; (6) resection of the rectum; (7) Bacon's operation.

The resections for gangrene, internal and external, including both large and small intestine, number 34, with 8 deaths, or very nearly 24 per cent. There were 15 cases of resection for the relief of fecal fistula, with 12 recoveries and 3 deaths. In one of these latter (No. 128) death occurred from collapse; the intestinal wall was enormously thickened and very friable, and in the manipulations it was impossible to properly close the button; a fissure was left and closed by suture. The other two cases both died of peritonitis. In No. 129 the inflammation

of the peritoneum existed at the time of operation, and in No. 111 the patient died 28 hours after the operation from septic peritonitis, but with the button in perfect position and without leakage. Dr. Peck kindly sent me the specimen for examination.

Resections of the bowel for obstruction from non-malignant disease number altogether 53, with 47 recoveries and 6 deaths, a mortality of about 11 per cent. If to these be added the 7 cases of Dr. Joseph Price, we have a total of 60 cases, with 7 deaths. To this also may be added 6 lateral approximations, previously reported, making a total of 66, with 7 deaths, a mortality-percentage of about 10 per cent.

The resections of the bowel for malignant disease show a larger mortality than do operations for malignant disease elsewhere in the body. There was a total of 41 operations, with 26 recoveries, and 15 deaths, a mortality of 37 per cent.

RESECTIONS FOR PERFORATIONS OF THE INTESTINES, TRAUMATIC AND PATHOLOGIC. The mortality in the cases operated on for perforations, both for gunshot-wounds, perforating ulcers, and laceration of the bowels has always been very great. The danger is not in the operation, but in the pathologic conditions produced by the lesion. Leube, in his collection of 322 cases, found that when the operation was performed within 12 hours after the injury, the mortality was 58.2 per cent.; if later than 12 hours, the mortality was 79.5 per cent. These statistics emphasize most forcibly the necessity of early operation in such cases. With bullet-wounds of the abdomen, there are the collapsed condition of the patient, the profuse hemorrhage, the shock to the nervous system, all contributing to increase the mortality. In operations for bullet-wounds, evisceration should never be practised; the intestine should be carefully examined from one end to the other without having more than one foot of their length exposed outside of the abdomen at any one time. Every opening should be clamped with forceps as soon as discovered and the uninjured portions immediately returned. The number of perforations made by one bullet ranges from 1 to 18. The openings in the small intestines, as a rule, are in close proximity to each other, and many may be included in a single resection of 2 or 3 feet. The perforation in the colon may be a long distance, by way of the canal, from those in the small intestine. The median incision is most practicable and available for wounds in the small intestine, the lateral incision for those of the cecum and sigmoid. An approximately accurate estimate of the position of the perforations can be made by noting the track of the bullet, and the bullet itself may be located by the ingenious telephonic probe of Dr. Girdner, of New York. Double resections may be made and two buttons used, as illustrated by the cases of Dr. R. R. Williams, Dr. F. H. Wiggins, and Dr. Stuart McGuire.

In this connection I desire to mention particularly a very interesting case reported to me by Dr. Wm. Hill, of Bloomington, Ill.:

The patient was a male, aged 13, in the sixth week of a recurrent typhoid, who was attacked with sudden abdominal pain, nausea, vomiting, and tenderness in the right iliac region. When seen by Dr. Hill, twelve hours later, the abdomen was tympanitic, the patient's pulse good, the temperature about 102°. The diagnosis was perforation. Immediate celiotomy was undertaken twelve hours after onset of symptoms. The perforation was located; there was considerable peritonitis. So much of the circumference of the bowel was involved in the ulcer that a resection was made, with end-to-end approximation with button No. 3. Recovery was uneventful. The button was voided on the seventeenth day.

(To be continued.)

FOOD-INFECTION WITH TOXICOGENIC GERMS.

BY VICTOR C. VAUGHAN, M.D.,
PROFESSOR OF HYGIENE AND DEAN OF THE DEPARTMENT OF MEDICINE AND SURGERY IN MICHIGAN UNIVERSITY,
AND
GEORGE D. PERKINS, M.D.,
OF ANN ARBOR, MICH.

WITHIN recent years there has apparently been a great increase in the number of instances of food-poisoning. This increase has been partly real and partly only apparent. The actual increase has been due to the larger consumption of preserved foods and the wider distribution of food from a given point. When we recognize the facts that the scientific principles of bacteriology are involved in the preparation of every can of preserved food and that this work is done wholly by those who are grossly ignorant of these principles, we can only wonder that harm does not come to the consumer more frequently than it does. Moreover, diseased and damaged articles of food can be worked in preserved preparations and sold as prime goods when they could not be so disposed of otherwise. We do not claim that this is a fraud frequently practised, but that it has been occasionally resorted to both in this country and in Europe has been abundantly demonstrated.

It is not our purpose in this paper to discuss the use of tuberculous meat and milk or of any other food invaded by specific infection; but we wish to give our attention to those cases of food-poisoning in which the infecting agent is a saprophytic poison-producing microorganism.

The apparent increase in the number of instances of this kind is due to the fact that the medical profession has but recently learned to recognize this form of food-infection as a cause of illness, or, at least, has been in the possession of the knowledge necessary to convert suspicion into demonstration.

Only a few years ago we were seeking for the cause of the summer diarrheas of infancy in mysterious telluric and meteorologic conditions, but now we know that these diseases are solely due to infected, and consequently poisonous, food. Formerly many cases of food-poisoning were supposed to be due to the accidental or criminal addition of some metallic or vegetable poison to the food, and unjust accusation, possibly in some instances unjust punishment, has resulted. Now we know that not only the symptoms of gastrointestinal irritant, inorganic poisons, but those of typhoid fever and typhus fever, scarlet fever, and other acute exanthemata, and even those of pneumonia, may be closely simulated by the symptoms induced by infected foods.

The effects of poisonous foods as gastrointestinal irritants are too well known to demand illustrative examples. The production of a continued fever closely simulating typhoid has been repeatedly observed. The following brief abstract of a case reported by Gaffky will serve as an illustration :

D., the chemist of the Hygienic Institute at Giessen, did not feel well on the morning of October 10th, but in company with assistant B. he visited Frankfort. During the day he had a severe headache, no appetite, and frequent chilly sensations. On returning to Giessen at night he was scarcely able to walk. On the next day he refused all food, was slightly delirious, and had one watery stool. On the 13th his condition showed serious infection. His face was red, his eyes sunken, his temperature 105.2°, and he lay in a half-unconscious state. The tongue was heavily coated ; the abdomen distended and painful on pressure. He had five dark-brown, later greenish, stools. The urine was concentrated and contained 2 per cent. of albumin, as determined by Esbach tubes ; it gave the diazo-reaction and the indican reaction and contained white blood corpuscles and numerous granular casts.

From the 13th to the 17th the patient was stupid, but not delirious. The abdomen was greatly distended and from 20 to 24 stools were passed each day, with great tenesmus. The temperature remained high notwithstanding repeated one-gram doses of antipyrin. Sleep was broken and one gram of sulfonal was given at night. The urine remained as before, and the pulse varied from 92 to 100.

From the 18th to the 20th the mental dulness was less marked. Appetite was somewhat improved and the number of stools decreased to from 8 to 10 in 24 hours. The amount of albumin in the urine was somewhat decreased and microscopic examination showed fatty casts and white blood-corpuscles. Small doses of opium were given by mouth and in suppositories.

On the morning of the 21st hemorrhage from the bowels, about 300 c.c. in amount, occurred. Several doses of opium were given and ice-bags were kept on the abdomen. After the hemorrhage there were three slightly bloody stools. From this time the improvement was slow, but fairly constant. The fever disappeared October 29th.

After recovery, marked anesthesia of the anterior surface of the thigh developed and remained for some weeks, the anesthetic area gradually becoming smaller. The hair fell out, mental activity tired, and the eyes were easily fatigued for some months. Two workers in the same laboratory were affected in the same manner, but less severely. The only food or drink which these three men had in common was some uncooked milk taken on the morning of October 9th. D. ordered the milk sent to the laboratory, drank the greater part of it himself, giving B. a small cupful, and the servant drank a little left by the others. The cow that gave this milk was suffering from a bloody diarrhea. Gaffky found in the stools of the cow and in those of the patients a small highly virulent form of the bacillus coli, and to this he ascribes the ill effects. He supposes that some of the liquid discharges from the cow fell on the udder and thus found its way into the milk.

Gaffky suggests that the epidemic in Christiana in 1888, in which 6000 persons sickened within three weeks, was probably due to milk-infection. Hausemann states that this epidemic was regarded as *morbus sui generis*. It was evidently neither cholera nor typhoid fever. Half of those affected were children, and yet nurslings escaped altogether. However, milk, as an etiologic factor, seems not to have been considered by the attending physicians.

A case of food-poisoning resembling scarlet fever was seen by one of us two years ago and may be briefly reported as follows :

K., a very vigorous man of 34, ate freely of canned salmon. Others at the table with him remarked that the taste of the salmon was peculiar and refrained from eating it. Twelve hours later K. began to suffer from nausea, vomiting, and a griping pain in the abdomen. Eighteen hours after he had eaten the fish, Dr. Vaughan saw him. He was vomiting small quantities of mucus, colored with bile, at frequent intervals. The bowels had not moved and the griping pain continued. He was covered with a scarlatinous rash from head to foot. His pulse was 140, temperature 102°, and respiration shallow and irregular. The stomach and large intestines were washed out thoroughly, and ten grains of calomel, soon followed by twelve ounces of solution of magnesium citrate, were administered, for the purpose of cleansing the small intestines. After these medicines had acted freely, K. began to improve. The next day the rash had disappeared, but the temperature remained above the normal for four or five days, and it was not until a week later that he was able to leave his house. The remainder of the salmon was submitted to various tests. The absence of inorganic poisons was demonstrated. It was found that the subcutaneous injection of twenty drops of the fluid expressed from the salmon caused evident illness and suffering in a white rat. The only germ that could be found either by direct microscopic examination or by the preparation of

plate-cultures was a micrococcus, and this was present in the salmon in great numbers. This germ grew fairly well in beef-tea, but the injection of five c.cm. of beef-tea cultures of different ages failed to affect white rats, kittens, or rabbits. However, this micrococcus when grown for twenty days in a sterilized egg, after Hueppe's method of anaerobic culture, produced a most potent poison. The white of the egg became thin, watery, markedly alkaline, and ten drops sufficed to kill white rats.

The resemblance of the symptoms of food-poisoning in some instances to epidemic pneumonia is well illustrated in the Middlesborough pneumonia-epidemic which has been reported by Ballard and is too well known to require further mention, except to state that 490 deaths resulted.

That Winckel's disease, a septic pneumonia, may be due to infection of the food with the bacillus enteritidis first discovered by Gärtner in poisonous meat has been demonstrated. Lubarsch has reported such a case in an infant.

The stools were greenish and of bad odor. The child became cyanotic and the respiration increased to sixty per minute. Auscultation and percussion were negative in results. The breathing was wholly costal and the abdomen distended. The urine contained neither albumin nor hemoglobin. Postmortem examination showed pneumonia of the left lower lobe, bilateral purulent bronchitis, atelectasis of the right lung, parenchymatous cloudiness of the kidneys, fatty infiltration and engorgement of the liver, and slightly enlarged spleen. All other pathologic conditions were believed to be consequent upon the septic pneumonia. Plates made from the diseased organs developed only the bacillus enteritidis.

It is quite impossible to draw any sharp line between intoxication and infection in the study of the symptoms of food-poisoning. Some of the bacterial poisons are slow in inducing their effects, and even when a germ-free preparation is used in our experiments upon animals, it sometimes happens that many hours elapse before any effects are observed, even in cases ultimately terminating fatally. The relation of the germ to the production of the untoward symptoms may, according to the case, be stated in one or the other of the following ways: (1) The chemic poison is generated only and wholly in the food before it is taken; (2) The infecting organism may begin the elaboration of its poisonous products outside, and continue the same within, the body; (3) The infection may not result in the production of poisons until the food is taken into the body. The first of these conditions is well illustrated by the "Iron Bridge" cases reported by Ballard. The infecting germ would not grow at a temperature above 86°. Of course animal inoculations with this germ were wholly without result, but cultures grown at 60° were markedly poisonous. It is probable that this condition holds good in a larger number of instances than we suspect. The second condition is the one existing in some cases of poisoning with milk and its products. However, in these the infecting microorganisms do not thrive in the body unless they be supplied with the food especially suited for them. The complete withdrawal of milk as a food leads to their speedy disappearance. The violent vomiting and purging which result are curative means and should not be checked unless there be danger of death from exhaustion. The most dangerous cases of cheese-poisoning are those in which vomiting and purging do not occur. Some months ago one of us saw some twenty persons who had been poisoned with cream. All but two were vomiting and purging and complaining most vehemently. These were sure that they would die. The two exceptional ones were uttering no complaints. In fact, they were practically comatose, and thorough washing out of the stomach and intestines was resorted to before they realized that they were in danger.

When the third condition mentioned exists, a true infection results. Such is the case most probably in those instances already cited as resembling typhoid fever and pneumonia.

We have been frequently called upon to examine food suspected of having caused untoward effects, and the method followed in these examinations may be of some interest. Whenever there is the slightest possibility that a metallic poison may be present, tests for the same are made. This is always done with canned foods. However, when a teaspoonful or less of ice-cream causes vomiting and purging, the idea that these effects can be due to zinc sulphate dissolved in the freezer or to artificially prepared vanillin used in flavoring is simply too preposterous to be entertained by anyone acquainted with the quantities of these substances necessary to induce such effects. Ten years ago we went through with all the tests for metallic poisons in many samples of poisonous cheese and ice-cream, but we no longer waste our time in this manner.

The examination of foods for bacterial poisons cannot be made except in a properly equipped bacteriologic laboratory. It is our purpose to merely point out at this time the methods that may be followed. We take it for granted that the one who undertakes work of this kind is already familiar with the ordinary technic of bacteriologic research. The line of procedure will vary somewhat with the kind of food to be examined, the form in which it has been prepared, and the quantity supplied the analyst. All samples should be examined with as little delay as possible after the article has become the object of suspicion. When delay is unavoidable, further bacterial growth should be retarded in the meantime as far as is possible by keeping the suspected article at a low temperature.

Germs not present at the time of the supposed poisoning may be accidentally introduced, or non-toxicogenic bacteria may multiply to such an extent that the detection of the harmful organisms is rendered impossible.

As a rule, the quantity of the food supplied the analyst is not sufficient to allow of the detection or the isolation of the chemic poison directly. To try to find the poison in a few ounces of cheese or a small bit of meat by direct extraction is a task that would be undertaken only by one quite ignorant of the nature of these poisons. In all but exceptional instances in which many pounds of the food are supplied, the portion that reaches the laboratory can only be regarded as the bearer of the germ to the activity of which the poison is due. This germ must be detected, isolated, grown in pure culture, and its toxicogenic properties demonstrated upon lower animals. It should be clearly understood that the most thorough study of the morphologic characteristics of the germ and of the chemic properties of the poison will not suffice without an accompanying determination of the toxicologic action of the cultures. The infectious nature of the bacterium should also be studied.

It should always be borne in mind that the article of food has probably been through several hands before reaching the analyst, some of which may not have been germ-free. In the examination of pieces of meat and cheese, the surface should be sterilized with a broad, heated knife or other piece of iron. It has been shown that bacteria deposited on such surfaces penetrate slowly. Then with other sterilized knives sections should be made and one or more small bits taken from the interior should be placed in sterilized bouillon. Not less than a dozen tubes should be inoculated in this way. Three of these should be grown aerobically at ordinary temperature; three anaerobically at the same temperature; three aerobically at 37°C.; and three anaerobically at 37°C. It is quite essential that all these conditions of growth should be tried. Some of the toxicogenic germs grow best at relatively low temperature, from 20° to 25°C., and fail wholly to develop at 37°C. Others have their optimum growth at the last-mentioned temperature. Some develop only when freely supplied with air, and others only when the air is excluded.

In the examination of liquid and semi-liquid foods, such as milk, custard, cream, broths, and jellies, small bits or a few drops should be placed in sterilized bouillon and grown under the conditions already mentioned.

A growth having appeared in one or more of these tubes, the bacteria should be examined in hanging drops and in stained mounts. If more than one organism be present, plate-cultures should be made and each germ should again be grown under the conditions mentioned.

The infectious character of each organism should be tested on the lower animals: (1) by feeding, (2) by subcutaneous inoculation, (3) by intraperitoneal inoculation, and (4) by intravenous inoculation. The animals generally employed in these experiments are white mice, white rats, guinea-pigs, kittens, and rabbits. A given germ may be toxicogenic to one of these animals and not to the others. Mice and kittens are specially suitable for feeding-experiments. Young kittens are quite susceptible to most of the bacterial poisons found in milk and its products. The quantity of the bouillon-culture, 24 hours old or older, first employed should be relatively large, from one to ten c.cm., according to the animal and the method of infection. If these amounts prove active, smaller quantities should be tried until the limit is reached.

Next, the action of cultures from which the bacteria have been removed by filtration through porcelain should be tested, and, if these prove active, the effect of different degrees of heat on the toxicity of the cultures should be determined.

If by the experiments already mentioned a toxicogenic germ has been discovered, its morphologic, cultural, tinctorial, and pathogenic properties may be studied as thoroughly as the investigator may desire. The study of the bacterial poison may also be carried to the same extent.

The following reports are taken as illustrations of the results obtained by the method given:

Dec. 31st, 1894, Dr. Traver, of Somerset, Mich., was called to see the family of Mr. Van Allen. He found the father, mother, and two children suffering from protracted vomiting and marked exhaustion. There was no fever and no diarrhea. Tyrotoxicon-poisoning was suspected, but inquiry showed that their supper had consisted of bread, butter, tea, dried beef, and raspberry-sauce. There was nothing in the appearance or odor of the meat to cause any suspicion. In fact, it seemed to be of exceptionally good quality. Anaerobic cultures from the interior of the meat were made and developed a bacillus, from two to three times as long as broad, taking the ordinary stains well, motile, with no spore-formation, not liquefying gelatin, but coagulating milk, growing best at the temperature of the body, but developing its poison at ordinary temperature, producing gas abundantly, and pathogenic to white rats, rabbits, and guinea-pigs. Sterilized cultures were also poisonous.

Of a large number of men at a banquet at Sturgis, Mich., April 26, 1894, everyone who ate of the pressed chicken served was made sick. Some who were not at the banquet, but who aided in preparing for it, ate small bits of the chicken, and were also sick. All were attacked, within from two to four hours after eating the chicken, with nausea, violent griping, and purging; many fainted while attempting to arise from bed.

The chickens were killed Tuesday afternoon, picked and left hanging in the market-room (not in a cooling-room) until Wednesday forenoon, when they were drawn and carried to a restaurant and here left in a warm room until Thursday morning, when they were cooked (not very thoroughly), pressed, and served at the banquet that night. Those who ate of the unpressed chicken were also made ill.

The pressed chicken contained two microorganisms, a slender bacillus, from four to five times as long as broad, and a streptococcus. The bacillus was fatal to white rats, guinea-pigs, and rabbits when administered intraperitoneally, intravenously, and subcutaneously. The streptococcus was not fatal when given in pure cultures, but mixed cultures of the two induced death, and in these instances, when administered subcutaneously, in addition to the lesions formed after the employment of pure cultures of the bacillus, there was extensive sloughing. This bacillus is motile, takes the ordinary stains readily, and is decolorized by Gram's method. It grows very slowly at ordinary temperature and rapidly at 98°F. Of two cultures of equal age, one grown at ordinary temperature and the other at 98°F., one c.cm. of the former was necessary to induce death, while one-fourth c.cm. of the other proved fatal. The anaerobic cultures were much more powerful than the aerobic. On gelatin-plates exposed to the air the growth was slow, while on those kept in an atmosphere of hydrogen it was much more rapid. Spores could not be detected. The bacillus coagulates milk and decolorizes litmus-gelatin. On potatoes it forms a dirty, thick, slimy growth. It does not liquefy gelatin and the production of gas was not observed. Streaks on agar-agar are yellowish white, slimy, and with but little tendency to spread. One half c.cm. of a beef-tea culture heated to 140°F. for 30 minutes killed guinea-pigs. One c.cm. heated to 212° F. for 15 minutes failed to kill. Animals inoculated by the methods mentioned showed evidences of abdominal pain within from one to two hours and several were found dead after twelve hours. The abdominal cavity was found filled with a clear fluid, the bloodvessels were much congested, and the peritoneum inflamed. In some instances a bloody fluid was found in the pleural cavity.

CASES ILLUSTRATIVE OF THE CHARACTER AND TREATMENT OF EXOPHTHALMIC GOITER AND ITS CONGENERS.

BY ROBERTS BARTHOLOW, M.D., LL.D.,
OF PHILADELPHIA;
EMERITUS PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN JEFFERSON MEDICAL COLLEGE.

ALTHOUGH the designation exophthalmic goiter expresses two of the more important symptoms of the affection known by this name, it does not indicate the real nature of the malady. The functional disturbances that make up the morbid complex in its fullest form—the quaternary of symptoms—may be wanting in part, and yet the case be typically developed in respect of those that appear. Exophthalmos is rarely entirely absent, but it may be little more than a staring expression without any alteration in the muscular co-ordination of the movements of the eyelids and the globe; the thyroid tumor is hardly discernible sometimes, and the tachycardia and the pulsation of the cervical vessels may not be sufficiently obvious to attract attention. The one condition, however, that serves to unite the various symptoms into an actual complex, is the state of the sympathetic system, or of that part of it having more immediately to do with the circulatory apparatus. The clinical facts as well as the results of treatment show a paretic state of the cervical sympathetic dependent on some change in the thyroid body. The cases to be described exhibit this relation, and the results of treatment based on this conception of their character.

CASE I.—*Curative effect of the treatment as shown in the condition of the patient three years after apparent cure; galvano faradization of the cervical sympathetic and of the pneumogastric nerve; internal use of duboisin, picrotoxins, and iron and manganese, etc.* A young lady of about 20, after a winter of much social excitement, following convalescence from rheumatism, began to fail in strength and became pale and anemic, exercise causing distress of breathing and tumultuous action of the heart. Her eyes put on a brilliant expression, and although naturally prominent, became staring and then protuberant, and a goiter formed on the right side, soon assuming large proportions, and involving the isthmus and also the left lobe. The action of the heart became rapid, remaining above 100 continually, and paroxysms of irregular palpitation occurred at frequent intervals, during which the pulse beat rose to 170 and even higher. Several years before these symptoms appeared she had an attack of acute rheumatism which left the heart damaged, a well-marked mitral murmur continuing afterward, and to this was now added the usual murmurs and venous hum of anemia.

When she presented herself at my office, the case was a typical example of exophthalmic goiter, and no condition was wanting to make the clinical picture complete. The quaternary of symptoms—the exophthalmos, the enlarged thyroid, the tachycardia, the pulsation of the vessels—were all present.

Although changes in the structure of the heart are often present, they are not essential—only functional derangements are necessary to make the case a consistent one.

In considering the question of treatment, I resolved to carry out a plan with which I have usually succeeded—namely, galvano-faradization of the central nervous apparatus—the cervical sympathetic and the pneumogastric. The combined current—stabile—was applied daily from 10 to 15 minutes in duration for a year, excepting intermissions in her

attendance, amounting to about three months of that time.

Considerable skepticism, I am fully aware, exists in respect to the real effects of this central electrization, and, on the other hand, extravagant claims have been put forward. My own experience is favorable to this mode of treatment in cases of the kind in question. It may be assumed that if a remedy on each application manifests a power of a curative kind, although transient in effect, some permanence of result may be expected by persistence in its use. In this case, as in many of a similar character, when I have passed the current from the neck to the epigastrium, there ensued an immediate diminution in the number of the cardiac pulsations, and a distinct rise in the tension of the vascular system. Frequent repetition of the impression presently secured a permanent gain in the condition of the apparatus concerned.

The effects of galvano-faradization were supported by the administration of duboisin, picrotoxin, eserin, arsenic, manganese, and iron. The curative effects of these remedies were enhanced by hygienic measures, including a suitable diet, systematic exercise, and change of scene and associations. The improvement manifest from the outset soon became pronounced, and after some months recovery ensued. By recovery is meant the complete disappearance of all of the symptoms, with restoration of the health. Whether the mitral lesion has, also, disappeared I am unable to say, as I have had no opportunity of ascertaining the state of the heart by physical examination, but, as no rational signs are visible, compensation must, at least, have taken place.

Case II.—*Disturbed circulation of the head and neck; flushing of the face and forehead; fulness of the head and exaggerated intracranial tension; persistent occipital pain; vertigo; staring eyes; rapid circulation.* This patient was a lady of 42, of full habit but not obese, in apparently high health, but suffering from headache, vertigo, occipital pain, and wearing glasses to correct visual troubles which were supposed to cause the head-symptoms. Every mental emotion was immediately represented by a more or less vivid flush extending over face, forehead, neck, and upper part of the chest. With the flush she experienced a sense of tension of the brain, and some occipital pain. Her eyes at the same time became suffused, and had a hot and tensive feeling. Any considerable use of her eyes caused burning, and vision became blurred. A variety of glasses adapted by an accomplished ophthalmologist failed to relieve the ocular symptoms, although persistently tried. Her eyes continued to have a staring expression, and were irritable from use. Her vision was good, barring some astigmatism. The movements of the ocular globe and of the eyelids were coordinate, and there was no ring of sclerotic visible above the iris.

The thyroid body was not enlarged. There were, however, persistent increase of heart-beat above the normal, and more or less constant pulsation of the cervical vessels, with paroxysms of more rapid action. Her morning temperature was 99° F. The tension of the radial and temporal arteries was above normal, but the condition of "rigid arteries" was not the cause; rather an overaction of the vasoconstrictor fibers, supplemented by a more rapid circulation, is, as I conceive, the true explanation.

During the period of suffering from the symptoms described, the eye-strain was supposed to be the real cause. The patient had no uterine disorder, nor, strange to say, had it been suggested to her to submit to some radical gynecologic operation.

The diagnosis lay between eye-strain as a cause of the visual and other disturbances and exophthalmic goiter incompletely developed.

The ocular headaches due to eye-strain arise from errors of refraction, errors of accommodation, and from defects in the extrinsic muscles of the eye. Of the errors of refraction that cause headache, the most common is hypermetropic astigmatism, and next in frequency is hypermetropia, but neither of these seemed to me to be in question here. According to some ophthalmologists, myopic astigmatism is a frequent cause, and even a slight degree of this defect may give rise to severe headaches. When the refraction of the two eyes is unequal hemicrania results, but the pain may also be diffused generally. The errors of accommodation causing headache may be due to paresis or paralysis or spasm of the ciliary muscle, and these conditions may depend on various causes of debility. Errors of the extrinsic ocular muscles, causing headache, are chiefly due to insufficiency of convergence. It is probable that none of these causes of eye-strain, if they existed, remained uncorrected. It may be assumed, therefore, that, as the symptoms persisted, some other influences were in operation, and that other measures beside correction of visual defects were necessary. That state of the vascular system which we find in exophthalmic goiter, in the absence of the exophthalmos and the enlarged thyroid, seemed to me responsible for the headache, the heavy tensive feeling, the occipital pain, the vertigo, and other symptoms.

The results of treatment confirmed this view; in other words, the therapeutic diagnosis harmonized with the results of treatment. The symptoms were promptly relieved by the administration of liquor barii chloridi, five drops every four hours. The high color, which had been constantly present, and the vivid flush, which appeared on every emotion, the staring expression of the eyes, and the tensive headache disappeared, the orderly balance of the circulation being restored. It seems to me, therefore, that the symptom-group manifest in this

case did not originate in any ocular defect, but the supposed eye-strain was one sign of a condition created by a functional derangement of the sympathetic. The study of this and analagous cases has seemed to me to illustrate how similar troubles occur at the climacteric period, and are due, no doubt, to corresponding causes.

CASE III.—*Goiter of several years' standing; persistent weakness and anemia; wasting; pulse habitually rapid, and occasional attacks of palpitation; efficacy of thyroid extract.* This lady, 35 years of age, after her first confinement, experienced an enlargement of the thyroid of the ordinary character. After her second delivery, the growth assumed larger proportions, and now after ten years it is increased somewhat. The right lobe of the gland is the larger, but the isthmus projects forward, and has the elastic condition of a cystic growth. The tumor must, therefore, be regarded as glandular and cystic. Beside the slow increase in size, it has been observed to fluctuate in size, becoming larger at the menstrual periods, and lessening in size in the intervals.

Although pale and anemic, the patient's face, neck, and upper chest were quickly flushed by even a transient mental emotion. Her eyes were prominent and had a rather brilliant expression, but there was no exophthalmos. The enlarged thyroid had no pulsatile thrill or movement, nor was there a pronounced beating of the cervical vessels. The action of the heart was constantly rapid. The pulse-rate was habitually about 90, and any mental or physical effort sent it above 100 per minute. Her temperature was never under 99° F. These symptoms had been present for several years, but had so increased within the past year as to render motion or action unpleasant. She walked up-stairs with the greatest difficulty, and she got out of breath so quickly that she had lately abandoned all outdoor walking. Her body-weight declined from 152 pounds to 117. The menstrual function was irregular in time and scanty in amount, there being usually but a mere "show," and the intervals were two and three months in duration.

There could be no question that in this case there was a morbid complex having the usual characteristics of exophthalmic goiter. The eyes, it is true, were only brilliant and staring, but not obviously protruding, but the other symptoms, to complete the quaternary, were present. Although the historic picture was thus complete, the manner in which the malady developed was unlike the usual course in this disease. The structural changes in the thyroid body, we may suppose, stopped the production of the peculiar principle whose absence leads to the derangement in the functions of the cervical sympathetic. It seemed necessary therefore to supply this principle by the administration of thyroid-extract.

Galvano-faradization of the central apparatus—the cervical sympathetic, and the pneumogastric—by the stabile method descending, was carried on for several months, and after some preparatory treatment intended to increase excretion, consisting of a nightly dose of pilocarpin, and three times a day fifteen grains of sodium iodid; the action of manganese, arsenic, and iron was maintained for several months. A marked improvement slowly ensued. The patient gained many pounds in weight, the menstrual function reappeared in the regular way, and the bodily strength and action were fully re-established.

When she had thus reached a point from which her recovery was to be expected, she was attacked with acute rheumatism, involving the joints of the right lower and left upper extremities, but especially affecting the left wrist and hand, which remained stiff and painful several months after the pain and fever had disappeared. Notwithstanding this mishap, which necessarily reduced her strength and nutrition, the improvement secured was maintained, and even the enlarged thyroid, except its cystic part, continues to diminish.

In the treatment of this group of cases, the remedies were adapted to that view of their pathology in which disordered states of the cervical sympathetic regulating the blood-supply, and of the pneumogastric regulating the heart's movements, are especially concerned. The lesson which they especially teach is that neither the relief of eye-strain nor the use of neurotics, will remove the symptoms. These cases further show us that the flushings and other phenomena of the climacteric period may be due to similar disturbances, and are to be relieved by a resort to the same kind of remedies.

THE VALUE OF INFILTRATION-ANESTHESIA.

BY WELLER VAN HOOK, A.B., M.D.,
OF CHICAGO.

THE use of cocain in local anesthesia was at first followed by the most satisfactory results in operations upon the mucous membranes, the resorptive powers of which facilitated the application of the drug directly to the nerve-endings. In imitation of this natural method of reaching the sensory nerves, hypodermic injections of the same solution were readily thought of, and at once it became a practice, which is still popular, to inject strong solutions of cocain (from 2 to 10 per cent.) into the subcutaneous lymphatic spaces. The best results by this method are obtained when, as in the finger or penis, the return-circulation can be interrupted by circular constriction, and the entire dose be retained as a depot of anesthetizing material. Corning has used hard rings pressed upon flat skin-areas, in order to similarly interrupt the circulation of the fluids that tend to carry away the anesthetizing substance. Under this practice there are three zones of sensory nerve-activity—a zone of complete anesthesia corresponding to the area in which the cocain is in sufficient concentration to completely overcome the

sensibility of the nerve-endings and filaments, a zone in which sensation is partially inhibited, and an area in which the anesthesia gradually fades away.

It was easily seen that if by osmosis or by the mechanic movement of fluids the cocain were brought into contact with all the nerve-structures in approximately one degree of concentration, and if this concentration were exactly that required to inhibit nerve-action, the desired result would be accomplished with a minimum quantity of the drug.

Liebreich has shown, however, that the injection of simple water into the tissues in such a way as to produce an artificial edema would induce with some discomfort a transitory anesthesia. C. L. Schleich found that by combining a small quantity of cocain with a weak salt-solution the discomfort was removed and the anesthesia prolonged; and it only remained to add a little morphin to the solution to prolong the beneficent action sufficiently to give opportunity for the performance of surgical operations. Anesthesia depends, in this method, upon the artificial ischemia established; upon the high pressure to which the tissues are subjected; upon the lowered temperature brought about by the introduction of the cool water; and, finally, upon the direct action of the anesthetizing drugs. Leaving aside alleged personal disinclination on the part of European clinicians to adopt the method of Dr. Schleich, it seems to me that the failure of the infiltration-method up to the present time to become popular depends upon the fact that a special technic is required. This technic is, however, so simple and easy that American physicians, I am sure, need only read an account of it to understand and practise it. And, as local anesthesia can be induced by it in a few moments for the opening of abscesses, furuncles, or carbuncles, for the removal of a prepuce, or for the amputation of fingers, or even of the forearm, with the use of a solution of *one part of cocain in a thousand of water*, every intelligent worker must grant its advantages and apply it in practice.

The materials required for the procedure consist of a weak solution of cocain, morphin, and common salt, in sterilized water at the temperature of living-rooms, and a good ordinary hypodermic syringe. The formula for the solution is:

R.—Cocain hydrochlorate . 0.1 (gr. iss).
Morphin hydrochlorate . 0.02 (gr. ⅓).
Sodium chlorid . . 0.2 (gr. iij).—M.
Fiat pulv.

Sig.—To be dissolved in 100 grams (℥iij–℥iij) sterilized water.

One will find it convenient to carry with him in his minor operating case a number of such powders, one of which can easily be dissolved in water, so that the solution is always fresh. Should the solution be kept for some days before being used, two drops of 5 per cent. phenol should be added to it.

Two other solutions are recommended—a stronger one containing double the quantity of cocain and a weaker solution containing only one-tenth the quantity of cocain. The very strong solution is useful for inflammatory lesions, the weak solution for prolonged and extensive operations; but for most cases the medium solution is best adapted.

It cannot too strongly be insisted that the value of these simple materials lies almost wholly in their application. The hypodermic syringe is to be used to fill the tissues to distention with the anesthetizing fluid. The needle is first introduced into the skin at the desired point, the syringe being held almost parallel with the skin. The first essential point for the beginner to learn is that the point of the syringe must not be pushed through the skin, as in administering an ordinary hypodermic injection of morphin, but must stop within the skin, so that the fluid when pressed out by the piston will distend the skin itself, raising a white, bloodless wheal somewhat like a mosquito-bite.

The author of the method, wishing absolutely to free his process from all pain, freezes the skin at the sight of the first puncture. This is easily done with ethyl chlorid, or with a spray of ether from an ordinary hand-atomizer. But the pain caused by introducing a hypodermic point is so small that I have never used the spray, especially as the application of cold is itself very unpleasant.

The area thus infiltrated is instantly anesthetic, and may be incised, punctured, or cauterized without sensation, so long as neighboring areas not yet rendered edematous are not interfered with. And this leads to the second imperative injunction upon the beginner—be sure the area you wish to operate upon is thoroughly infiltrated. The obvious converse to the proposition that the infiltrated area is anesthetized is that when pain is produced it is due to the operator's carelessness in not infiltrating the tissues incised.

The first small area having been anesthetized, it only remains to infiltrate a sufficient number of new circles adjoining the first to include the field of operation; and, as the first area is devoid of sensibility, the neighboring skin can be made edematous by painlessly inserting the needle near the edge of the wheal and forcing the fluid into the tissues from this insensitive point of vantage. Having repeated this process often enough to anesthetize the skin-area, the subcutaneous tissue is squirted full of fluid by passing the needle through the anesthetized skin. The fasciæ, muscles, and periosteum must be carefully anesthetized in the same way, and the operation may then be begun. It is needless to say that these proceedings are always to be carried out aseptically, the syringe and the water used being sterilized be-

fore being used. The anesthesia lasts about twenty minutes. If the operation is not finished in time the infiltration can be repeated.

Several simple but important points must be borne in mind in order to insure success under special circumstances. Of these, probably the most important is that inflamed tissues are hypersensitive and must not themselves be infiltrated until the neighboring normal tissues have been anesthetized. For example, to inject fluid into the apex of a furuncle without preparation would be a cruelly painful procedure; but if the operator carefully anesthetizes the skin all around the boil before infiltrating the inflamed structures, he will be able to open the suppurating focus absolutely without pain. Schleich is in the habit of advancing upon such abscesses from two foci upon opposite sides of the seat of infection.

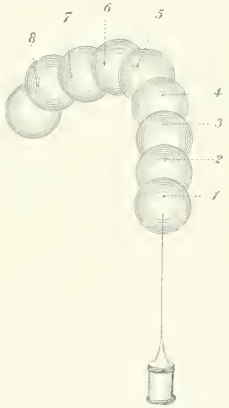

Diagram I. (After SCHLEICH.) Showing how the successive wheals are raised, the point of the syringe being inserted at the points marked by the dots.

I have found it necessary to use the finest and sharpest needle-points in working on such delicate tissues as the skin and mucous membrane of the prepuce, since, if the needle is pushed a trifle too far, the fluid lodges not in the skin, but under it, leaving the cutis sensitive. By observing this precaution I was able to avoid a general anesthetic in removing an inflamed tight foreskin from a man 72 years of age.

When large nerve-trunks have to be severed, a drop or two of five per cent. phenol is recommended to be injected as nearly as possible into the sheath of the nerve.

In amputating digits the infiltration should be begun from two points at opposite sides of the member, the infiltration being continued all along the line of proposed incision, and the deeper tissues, including the periosteum, being infiltrated with great care.

Recently I had occasion to extract a large, loose body from a man's knee-joint. After infiltrating the skin and subcutaneous areolar tissue, the capsule of the joint was similarly infiltrated, and with no pain whatever the joint-body—about 1½ in. long—was removed. The wound was sutured and the patient made a good recovery.[1]

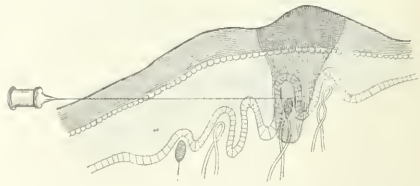

Diagram II. The syringe-point stops at the papillary layer and the fluid lodges in the skin itself.

At my request, Dr. A. F. Lemke, interne in the Cook County Hospital, has used this method in minor cases. His reports are quite satisfactory, numerous abscesses having been opened and a number of infected inguinal glands having been removed.

The most serious case in which I have practised the method was that of an operation (upon Dr. L.) for varicocele. Without my knowledge the doctor had taken so large a dose of whisky that he was in a state of hilarity, which interfered with the application of the anesthetic. Nevertheless, the veins were ligated through an incision an inch long; and, as the scrotum was very long and lax, it was amputated. The extensive wound was sutured. The pain felt was slight, and, I think, would have been almost

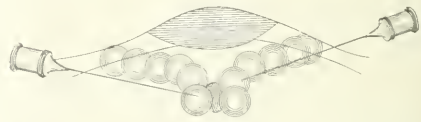

Diagram III. (SCHLEICH.) Showing mode of injecting the fluid under an abscess.

none at all if the patient had been in such a mental state as to give warning when imperfectly anesthetized areas were encroached upon.

Schleich has performed a number of celiotomies under infiltration-anesthesia, removing ovaries and tubes, etc. He will find few imitators in any but the most uncomplicated cases. But everyone will see the advantage of dispensing with general anesthesia

[1] This case was reported, with my permission, in the "Annals of Surgery," September, 1895, p. 328, Case II.

when abscesses originating in the appendix vermiformis are adherent to the abdominal walls and require simple drainage. Perhaps in no cases is local anesthesia more desirable in preference to general narcosis than in the primary opening and drainage of empyema-cavities, since even ether-anesthesia is dangerous when the thoracic viscera are compressed.

SOME THERAPEUTIC (SURGICAL) NOTES.

By ROSWELL PARK, A.M., M.D.,
OF BUFFALO, N.Y.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

A NEW EXPEDIENT FOR DEALING WITH TOUGH AND INTRACTABLE STRICTURES OF THE URETHRA.

I have recently had to deal with a long-recurring, exceedingly dense, and tough cicatricial contraction of the urethra, through which, after tedious effort, I succeeded in passing a filiform whalebone-bougie. Over this, as a guide, I endeavored to pass a variety of urethral instruments, but could coax nothing in the shape of a metallic instrument through the dense tissue. I then opened the deep urethra by perineal section, having the fine whalebone as a guide. Over the slightly bulbous extremity of this filiform bougie I tied tightly a piece of fine, braided silk. Withdrawing this through the urethra in a forward direction, I pulled through with it the silk, which I then proceeded to utilize as a fine chain-saw, in the same way that Abbe has succeeded in attacking esophageal strictures. With the fingers of one hand in the deep perineal opening, and with the other hand free outside, I could pull the silk backward and forward. Using it in this way as a very fine chain-saw, I succeeded in enlarging the canal. After repeated efforts the stricture was divided to a degree permitting a threading of the silk through the eye of a tunnelled urethrotome, which was at last passed down through the urethra, its blade separated, and the obstruction divided without further difficulty.

I am quite well aware that the necessity will very rarely arise for adopting this expedient. Indeed, this is the only time that I have ever failed in passing a metallic instrument over a whalebone, when once it had been made to find the passage. Possibly in this instance further maneuvering would have enabled me to adhere to former practices. So soon, however, as this expedient suggested itself, and was tried, I found that I saved time and accomplished my purpose more speedily, and consequently more easily for the patient, than I had feared was possible. The patient's recovery in this instance was uneventful.

A NEW AND IDEAL STYPTIC; A NEW COMPOUND OF ANTIPYRIN AND TANNIC ACID.

In The Medical News of December 15 and 22d, 1894, I rehearsed some of my experiences with antipyrin as a styptic in surgical practice, stating that I had for years used a 5 per cent. solution as a spray, sterilizing the water before making the solution. This I had no hesitation in spraying upon any surface, peritoneal, cerebral, or other, from which parenchymatous oozing was taking place to an extent complicating the operation or jeopardizing the success of an ideal dressing. This therapeutic note attracted at least sufficient attention to lead to its pretty general use by surgeons in various parts of the country, from many of whom I have heard commendatory remarks, and from none of whom I have ever heard of disappointment in its use. The present note is to corroborate the favorable esteem in which I have long held this procedure, and to state that I have since resorted to it more widely and more generally for styptic purposes. Thus, I have no hesitation in using it in the urethra, or even in the bladder, in cases of hematuria proceeding from either of these locations. Even in the eye it may be used without fear, preceding its use by that of weak solution of cocain, though in this location the antipyrin-solutions need not be made so strong. On the other hand, it may be used in much larger percentage when the 5 per cent. solution fails to accomplish the purpose; even when small vessels spurt, compression for a few moments with iodoform-gauze or acetanilid-gauze sopped in this solution will often be effective.

As every physician will realize, there occur cases of bleeding—for instance, from the nasal cavity or from divided bone—in which even these solutions will be ineffective. My present object is to call attention to the *combination of antipyrin and tannic acid*, in solution, by which there is precipitated an intensely agglutinative and cohesive substance, of to me unknown chemic composition, which offers the most ideal styptic for certain purposes that I have ever dreamed of. This combination I hit upon by accident, and first resorted to in a case of apparently intractable hemorrhage from removal of adenoid tissue in the vault of the pharynx, in which I was called in consultation by my colleague, Dr. Hinkel. He happened to have at hand a bottle of alcoholic solution of tannin, while I was provided with antipyrin in powder. The case being emergent, I suggested the combination of the two styptics, and added the dry powder to the solution. To our surprise there was formed at once a gummy mass, at first flocculent, which quickly cohered, the result being a combination, the stickiness and adhesiveness of which quite astonished us. A small sponge dipped into the fluid containing this material in suspension was inserted into the postnasal space, and hemorrhage was instantly checked, not to again recur.

I have since experimented with these materials, and have found that they may be united in almost

any proportion with the formation of the gummy mass, and would suggest that the substances be mixed in proportion to the emergency of the case, and to the desire for little or much of the resulting compound. It is possible by adding strong solutions, or of pouring the powder of one into the solution of the other, to precipitate so much of the agglutinative composition as to make a gum that may be placed about the margin of the bleeding bone—for instance, in operations upon the cranium. Or a small piece of sponge or cotton sopped in this material may be forced into a tooth-socket, or in various other ways its use may be made to result in benefit and satisfaction. There is but one attendant difficulty: that it is so remarkably cohesive that when the time comes for detachment or separation of the tampon it is difficult to remove it. It may be even necessary to wait for sufficient time for the formation of granulations and separation by natural processes.

I strongly commend to surgeons experimentation with these solutions, and their own determination as to the strength in which it may be best to use them.

MORE WITH REGARD TO MUSTARD AS AN ANTISEPTIC.

In the same issue of The Medical News to which I have referred, I endeavored to call attention to the remarkably efficient properties possessed by mustard as an antiseptic or sterilizing agent for the surgeon's hands, and for the skin of the part to be operated upon. One never goes into a house, or at least a locality, in which mustard cannot be easily procured, and my custom is to thoroughly rub and scrub my hands with a mixture of green or other soap, corn-meal and mustard-flour, using this for about five minutes. After rubbing it thoroughly into all the crevices and creases of the hands and nails by aid of a nail-brush, one may be absolutely certain that his hands are sterilized, no matter what he may have been doing previously. I have no hesitation in proceeding from an autopsy to the operating-room, if I may thus protect my hands. Used as indicated, the mustard leaves no unpleasant sensation; and one may feel that by the time it produces unpleasant tingling or rubefaction of the skin its essential oil has done its desired work as an antiseptic. I have discarded all other means of preparing the hands, and in several years' use of mustard in this way have never been disappointed, nor had the slightest reason to question its effectiveness. I might add also that it is an admirable deodorizing agent, and will take away from the hands all offensive odor of dead or dying tissues, all redolence of iodoform, etc.

Prof. König, of Göttingen, has been selected as the successor of the late Prof. Bardeleben in the Chair of Surgery in the University of Berlin.

CARDIAC MURMURS; THEIR DIFFERENTIATION AND INTERPRETATION; WITH SPECIAL REFERENCE TO "ACCIDENTAL" MURMURS.

By ARTHUR R. EDWARDS, A.M., M.D.,
OF CHICAGO;
ATTENDING PHYSICIAN TO COOK COUNTY HOSPITAL; INSTRUCTOR IN PRACTICAL MEDICINE, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

The cardiac murmur is a subject of greatest diagnostic, prognostic, and therapeutic importance, regarding which certain authoritative and popular misconceptions prevail. Authors, especially of the French school, were inclined to draw broadest inferences from the loudness and timbre of heart-bruits, a tendency still manifest.

The loudness of a murmur sustains no invariable relation to the severity of the causal lesion. Guttmann states that the stronger the murmur the more marked is the underlying pathologic alteration, although he admits many exceptions and relies more upon other methods of examination. Dilatation and hypertrophy of a cardiac chamber signify more than a mere murmur of given intensity. I recall an instance of an enormously dilated heart characterized by a very loud, rough murmur, in which, after death, the valves were perfectly smooth. Gradually increasing stenosis and insufficiency frequently present physical conditions under which murmurs disappear. Cardiac examination in the ultimate stage of disordered compensation is often unsatisfactory, as an accurate study cannot then be made. I have observed a case of aortic regurgitation in which the murmur, previously recorded, disappeared three weeks before death. In such cases the diagnosis from myocarditis and kindred affections may be impossible. Valvular murmurs may disappear temporarily during an intercurrent febrile affection or be permanently buried under terminal tachycardia. Loudness bears an important relation to cardiac activity, a fact in which lies a diagnostic suggestion. Loudness may vary from day to day, and intensity alone does not influence prognosis, as a fainter murmur can signalize heart-failure.

Sahli states that standing or sitting intensifies murmurs that are weak in the prone position, while Eichhorst describes endocardial murmurs as becoming weaker or disappearing on standing. I have never been able to demonstrate any constancy between intensity and position, although Eichhorst's practice of examining patients in different positions obviates many errors.

French writers have said much regarding the timbre of cardiac murmurs, and have dogmatized that their acoustic characters determined sclerosis, calcification, or the degree of lesion. Eichhorst deprecates such generalizations, and denies their diagnostic value. Rough, smooth, blowing, or sawing murmurs depend on purely physical condi-

tions of the valves and bloodcurrent. Particular importance is attached to musical murmurs and those that may be heard at a distance. Aortic and mitral lesions have produced musical murmurs. At autopsies are found perforation of the semilunar valves (Schrötter), abnormal chordæ tendineæ across the ventricle (v. Drozda), torn papillary muscles, or relative aortic regurgitation (Groedel), but often no cause is found. Murmurs *par distance*, heard by the patient himself or by those around him, are musical, singing, or squeaking, and are observed in aortic stenosis (Stokes, Ebstein) and aortic regurgitation, but are sometimes accidental (Ebstein, Eichhorst). During the last year I attended a physician with great cardiac dilatation of arterio-sclerotic origin, in whom a relative mitral regurgitant murmur could be heard from the foot of the bed. It disappeared when rest removed the dilatation. Timbre has, however, a relative significance. Hard, calcified, rough valves often produce rough murmurs, as do also torn chordæ tendineæ, and loosened valves. Aortic regurgitant bruits are soft and blowing, while those of aortic stenosis are harsh and sawing. In mitral leakage the murmurs are loud but short, and in mitral stenosis faint, rolling, rippling.

One of the most important cardiac bruits is the "accidental" murmur, also known as inorganic, accessory, adventitious, functional, hemic, or anemic. Sahli properly objects to calling accidental murmurs inorganic or functional, as they may depend upon functional valvular disturbance; and, beside, not all accidental murmurs rest upon an anatomic basis. He rejects the term anemic, as accidental murmurs may occur from valvular insufficiency even in chlorosis and anemia; and, again, not all accidental murmurs are anemic. The division of murmurs as follows is proposed: 1. Valvular. 2. Functional valvular. 3. Accidental.

We can only speculate as to the pathogenesis of accidental murmurs. There are theories innumerable, but that advocated by Sahli seems most applicable, that the rapidity of the cardiac contraction explains the murmur. In acute anemia, as from hemorrhage, the resistance to the systole is reduced, and accidental murmurs intervene. In chronic anemia the quality of the blood is altered, and thereby the resistance to the systole is reduced, with consequent acceleration and accidental murmur. Cohnheim has produced a cervical venous hum by artificial hydremia.

The differential diagnosis of accidental murmurs is often difficult. Many sweeping statements have been made and criteria established whose unreliability has, in my experience, been conclusively proved.

The etiologic differentiation. Accidental murmurs may occur in health. Skoda found them in acute rheumatism, pregnancy, puerperal disease, carcinoma, typhoid fever, smallpox, and anemia. (*Percussion*, S. 212.) They are found in fevers, anemia, cachexia, and inanition from whatever cause. Whatever lowers bloodpressure, relaxes the arteries, and increases the heart's action may produce accidental murmurs.

Groedel affirms that the diagnosis is easy when there is a concomitant venous hum in the neck, which, according to Filatow, accompanies "anemic" bruits. Walshe could not remember an instance of organic heart-disease associated with an anemic *bruit de diable*. Rheumatism may argue for valvular disease. These laws assist in certain instances, but, like all statements that are not absolutely true, fail when infallibility is most imperative. For example, in a case without previous history, with high and somewhat irregular temperature, rapid pulse, diffuse furunculosis, delirium, involuntary evacuations, a dilated left heart, a loud, harsh, mitral murmur, no roseolæ, no diarrhea, no tympany, and no splenic tumor, the diagnosis lay between a late typhoid with an accidental murmur and septicopyemia with cardiac localization. The lack of alteration in the right ventricle turned the scale in favor of typhoid, and the diagnosis was established at the autopsy.

For the same reason the case of a Chinaman with a parotid abscess, meningeal symptoms, high temperature, and a loud, blowing, apical systolic bruit was diagnosticated sepsis without valvular involvement, and was confirmed after death.

Not every murmur observed in anemic patients is inorganic. Many are relative valvular insufficiencies, and Vierordt recounts two cases of pernicious anemia in which the diagnosis oscillated between organic and inorganic murmurs, with a final decision in favor of their functional origin. The autopsy, however, revealed endocarditis and very slight ventricular hypertrophy, the diagnostician having been baffled by concomitant emphysema. Valvular heart-disease may produce a profound secondary anemia, a confusing point rarely mentioned in this connection.

Physical examination of the heart. Only physical examination of the heart by methods other than auscultation can determine the status of a cardiac murmur. In organic cardiac disease are found hypertrophy, dilatation, loud or accentuated tones, tones replaced or accompanied by murmurs, and abnormal arterial phenomena, *e. g.*, anomalous sounds, the pulse, capillary pulse, etc. While considerable dilatation may complicate anemia, yet hypertrophy argues for organic change. Dilatation of either or both ventricles in anemia is neither marked nor attended with hypertrophy. Leube says that while the second pulmonary sound may be somewhat accentuated in anemia it is not markedly

so, nor is it palpable. In neglecting careful cardiac percussion physicians often err. With reliance upon exhaustive physical examination the diagnosis of heart-disease becomes one of the easiest, most satisfactory, and most accurate.

Systolic and diastolic murmurs. Regarding the cardiac phase of murmurs, the formal teaching prevails that anemic bruits are always systolic (Finlayson, Flint, Guttmann, and others). While they are usually systolic, such dogmatic statements cannot, I believe, maintain. I have observed and reported cases[1] in which anemic diastolic bruits were heard over the large thoracic and abdominal venous trunks, and functional diastolic murmurs were observed in relative aortic regurgitation. Sahli[2] has recently reported a similar series. A case of chronic cardiac exhaustion from overwork has recently been in my ward in which was heard an apical presystolic murmur, disappearing under rest, digitalis, and purgation. Fisher[3] cites cases of presystolic murmur dependent upon aortic disease, cardiac dilatation (concretio cordis cum pericardio), and once upon hypertrophy and dilatation of the right ventricle. The diastolic and presystolic phase *per se* has been overestimated in the exclusion of inorganic murmurs. I think I may expand Fraentzel's rule that systolic murmurs without other cardiac change do not imply organic disease, and assert that no murmur in itself, whether systolic, diastolic, or presystolic, definitely determines valvular lesion.

Localization. Hemic murmurs are heard mostly over the pulmonary area, but are often propagated to the apex. They occur rarely over the aortic and tricuspid valves. Latent aortic stenosis, without murmur or with ventricular change, may simulate inorganic bruits. Vierordt has found inorganic pulmonary murmurs sometimes quite confusing, especially when widely propagated.

Organic mitral lesions may be heard only over the anatomic seat of the valve at the base of the heart, on account of the retraction of the lung from the enlarged left auricle (Naunyn).

Timbre. In the earliest days of auscultation, Gendrin described inorganic murmurs as blowing, and sharply separated them by this point alone from the harsher organic bruits. Skoda (p. 212) expressly disagreed with Gendrin and insisted that no special emphasis could be attached to the character of a bruit. Guttmann describes accidental murmurs as being always short and blowing. Sahli explicitly states that a sawing, musical, or blowing murmur is not necessarily—although usually—organic. I have heard numerous very loud and coarse murmurs which were proved accidental by their ultimate clinical course or by postmortem examination. It is usually affirmed that inorganic are not as loud as organic murmurs (Leube, Sahli, and others). The murmurs of valvular disease may become very weak, or pronounced lesions may pass to autopsy without a bruit. Petit characterizes anemic murmurs as superficial, inhalation-like, and dependent on respiration.

Frémissement cataire, thrill, has been claimed as exclusively a sign of organic cardiac disease, a statement to which Eichhorst justly takes exception. V. Bamberger has said that anemic murmurs seldom cover a tone, but rather "hang on to it." Hutchinson's statement that anemic murmurs disappear on lying down has been disproved, although French authors (Petit, Potain) maintain that change of position alters the murmur. This fact cannot have differential value, for organic murmurs behave in the same fashion.

Feeble propagation has been long held as typical of accidental murmurs, but the same is true of mitral stenosis, and inorganic murmurs may be heard par distance. I have heard two anemic bruits in tuberculous cases in which the murmur was transmitted over the entire chest.

Appropriate therapy may differentiate organic from inorganic murmurs. Chalybeate treatment will often remove the anemic murmur and digitalis frequently correct functional valvular insufficiency.

A protracted clinical course will exclude accidental murmurs, which are inherently short-lived.

Hochsinger[1] has found that accidental murmurs do not occur before the fourth year; hence murmurs occurring before that age are organic, even though the physical findings do not concur, *i. e.*, are unattended with hypertrophy and dilatation.

Finally, accidental murmurs are diagnosticated only after logical exhaustive exclusion.

PROGNOSIS IN PUERPERAL INSANITY.

By J. E. McCUAIG, M.D.,
Assistant Superintendent, Kansas State Insane Asylum, Topeka; formerly Assistant Physician, State Hospital for Insane, Danville, Pa.

In no class of cases of insanity is the prognosis so favorable as in those occurring in the puerperal state, either during pregnancy or lactation, the so-called puerperal insanity. Of 69 cases having this etiologic factor admitted to the State Hospital for the Insane at Danville, Pa., during the decade between 1883 and 1893, 53 were considered curable as having a duration of 2 years or less before coming under treatment. Of these latter 32 were classified as mania, and 21 as melancholia. Of the former 28 showed insanity of less than one year's

duration. Of this number 23 were discharged restored, and 1 as so far improved as to give a reasonable probability of complete recovery at home, making a percentage of 85.4 of recovery. Two were discharged not improved, after a residence in the hospital so short as to preclude any hope of change. The ultimate result in these cases is unknown to me. One died on the fifth day after admission, of the exhaustion of acute mania, complicated with septicemia, making the only case in which death was in any degree traceable to the mental disorder. But 1 is known to have become chronic, a percentage of 3.3 on the number of curable cases under treatment.

In the next class of patients, those having a duration before admission of from 1 to 2 years, the results were far less favorable, and emphasize the detrimental effect of long duration previous to treatment in this as in other forms of insanity. Of 4 cases but 1 was restored and 3 are known to have become chronic.

Of the melancholiacs 16 had a previous duration of less than a year. Of these 10 were discharged recovered and 3 improved, a percentage of 81.1. One was discharged not improved after a residence of 2 days, leaving an incurable residue of 3, or 12.4 per cent. Of 5 cases of from 1 to 2 years' standing, 1 was restored and 1 improved, and 3 became chronic.

That the prognosis is favorably influenced by the time that is allowed to elapse before placing the patient under suitable treatment, especially in maniacal cases, is shown in the percentages based upon the duration before admission. Of 21 cases of mania, having a previous duration of less than 3 months, 89.3 per cent. recovered, and none is known to have become chronic, the balance being made up of 1 who died, and 1 discharged not improved after insufficient residence. Of those of from 3 to 6 months' standing, 72 per cent. were restored, while 14 per cent. became chronic. Of those of longer standing than 6 months, 50 per cent. were restored, and 50 per cent. became chronic. Probably on account of the slower nature of melancholia, the influence exerted by treatment in the earlier stages does not seem to be so pronounced as in mania, though the rule holds good. Thus, of 8 cases under 3 months' duration, 75 per cent. recovered and 25 per cent. became chronic. Of 5 cases between 3 and 6 months, 80 per cent. were restored and 20 per cent. discharged, not improved, as stated. Eight cases having a duration of longer than 6 months, gave a recovery-rate of 62.5 per cent., while 37.5 per cent. are known to have become chronic.

The number of previous pregnancies does not appear to be a factor of importance in prognosis, as the results were about equally good in all cases, irrespective of the number of gestations.

Probably of more weight is the question of age at the first attack. Of 3 cases below 20 years of age none is known to have become chronic; of 14 between 20 and 25, 1 became chronic; of 14 between 25 and 30, 1 chronic; of 15 between 30 and 35, 5 or one-third failed to recover; and of those above 35, 3 in number, 1 became incurable.

The meager information obtainable in regard to the character of the labor fails to throw much light upon the influence of this factor in causing mental disturbance. From what could be learned, however, it would seem that in most of my cases the labor was normal, and that the complications incident to childbirth had little to do with the mental difficulty.

In this, as in all other forms of insanity, heredity plays an important part. Despite the well-recognized difficulty in obtaining reliable data as to predisposition, 20 of the 53 curable cases had neurotic histories. This fact does not seem to have exercised an unfavorable influence on the prognosis, as of these 20, 18 recovered, and only 2 became chronic.

CLINICAL MEMORANDUM.

A CASE OF ADDISON'S DISEASE,

Treated by Ingestion of the Adrenals of the Sheep. Floating Kidney with Diseased Adrenal Palpable.

By CHARLES G. STOCKTON, M.D.,
OF BUFFALO, N. Y.,
PROFESSOR OF MEDICINE, UNIVERSITY OF BUFFALO.

On the 17th of June last there appeared for examination Mrs. P., aged 40, married, and the mother of one healthy child. Her father died at 68 from debility. Her mother, who died at the same age, was never strong; was tall, thin, and very much resembled the patient in every way, and it is said that she suffered from some affection resembling that for which the daughter now sought relief. No other deaths had occurred in the family. There are three brothers and four sisters living and well.

Previous to the advent of the present disease the patient had never been seriously ill, but had always been constipated, and when young suffered from sick-headaches. After her confinement she had some uterine affection. For the last seven years she has suffered from diarrhea, and her strength was thereby so much reduced that it is difficult to determine the inception of her present trouble. At present, and for at least three years past, she has complained of weakness, shortness of breath, palpitation of the heart, loss of flesh, vomiting and diarrhea, great muscular debility and intense bronzing of the skin, which, over the region naturally pigmented, presents the color of dark mahogany. There is also unnatural pigmentation of the mucous membrane of the lips, cheeks, and pharynx.

The patient now weighs 112 pounds; her former weight varied from 130 to 150. She suffers no pain, and, indeed, there are few abnormal manifestations save that she is sleepy much of the time. She has imbalance of the ocular muscles, and doubtless has astigmatism. The pulse is somewhat slow and

feeble, at times very infrequent, and there is moderate arterial sclerosis. The area of cardiac dulness is slightly increased; the heart-sounds are feeble, but without bruit; on exercise the heart is tumultuous. The capillary circulation is poor, the extremities cold and often clammy. The respiratory apparatus is without apparent fault. She suffers much from sore-mouth; at present there is a deficiency of epithelium, particularly over the tongue. This organ is tremulous, flabby, and shows too much venous engorgement.

During the past year the patient has suffered from regurgitation of food, and that retained shows but little change after having been in the stomach for hours. The gastric contents were aspirated on June 21st, three hours after a test-meal of meat, bread, and water. The food was found all present, water-soaked, and not digested. It was necessary to introduce the tube 25 inches from the teeth in order to empty the stomach. There was slight obstruction to the passage of the tube through the cardia; there was no evidence of digestion. There was an absence of odor and of mucus; the acidity was very faint; hydrochloric acid was absent; lactic acid appeared as a mere trace.

Although occasionally annoying, the diarrhea is not now so much in evidence as in the past. The area of liver-dulness is four inches in the nipple line; the liver lies lower than usual, and is to be felt below the free border of the ribs. The spleen is slightly enlarged; both kidneys are movable, the left distinctly floating. Above the left kidney, closely connected with it, moving with the kidney, yet movable while the kidney is held still, is an irregularly shaped body, about the size of a hen's egg, which is slightly tender upon pressure. It is presumed to be a diseased adrenal.

The examination of a 24-hours' specimen of urine showed that it was highly acid, brownish, cloudy in appearance, its specific gravity 1025, without albumin or sugar, a moderate reaction for indican, and no reaction for urobilin or bile. The total amount passed is 832 c.cm., containing 18.30 grains of urea. Microscopically, nothing of importance was revealed. Examination of the blood showed 1,800,000 red corpuscles to the cubic millimeter. There was 30 per cent. of hemoglobin present; there were many megalocytes and macrocytes and marked poikilocytosis. The lymphocytes were present in large numbers.

Previous to the examination described the patient had, for some months, been taking iron and arsenic, besides other tonics. These remedies were continued, and in addition she was advised to inhale five gallons of oxygen-gas three times daily, and to eat daily two uncooked adrenals from a sheep.

This treatment was begun June 23d, and on the 6th of July the patient returned and showed great improvement in color and general appearance. Her courage had returned with her appetite. She was hungry for the first time in five years, she said. There was a diminution of the pigmentation; there was a decided increase in strength, and the red blood-cells had risen to 3,000,000 to the cubic millimeter; there was also a decided change for the better in the appearance of the cells. The improvement has since then steadily progressed, and on September 14th there were 4,000,000 red blood-cells to the cubic millimeter, 80 per cent. of hemoglobin, and a very striking change for the better in the shape of the corpuscles. There was now polymorphous leukocytosis, with perinuclear granules taking the basic stain. Subsequently there was a polynuclear leukocytosis.

On September 27th, the stomach-contents were again examined, and although the patient had shown so much general improvement, and had regained six pounds in weight, no change for the better could be discovered in her digestion. Hydrochloric acid and pepsin had been added to the treatment during the past four weeks. Her bowels had been occasionally loose and some undigested food had passed, but with these exceptions there had been no complaint referred to the digestive tract. From her sensations she supposed that her stomach was quite well. As to the pigmentation, it has at this writing almost entirely disappeared from the hands, face, and breast. There are slight remains of the patches of dark brown about the cheeks, but these are scarcely noticeable. The areolæ of the nipples are no darker than is common with women who have borne children. About the waist and over the abdomen a moderate amount of pigmentation is still observed. The most striking improvement is seen in the pulse, which is now large, strong and frequent. The blood-pressure is considerably above that of health, but it does not show that high tension mentioned by Prof. Schäfer[1] and Mr. Oliver.[2]

This treatment was begun some weeks before the experiments reported by Schäfer and Oliver had reached me, otherwise I should have been more careful as to the quantity of adrenal allowed the patient. I discovered that she rather enjoyed the glands, prepared as a sandwich, and on some days had taken three instead of one or two as originally directed. As no untoward effects followed the ingestion of the adrenals I have allowed the patient to continue without restriction. It is a matter of interest that so large an amount can be taken without causing discomfort to the patient. At this day, October 1st, the patient is in better health than she has been for five years, and insists on pronouncing herself well. All medication has of late been withdrawn save hydrochloric acid and pepsin.

I am not prepared to say how much benefit may have been obtained from the oxygen administered, although so far as the arsenic and iron are concerned they had been taken by the patient some time before she had come under my observation, and without benefit. It is my judgment that improvement has been wrought mostly by the eating of adrenals from the sheep. One cannot but be suspicious of an adrenal that is palpable in a woman forty years of age, such an enlargement being too suggestive of malignancy. It will be noted, however, that the blood-examinations afford the hope that the adrenal disease is not carcinomatous in nature.

436 FRANKLIN ST.

The Revival of the Index Medicus.—The number of subscriptions to the *Index Medicus* officially received up to November 5th is 174. It is earnestly hoped that the requisite two hundred will have been received by December 1st, when the question of discontinuance or revival will be definitively determined.

Dr. David D. Stewart has been elected Professor of Diseases of the Stomach and Intestines in the Philadelphia Polyclinic.

THERAPEUTIC NOTE.

THE USE OF BELLADONNA IN PEMPHIGUS.

By DOUGLASS W. MONTGOMERY, M.D.,
OF SAN FRANCISCO, CAL.;
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA; CONSULTING PHYSICIAN FOR DISEASES OF THE SKIN AND FOR PATHOLOGY, GERMAN HOSPITAL.

In a disease that is so stubborn to treatment and frequently so distressing as pemphigus, any amelioration by means of a drug is thankfully acknowledged. Belladonna and its alkaloid atropin have been used in pemphigus, and some benefit has been ascribed to them. The main interest in the case in hand, however, lies in the circumstance that the reason for the improvement seems to be clearly shown.

On August 5, 1893, a brunet boy of 15, of Polish Jew parentage, limped into the San Francisco Polyclinic. He was suffering from blebs of the feet of such severity as to seriously interfere with locomotion. They had never appeared in any other locality and the majority of them came on the soles.

His father, whom I saw later, said that these blisters first appeared at four years of age, coming on in the summer and ceasing in the winter, but for the past three years they had been continuous through both summer and winter, being, however, worse in summer. The severest attack

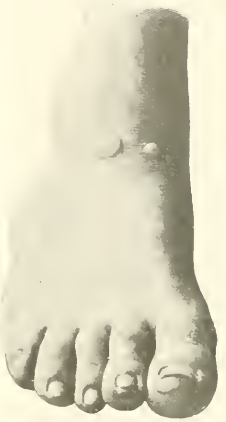
FIG. 1.

Aspect of sole of foot.

the boy had ever had was that for which he first consulted me in the summer of 1893. The severity of the affection in the summer season is a noteworthy fact, because, as we shall see further on, temperature has always had a decided influence in this case.

The contents of the blebs were of a clear, amber color, of alkaline reaction, and with heat and nitric acid, gave an abundant precipitate of albumin. There were enough red blood-corpuscles in some of the blebs to tinge the contents red, or even give them a violet color, and sometimes enough fibrin to coagulate the whole or a part of the fluid into a jelly. Apparently there never was enough migration of white blood-corpuscles to make the contents purulent, except as a consequence of

FIG. 2.



Aspect of dorsum of foot.

secondary infection, and unless such infection took place there was no inflammatory areola around any of the blisters. Aside from undue perspiration of the feet, there were absolutely no symptoms that could be referred to the nervous system, unless the formation of the blisters themselves be looked upon as evidence of nerve-derangement.

The boy had wet the bed almost every night as long as he could remember. In every other respect he enjoyed good health. There was no spontaneous pain, only tenderness due to the lesion of the epidermis; there was no analgesia, no paralysis, and no tenderness along the nerves. The muscle-reflexes were normal and the boy could stand with his eyes closed. The sensations of touch, pain, locality, heat, and cold were also normal. These facts are brought out to show that the pemphigus in this case was not a mere symptom of leprosy or of some disease of the nervous system, but, so far as our present knowledge goes, it was an independent disease.

There is a curious disease characterized by an hereditary propensity to the formation of blisters on the reception of slight injuries. This affection is now named hereditary inclination to the formation of blebs, and was first described almost simultaneously by J. Wickham Legg[1] and by Goldscheider,[2] and I at first supposed that the present case might be an instance of it, for the history given me was misleading. The patient told me that he had been subject to this affection from his earliest recollection, and his aunt said also that he had always had it.

[1] St. Bartholomew's Hospital Reports, 1883, vol. xix.

[2] Hereditaere Neigung zur Blasenbildung, Monatshefte f. prakt. Derm., 1882, No. 6; Abstract in Vierteljahressch. f. Derm. u. Syph., 1883, p. 145.

Furthermore, the immediate cause of the bad outbreak for which he came to me seemed to me to be the wearing of a new pair of shoes. Later on, however, I learned from his father that the boy had been perfectly well up to the age of four, when the present affection began, and that it had appeared intermittently ever since. The father, who was a worthless fellow, enjoyed good health, and said that none of the other members of his own family, or, as far as he knew, of the family of the boy's mother, had ever had any such affection. The boy had a sister and a brother, aged respectively 17 and 13, both of whom enjoyed good health, and had never been afflicted with any trouble resembling pemphigus. His mother had died about seven years previously, probably from some accident during confinement.

Now the essential features of the disease described by Legg and Goldscheider are that it is hereditary and congenital, and that the blebs appear on the reception of a slight trauma. The affection in the case under consideration was neither hereditary nor congenital, and I concluded on longer observation that the appearance of the bad attack mentioned and the wearing of the new shoes were simply coincident, for he had no special inclination to get blisters from traumatisms. Therefore the disease described by Wickham Legg and Goldscheider was definitely excluded. The case was not one of dermatitis herpetiformis, or Duhring's disease, for there was no dermatitis. It was not at all like a case of cheiropompholyx, lacking entirely the little sago-grain-like vesicles between the fingers and toes.

There seemed, therefore, no doubt that this was an instance of that interesting group of cases to which probably the name of pemphigus ought to be limited, in which the entire lesion consists of an eruption of blebs, having a symmetric distribution, a chronic course, and a tendency to recur.

We had, therefore, the kind of case, which, according to Hutchinson, should yield readily to treatment with arsenic, for the patient was young and in good health, and had a sound stomach, and, above all, had no blisters in the mouth. The boy began taking Fowler's solution on August 5, 1893, in two-drop doses, t. d.; on the 8th the dose was doubled; on the 12th, he took 5 drops; on the 15th, 7 drops; on the 22d, 10 drops; on the 26th, 12 drops, which he continued up to August 29th. He then complained of severe frontal headache, and as the blistering continued without cessation or amelioration of any kind, and, as I feared, because of the intense headache, one of those sudden explosions of arsenic in the nervous system, it was determined to abandon this line of treatment.

About this time it was noticed that the cutting-edge of the upper central incisors, instead of being straight, was concave. The teeth were excellently shaped in every other respect, being of normal size, with straight lateral borders, perfect enamel, and well set, so that they could not be called Hutchinsonian. Furthermore the boy had a well-shaped head and good skeleton, with no affection or history of disease of the eyes, ears, or nose. The father denied ever having had venereal disease, and there was no history of miscarriages in the family. In addition to this, the pemphigus in this case was decidedly unlike a bullous syphilid, which is inflammatory from the start, occurs almost exclusively in infants, lasts only during the secondary stage of syphilis, and denotes a profound cachexia. Potassium iodid was, however, tried for a short time, without results.

On September 12, 1893, the potassium iodid was stopped and the boy was then given 3 drops of tincture of belladonna, increased, on the 19th, to 4 drops. Decided improvement now set in and for about one week no new blebs formed. A few new blisters then appeared and the belladonna was increased up to 6 drops t. d., but without entirely controlling the formation of the blebs.

The patient now disappeared for a number of months, to return the following summer, and it was then that I hit upon the probable mode of action of the belladonna. While he lived in Denver, which is cold in winter and warm in summer, his feet perspired profusely only in summer, and he had pemphigus there only in the summer season. On coming to San Francisco, where it is never very cold, blebs formed all the year round, but in sufficient number to seriously inconvenience him only in summer. One of the best-known actions of belladonna is its power of controlling perspiration, and in doing this it put this lad's feet in the same condition in this regard in summer as in winter. It was then thought that if this were the only action of the drug, it would be as well to use it locally, and a small amount of belladonna was applied to the soles, and with satisfactory results. Blebs formed, but not in sufficient numbers to especially incommode the boy. One of the great objects of medication was fulfilled; although it did not cure the disease, it rendered this tolerable.

MEDICAL PROGRESS.

An Effectual Method of Treating Extensive Malignant Disease of the Breast.—LANE (*Lancet*, No. 3763, p. 904) recommends amputation of the arm at the shoulder in certain cases of carcinoma of the breast in which the skin is so extensively infected that sufficient covering for the raw surface is obtained with difficulty, if at all. It is reasoned that the patient will die if not operated upon, and the arm will be a source of distress, owing to interference with its circulation; so that the removal of the member is really not a serious deprivation. An illustrative case is reported. An unmarried woman, 29 years old, presented a carcinoma of the breast, which had been observed for five months. The mass was large, and involved almost the entire breast. The skin over it was adherent, and was ulcerated over a space perhaps 1½ in. in diameter. All about the ulcer and for an area around the breast the skin presented minute nodules of infection. There were enlarged glands in the axilla, and in the subcutaneous tissue over the coracoid process a gland could be felt, which had apparently been infected from some cutaneous nodules just below it. There was no evidence of general metastasis. The situation was explained to the patient, and extirpation of the malignant disease with amputation of the arm proposed and acceded to. An incision was made along the length of the clavicle to the middle line and the middle third or more of the clavicle exposed and removed. The subclavian artery and vein were tied at the margin of the scalenus anticus, and all the areolar tissue and glands in the subclavian triangle carefully dissected out. There was no obvious infection of these glands, but beneath the clavicle the upper limit of the enlarged axillary

glands was defined and the glands were turned downward. Great care was taken not to injure the suprascapular or other vessels crossing the subclavian triangle. From the inner limit of the horizontal incision another was carried down vertically along the middle line for about 9 in., well outside the limits of skin-infection. From the lower end of this another incision was carried backward to the posterior axillary fold, at what seemed to be a safe distance from the growth, and then it was run upward along the posterior fold to the axilla, whence it ran across the arm to the outer end of the clavicle. A vertical incision was made from the upper limit of the posterior axillary fold to the elbow, where it was crossed by a circular incision. The skin and subcutaneous tissues were dissected up off the deep fascia as far as the deltoid, out of which a large and sufficient flap was cut to insure as much vascularity of the flap as possible. The inner part of deltoid was removed and the limb disarticulated. The skin and the subjacent soft parts were dissected off the sternum, clavicle, ribs, cartilages, intercostal muscles, serratus magnus, and posterior wall of the axilla; and the great square flap, which measured more than nine inches along each side, was fitted accurately and comfortably into the large exposed raw area. The part that corresponded to the circular incision around the arm was united to the edge of the median or sternal incision, while the edges of the vertical incision in the arm were connected with the upper and lower horizontal incisions in the thorax. Very little blood was lost during the operation. The growth was found to involve the greater pectoral, but the most careful subsequent examination of the parts excised showed that the primary growth, the skin, and the glands were very freely removed. The wound ran the usual aseptic course, and was unattended with pain or discomfort.

Changes in the Lungs of a Patient Treated with Tuberculin.—Adami (*Montreal Medical Journal*, September, 1895) relates the history and the post-mortem appearances in the case of a man who had been treated with tuberculin for a year. At the time of coming under observation the man presented cough, hemoptysis, nightsweats, and progressive emaciation. These disappeared and health seemed to be entirely restored. In the course of five years, however, the symptoms returned and death took place in an attack of hemoptysis. Upon postmortem examination firm adhesions were found at the apices of the lungs, which showed marked fibroid changes, and contained well-encapsulated caseous masses and small, contracted cavities. In these parts the tuberculous process had evidently been arrested, but the rest of the lung-tissue contained numerous miliary tubercles distributed along the course of sundry bronchi. The tubercles were most numerous in the neighborhood of the old mischief; they were surrounded by very little pneumonic disturbance and were rather of the fibroid than of the rapidly advancing type. The second attack was thus not the result of fresh infection, but of the recrudescence of the old process starting from the incompletely healed disease-foci. The nature of the lesions indicated either relative attenuation of the virulence of the bacilli or increased resistance on the part of the tissues.—*British Medical Journal*, No. 1817; Epitome, p. 68.

Fever in Nephritis.—As the result of a clinical study, Stengel (*American Journal of the Medical Sciences*, November, 1895, p. 522) maintains that fever may occur in the course of nephritis at the onset of an acute attack, as a result of the infection or intoxication causing the disease or of the inflammatory or degenerative lesions in the kidneys themselves; in the course of acute or chronic nephritis as a result of various complications; and in the uremic state. The fever associated with uremia may be sudden and pronounced and attended with coma, delirium, and convulsions; or it may be more general, more lasting, less marked, and associated with typhoidal symptoms.

Metritis of Uremic Origin.—At the French Congress of Internal Medicine, recently held at Bordeaux, du Magny (*Mercredi Médical*, 1895, No. 41, p. 487) described a special form of metritis developing in the course of uremia, and characterized by a vaginal discharge of varying degree and color, of irritating properties, and manifesting an odor like that present in cases of uterine carcinoma. On palpation the uterus feels enlarged and softened in places. On ocular examination the cervix appears reddened and swollen, and its lips are the seat of numerous small prominences of varying size, resembling nodules of epithelioma. All of these phenomena disappear with the other uremic manifestations.

THERAPEUTIC NOTES.

Toxic Effects from Acetanilid Applied Topically.—Briggs (*Occidental Medical Times*, October, 1895, p. 596) has reported a case of circumcision in an infant a week old in which topical applications of acetanilid were followed in the course of 24 hours by profound general cyanosis and a pinched expression of countenance, with coldness of the extremities. The removal of the drug from the wound, in conjunction with the employment of artificial heat, was soon followed by disappearance of threatening symptoms.

The Serum-treatment of Anthrax.—At the recent Congress of the Italian Society for Internal Medicine Sclavo (*Lemaine Médicale*, 1895, No. 54, p. 466) related the results of experiments with the blood-serum of goats immunized to anthrax. Such serum injected into rabbits conferred immunity and displayed also therapeutic activity. An injection of from 5 to 10 c.cm. made twelve hours after the injection of a fatal dose of virulent anthrax-bacilli prevented death. A rabbit injected with protective serum twenty-four hours after receiving an injection of virulent anthrax-bacilli lived four days longer than a control-animal untreated with the serum.

The Treatment of Diphtheria with the Antitoxin.—According to the results of an official collective investigation there were treated in Germany with the antitoxin, during the year 1894, 6626 cases of diphtheria—2460 in the hospitals, 4166 in private practice. Among this number there were 5726 recoveries (86.5 per cent.—80 per cent. in the hospitals, 91 per cent. in private practice) and 855 deaths (12.9 per cent.); while 45 cases (0.67 per cent.) were under observation at the time of report.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, NOVEMBER 16, 1895.

PROGRESS IN MEDICAL LANGUAGE?

THE last thing people study accurately and with interest is the thing that is nearest them. Astronomy was among the first objects to interest the human mind, and to-day we know more about geology than we do about physiology, more about physiology than about psychology. Educators have lately been in turn perplexed, amused, and disgusted by the fact that our undergraduates in the leading colleges of our country, after studying a half-dozen other languages, and "all things knowable," cannot write a single grammatic or accurate English sentence. This instrument, their native language, used earliest, most constantly, and throughout all intellectual and social life, is not studied, not improved, and not cared for. This fact seems strange, and strange it is, but it is as true as it is strange.

An equally astonishing fact, but one that is a mere corollary of the first, is the ludicrous conservatism of a few people about their language. We say this is a corollary because the blind opposition on the part of these people is due to utter inattention, to complete philologic ignorance. Their scholarship ends in having deep-rooted prejudices, the bases of which they have never for a moment examined. They have never examined the laws of language-formation ten minutes. Ask them what is Grimm's law or what are Skeat's rules, and they would be sorely puzzled; but ask them what the proper spelling of *hemorrhage*, or of *symphysiotomy* is, or what is the proper pronunciation of *phthisis*, and they are ready with a cocksure answer—an answer, of course, that coincides with that of the dictionary they happen to have bought.

It only needs, it would seem, a very moderate degree of critical acumen to observe that languages are formed by variations from a parent stem, and this process of variation can no more be stopped than can any evolutionary process. The appeal to authority, the attempt to thump an objector into silence with a dictionary, is of no avail. The truth is that language, perhaps more than any other product of the human mind, is convincing evidence of the character of the people who speak it. When a language ceases to grow and change, it is because the minds of the nation have ceased to be expansive and progressive. Look over the nations of the modern world and each is an illustration. The Latin is dead and changeless, the Spanish, if not dead, is as changeless as the speakers; the French is as crystallized as the French character; but it is the German and the English that are alive and rapidly undergoing modifications. In English the living, nervous, mobile-minded American is making additions to and modifications of his language that justly or unjustly provoke the amusement or scorn of his slower-going insular parent.

If minds and civilization are progressing this progress will find expression and proof in language. Whether written or spoken, language is a tool of thought and intercourse, and it is indubitable that all progress is conditioned upon perfection of instruments. It is, therefore, fatuous idleness to oppose the trend of change bound to take place in the word-tool of a people so ingenious and pushing as the American. Call it slang for a while, keep it out of print, stigmatize it with quotation-marks—do what you will—all is in vain. The part of discretion would seem to be conservative change. Genuine, that is wise, conservatism will bow to the inevitable and use it. Blind prejudice will oppose every sign or hint of change, whether good or not so good, and thus transform evolution into revolution.

An hour's reading of the results of philologic study would, or should, upset the prejudice of those who withstand as outrage any slightest suggestion of shortening the language. We argue for no sudden

and violent changes; phonetic spelling is as impossible as it is (at present and to us) absurd. This is true at least as regards English. In Germany scientific and medical books are to-day printed with phonetic modifications that seem utterly revolutionary, and that certainly would have made each particular hair of Goethe's head stand on end in horror. It argues well for the quick adaptiveness and the scientific thoroughness of the German character, and bespeaks an originality and perpetuity of German science for which we may sigh in vain. In comparison with it how silly and stupid seems the bigotry of the few Americans and the many English who look upon the abolition of a hyphen, a dieresis, or a diphthong, as a sin and crime against Heaven's high law.

Much confusion of mind and ridiculousness of practice exist as to the anglicization of foreign words. This confusion arises from nonobservation of a simple rule of common sense. If the word is so infrequently used as not to be understood by the majority of readers it would seem plain that it should be considered a foreign word and italicized. But if it is a word so common that everybody knows at once what it means, why bother the editors, printers, proof-readers, and ten-thousand readers with the absurd italics? Let us abolish such useless foreign expressions as *per rectum, per os*, etc., when English can express the thought as well or better.

But if not italicized, what reason, anthropologic or philologic, is there for accents, diereses, and diacritic marks? They are not only useless, but are "eye-sores" and botherations to everybody concerned. They increase pedagogic labor and handicap education. They can never teach pronunciation, and in nine journals out of ten they are bunglingly and erroneously placed. They spoil the dispositions of type-setters, of teachers, and of pupils. Let us away with them! Let us write and print in "Roman" and in English, role, debris, ecraseur, raphe, regime, etc., etc.

Dieresis, accents, and diacritic marks are not in harmony with the spirit of the English language. They cannot teach pronunciation, and they are wholly unnecessary to separate two adjacent vowels that are to be pronounced separately. Who to-day writes *poëtry, poëtic, coöperation, diëresis, myösis, mammalïa, aërial, aörist, aörta, manïa, aërate*, and a thousand words ending in *eöus, ïa, ïöus, etc.*, as we have here written them? Why not also drop the dieresis out of *zoology, microorganism, oophorectomy, ptomain, leukomain, etc.*? If one pronounces them *zool-og-je, oof-or-ek-to-me, to man*, etc., he needs a common-school teacher's birch rod and not diereses and hyphens to help him. There are seven different ways of pronouncing the termination *ough*. Who will undertake to tell an ignoramus by diacritic marks how to pronounce it in all cases?

A great idol of the verbal idolater is the little hyphen, a somewhat that is rarely used when it should be used, and is used a thousand times when it should not be used. The conservative stickler is up in arms if you leave it out of *postmortem, antitoxin, culdesac, postpartum*, and the like, and yet it cannot be found in the Latin or the French originals. His scholarship is exhausted by the fact that in his dictionary the hyphen is there. Who put it there, and why it is there, what wonderful function or sense it has there, would puzzle any philologist, but it doesn't trouble protester. One correspondent was shocked because he saw the word extrauterine printed thus. Extra-ordinary, certainly! If the hyphen were stuck in between the compounds of every word made up of *extra, intra, ex, ab*, and the rest, the type-founders would for long be kept busy making hyphens, and our printed pages would look much as if composed of telegrapher's signs. The chief function of the hyphen is to conjoin two English words (complete in themselves when standing alone) when the double term is used as a single idea, and especially when the two words are nouns. It is a growing and reprehensible habit of all of us to use nouns as adjectives. Thus, instead of saying *renal disease, cardiac lesion, dermal affection*, etc., we seem determined to say *kidney-disease, heart-lesion, skin-affection*, etc. If we feel compelled to do so, let us at least see the hyphen.[1] But when we use nonanglicized Latin words, such as *post, extra, intra*, etc., the hyphen is useless luggage, and the component parts should, with rare exceptions, be run together, as is done with tens of thousands of our common words. *Anti-toxin* is as absurd as would be *anti-pathy* or *anti-septic*. The hyphen in *extra-uterine* is as redundant as it would be in *extra-ordinary*. And so on to the end! There are a number of words that, thoroughly anglicized as they are, and commonly printed as two words, might with great advantage be run together and form one word. Such, for example, are *postmortem*

[1] We recently saw an advertisement of a lost child—"A dark skinned boy," it read.

(either as a noun or an adjective), *postpartum*, *vasomotor*, *microorganism*, *nonelastic*, *culdesac*, etc., etc.

In the crying need of condensation in medical writing that exists, it would save tons of paper every year, and much besides the paper-bill, if we would usually put our numbers in figures instead of spelling them out.

There is nothing more suggestive of the originality and progressive character of the American medical mind than the almost universal acceptance within the past few years of a few changes in the direction of brevity and usefulness in the spelling of a few of our medical terms. To be sure these changes[1] are at best or at worst somewhat trivial, but they prove that just as we are anxious to perfect our therapeutic and surgical instruments so we may hope for further progress in our most used (and most barbaric) tool, language.

LIGHTNING AS A REMEDY.

THE privilege of having been born in the nineteenth century is not confined to the enjoyment of trolley-cars, bicycles, and football. A still greater blessing is to be a contemporary of the New York electro-therapeutist, who was recently exploited by the *Herald*. The reporter who got up the interview and designed the headlines must have had more reward for his trouble than the mere consciousness of having done good. Perhaps he took a "shock," in part payment—his style, in fact, suggests that he he had had several shocks, some electric, and others alcoholic.

The reporter announces, through the columns of the *Herald*, that there is a female physician in New York City who has attained a good practice, and that "lightning is her remedy." We should like to give her name; and would, but that it is against our conscience to advertise anyone gratuitously. We simply wish to call attention to her lightning. She keeps this on tap somewhere "near to the heart of the East Side" of Gotham, where it seems from all reports to be badly needed. She has a dispensary, "which is fitted up with a thought for the impression in the way of an example in house-furnishing it might leave upon the minds of the housekeepers who wait within its walls for medical help." How like a woman! Tidy, neat, suggestive, hypnotic! House-furnishing and lightning—all in one dispensary and in one paragraph. And then, too—how like a reporter, to write of a room being fitted up with a thought!

This wondrous dispensary, thus fitted up with lightning and with a thought, contains also a Thomson-Houston alternating current with a pressure at 104 volts; also a dark-room for an electric bath; also tiny electric globes for insertion into the mouth or nose, which impress the imaginative reporter as "fairy-like;" also a room for the electro-gynecologists, into which we hope the reporter was not admitted. But the most wondrous is a closet just large enough to contain a cot-bed, and with two big arc-lights in the ceiling. These are turned on, and the patient "absorbs light into every pore of his body for hours at a time."

At one side is another room, "where the thunderbolts are stored." Finally, the reporter tells us that in the midst of this scene the doctor "handles the enormous amounts of electricity which is (*sic*) chained in the dispensary with the most fascinating ease, touching buttons, starting belts and bands on great machines, which fill a room with fireworks with as much complacency as a typewriter would touch the keys of her machine." This, we submit, is rather hard on the typewriter. She is so monopolized nowadays by the humorous journals that it does not seem fair to drag her in to decorate the authentic descriptions of newspaper-reporters. To fill a room with fireworks from a machine which also displays complacency was enough of a task, one would think, to have kept the reporter's mind off the typewriter for a few moments at least; the fact that it did not shows plainly that the poor scribe had had a shock or a glass too many, and was already seeing stars. Else why does he tell us that the way to chain electricity is with fascinating ease?

Sincerely, we esteem it a great privilege to live in the age of lightning-dispensaries and newspaper-reporters. These latter are a versatile fraternity of whom it may be said, as Dr. Johnson said of Goldsmith, that they leave scarcely any style of writing untouched; but of whom it cannot be said with equal justice, that they touch nothing that they do not adorn. When they touch a medical or scientific subject we are reminded that we live in an age, not of culture, but of popular literature; and that the newspaper-reporter who, when he wants to advertise an electro-therapeutist, announces that "lightning is her remedy," is, after all, not writing to adorn

[1] E. g., æ and œ to *e*; dropping the *al* from a few adjectives: in chemic nomenclature, etc.

literature and to tell the truth, but rather to catch the eye of the populace and to sell an edition.

As for the enterprising electro-therapeutist, if it be true that she is a member of numerous learned and highly honorable scientific bodies, we adjure her not to make her presence in them uncomfortable to her fellow-members by creating the suspicion that like some cloud-compelling and bolt-hurling Jove—disguised as a woman-doctor—she is ready on the slightest provocation, as in the heat of debate, to shoot forth lightning. If she does this, especially by advertising, they might take a notion to put her out.

EDITORIAL COMMENTS.

Infectious Diseases in Poultry.—*Bulletin* No. 8 of the United States Department of Agriculture contains an account of some interesting investigations concerning infectious diseases among poultry. The Bureau of Animal Industry has been doing some excellent work, Theobald Smith and Veranus A. Moore being conscientious workers, and their contributions to animal pathology have been many and valuable.

In the present *Bulletin* Dr. Smith describes an infectious disease among turkeys caused by protozoa and producing an enterohepatitis in the fowls affected. Turkeys normally have two ceca, two blind tubes opening into the intestine about 6 in. from the cloaca. These tubes are nearly a foot in length, and in the disease under consideration they were found invaded by the parasite, the mucous and submucous coats being thickened and inflamed, and a coagulable exudate poured out into the cecum. The parasites occupy the tissue in groups or nests. Other regions of the intestine were not affected, but the liver was extensively diseased in the greater number of animals examined. The organ is enlarged to almost twice its normal size, and round, discolored spots, varying in number and size, are distributed over the surface; these spots are made up of dead liver-cells, and in the reticulum lie large numbers of protozoa.

The organism is a form of ameba, and its effect on the body of the turkey resembles somewhat that of the ameba of dysentery in the human being. Dr. Smith points out the differences between the two amebæ, but does not answer the question whether any causal relation exists between them. The fact that an ameba is found causing similar disturbances in fowls to those produced by the amœba coli in man is of sufficient importance to bear further investigation.

A second paper in the same *Bulletin*, entitled "A Preliminary Investigation of Diphtheria in Fowls," by Dr. Veranus A. Moore, has a close connection with the foregoing question, inasmuch as some observers consider the diphtheria of fowls identical with that found in man, at least so far as clinical symptoms go, and several cases have been reported in which children became infected through the handling of diseased fowls. Dr. Moore found the lesions present in the poultry examined by him similar to those described by European observers; the bacillus detected, however, could not be identified with the one usually described as the cause of fowl-diphtheria.

While the microorganisms found associated with diphtheria in swine, fowl-cholera, and diphtheria in birds and poultry differ considerably from the Klebs-Lœffler bacillus of human diphtheria, still the latter presents such a varying morphology, under different conditions of growth, that it is not out of the question to attribute the differences between the bacillus of human diphtheria and the bacillus of fowl-diphtheria to a difference in habitat, and consider all the membrane-producing bacteria as belonging to one family or species. It is hoped that further studies along this line will be made by the Bureau of Animal Industry, as the economic importance of the subject is very considerable.[1]

Evidence is accumulating day by day showing how great a part the lower animals play in the causation of disease in man, and the time is not far off when zoology and comparative medicine will receive as much attention in our medical schools as materia medica and pharmacy.

Scientific Cooking.—The question of food has received much light from recent practical investigations in laboratories designed especially for studying the needs of the poorer classes. Such laboratories have been established in the cities of Boston, Chicago, New York, and now in Philadelphia, in the shape of scientific kitchens, where the effort is made to furnish food of sufficient nutritive value for the lowest possible price. Here the wants of the people are carefully studied, and as far as possible supplied. It has been found that much food is wasted because it is improperly prepared; the method of cooking does not bring out the quality of nourishment contained in the food or destroys it altogether.

It has likewise been shown that a great saving can be made in fuel by using ovens fashioned somewhat after the manner of incubators, the cooking being done slowly, the oven covered with felt retaining an even heat for a long period of time. By this slow process of cooking much greater nutritive value is obtained out of the food, and an oil-lamp can serve as a means of fuel. According to this new method a broth is made by placing meat and bone in an *Aladdin* oven (the name given to a simple incubator invented by Edward Atkinson), covering the meat with water and allowing it to stand over night at a temperature of 190° F. This continuation of the cooking at a temperature below the point of coagulation secures from the material the greatest amount of gelatin, retains the flavor, and makes a product richer in albumins and extractives. The long cooking of the vegetables at the temperature named likewise improves their flavor and increases their nutritive value.

In Philadelphia a scientific kitchen has lately been started under the auspices of the College-settlement Association in a section of the city once designated as the "slums," and here under a competent "chef," trained in scientific cooking in the Technical Institute of Boston and in the Drexel Institute of this city, the latest knowledge on the subject is being put to practical test. The kitchens in other cities have hardly proved a success in

[1] The eleventh census shows that in 1890 there were in the United States 258,472,155 barnyard-fowls (exclusive of ducks, turkeys, and geese), and that the egg-product for 1889 was 817,211,146 dozens, with a money-value of $98,000,000.

the financial sense of the term, but they have served as experiments and have made the work easier for others.

Many valuable dietaries have already been constructed combining proper food-value with cheapness and palatableness, and much is yet to be done in educating the public—both rich and poor—to make use of them. Lunches for school-children to take the place of indigestible sweetmeats and pastry form one of the successful ventures these kitchens have been engaged in. A luncheon in the college-settlement kitchen consists of a bowl of soup, home-made bread (baked on the premises), a cup of cocoa or coffee, and a plate of prunes or baked apples. This can be had for fifteen cents. Frying in the ordinary way is not made use of, but fish-cakes and meat-croquets are prepared by being cooked in boiling fat, this process rendering them quite digestible. A "portion" consisting of baked beans, brown bread and butter contains proteids 35 gm., fats 25 gm., carbohydrates 108 gm., calories 824 gm., costs five cents, and has in it almost one-third of the food-value required by an ordinary workingman in twenty-four hours.

While we think there is not much room for waste in the average day-laborer's kitchen, no doubt he could live much better for the same money if his wife knew something about the chemistry of foods; and it seems to us these kitchen-laboratories can be made to serve a great purpose by conducting classes in them, say for servant-girls, and inviting the co-operation of their employers. The whole subject is of vital interest to the physician, as it is related so intimately to disease-processes and to therapensis, and it is worth his while to to give it serious consideration.

Microbes on Money.—We have all heard much of the drawbacks of riches. They take unto themselves wings, they entail anxious days and sleepless nights, they breed discord, and strangle family-affection. Yet most of us in viewing these terrors have usually felt "our courage rise with danger," as the good old hymn says, and inclined to the opinion that we would personally be willing to take the risk of them, if the condition they accompany happened to fall within our reach. The dangers are so incidental and remote that we feel sure *our* skill and judgment would enable us to avoid them. Within the last few years, however, the microscope has demonstrated another danger of more serious nature, in that it is not merely a consequence or incident of the possession of riches, but actually attaches and belongs bodily to the material wealth itself. The bacteriologist has declared that, although we may acquire riches and escape unhappiness, we must accept the risk of serious contagion every time we realize any of them in the form of money; that the surfaces of coins of all metals and denominations and bank-notes of every description are simply swarming with germs of various degrees of virulence. Cultures have shown the presence of from 450 to 3500 germs upon a single coin, ranging from the *streptococcus* and *staphylococcus pyogenes* to tubercle-bacilli and typhoid-bacilli. These have been deposited of course from contact with saliva, pus, discharges, soiled fingers, and dirty pockets. The list is an appalling one, and literally supports the Apostle's statement that "money is the root of all kinds of evil." That these germs are virulent has recently been shown by inoculating rabbits with their cultures and obtaining characteristic reactions. So far everything is discouraging, and the bacteriologist simply emphasizes the maledictions of the preacher upon literally "filthy lucre." But it was soon noticed that the proportion of fatal results from these inoculations was extremely small considering the nature of the germs present, and a series of recent experiments at an Algerian military hospital has developed the surprising fact that coins possess actual bactericidal properties and rapidly destroy or weaken any germs lodged upon their surfaces. In a cold chamber the germs of typhoid and the Friedlander bacillus were destroyed upon sterilized silver or copper coins in eighteen hours; at a temperature of 37° C., about that of the pocket, the bacilli of typhoid, of diphtheria, of blue pus, and the streptococcus are destroyed in 6 hours. The Lœffler bacillus is the most resistant and upon cold silver or copper coins will live for from 3 to 6 days. Moisture and warmth greatly hasten the process, which is probably due to the formation of poisonous oxids and other salts of the metals. A similar action upon the germs of dental caries has been noted by Willoughby as due to the copper amalgam used in filling teeth. Nature's protective mechanisms are even more wonderful than her destructive ones. We have been loudly assured by the socialist and labor-sympathizer that "capital can always be relied upon to protect itself," but we little thought to see the statement verified in this wise. Gold coins are much less actively bactericidal than either silver or copper, and germs may survive upon them for 5 or 6 days, which may partially console us for their infrequency in our professional pockets. Some kindly disposed individual should certainly bring this latter fact to the knowledge of our bimetallist friends, as it would furnish them with a strong argument against "the yellow metal."

CORRESPONDENCE.

THE RELATION OF PELVIC DISEASES TO MENTAL DISORDERS.

A Correction.

To the Editor of THE MEDICAL NEWS,

SIR: The proof of my article which was published in the MEDICAL NEWS of October 5, 1895, came to me while watching at the bedside of a near relative who was seriously ill, and this probably accounts for the fact that I did not notice the omission of cases from Dr. Rohé's report, which should have been as follows:

Puerperal mania 6 cases, with recovery in 3; melancholia 6 cases—recovery in 1, improvement in 4; simple mania 1 case, with slight mental improvement; hystero-epilepsy with mania 2 cases—recovery in 1, operation too recent in 1 to give the result. Epileptic insanity 3 cases, with 2 deaths and slight improvement in 1; periodic mania 3 cases, with decided progressive mental improvement in all; paranoia 1 case, with slight but not permanent improvement—making 22 cases, with recovery in 5 cases and decided improvement in 7.

Very respectfully,

ISABEL M. DAVENPORT.

ILLINOIS EASTERN HOSPITAL FOR THE INSANE

ORIGINAL ARTICLES.

THE PRACTICAL VALUE OF LAVERAN'S DISCOVERIES.[1]

BY WILLIAM OSLER, M.D.,
OF BALTIMORE, MD.,
PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY.

EVEN in well-known affections advances are made from time to time that render necessary a revision of our accumulated knowledge, a readjustment of old positions, a removal even of the old landmarks. Perhaps the most remarkable illustration of this is offered by the discovery of the tubercle-bacillus. What a *volte face* for those of us who were teachers before 1881! Happy those who had agility and wit sufficient for the somersault! Scarcely less important has been the revolution in our knowledge of malaria since the researches of Laveran, in 1881, on the parasite of the disease. His discovery attracted for a time little attention, chiefly because the workers in pathology, the world over, had not opportunities for studying the disease. The verification of his work came slowly, while the conception of its far-reaching consequences has not yet filtered from the laboratories and clinics into the wide field of every-day practical medicine.

There are several aspects in which Laveran's studies may be considered as of immense value:

THE RELATION OF THE PROTOZOA TO THE ACUTE INFECTIONS.

A stimulus has been given to research that has already borne fruit in observations upon amebic dysentery, Texas cattle-fever, and certain skin-affections. The question of the protozoal origin of carcinoma has been revived, and prosecuted with an energy that must result in a valuable addition to our knowledge of the structure, and possibly, too, of the etiology of malignant growths. Although the life-history of the parasite is as yet imperfectly known, sufficient details are available to furnish one of the most interesting chapters in pathology, and at last we have revealed the meaning of that periodicity, so mysterious a feature in the malarial fevers, which has puzzled generations of physicians since Hippocrates. As a direct outcome of the study of the protozoal parasites of paludism may be mentioned the really brilliant discovery by Theobald Smith of the parasite of Texas fever, also a hematozoon, connected in its life-history with the cattle-tick (Boöphilus bovis). No more interesting problem in comparative pathology has been solved of late years, and the life-history of the parasite is better known than that of any other pathogenic protozoon.

THE DIAGNOSIS OF MALARIAL FEVER.

The best guarantee of a truth, as some one has said, is the wisest men's acceptance of it. There has been an extraordinary unanimity in the verification of Leveran's main facts by every competent worker who has had suitable opportunities for the study. The extensive and complete bibliography—the most complete yet published—in the monograph by my assistants, Drs. Thayer and Hewetson,[1] gives some idea of the widespread interest which the question has aroused. It is not too much to say that Laveran's work has revolutionized the study of fevers, as now a trained observer can determine whether any given case of fever depends upon a malarial infection. The parasites are present in all forms of the disease, and constitute a diagnostic criterion of unfailing accuracy in uncinchonized subjects. A certain technic and training are required, which a season in any malarial center can give, but which is not so easy to get in other localities. I shall refer shortly to the extraordinary abuse of the term malaria, which is used as a cloak to cover our ignorance of the nature of obscure fevers. A more extended knowledge of the fact that the malarial fevers are readily and quickly recognizable will give the physician pause in a hasty diagnosis, and will in time obviate one of the most glaring inaccuracies in the mortuary returns of certain towns.

But it is in the study of the fevers in the tropics that Laveran's discovery will prove of the greatest service, and as shown by the work of Vandyke Carter, in India, and Dock, in Galveston, the differentiation of malarial from other fevers is quickly made. It is most important that men who desire to study this problem should be equipped with the necessary technic. Several recent reports on malaria in the tropics have been sadly defective, and show that valuable opportunities have been wasted from lack of proper training on the part of the observer. Accurate information on the subject, in

[1] Read before the Medical Society of the District of Columbia.

[1] "The Malarial Fevers of Baltimore." Johns Hopkins Hospital Reports, 1895. Vol. v.

English, has not been until recently available. My article in the *British Medical Journal* (1887, I), remained for several years the only one which had a wide circulation, and the letters which I have received from practitioners in distant parts of the world indicate that, with the imperfect literature, there coexisted as a rule imperfect training and faulty apparatus. Now, however, the publication by the New Sydenham Society of Laveran's monograph, and of the works of Marchiafava and Bignami, of Mannaberg, and the monograph of Thayer and Hewetson, already referred to, gives access to all the available literature, and should prove a great stimulus to the study of tropical fevers from the new standpoint.

For so many generations the paroxysm of intermittent fever has stood for the type and representative of the class of fevers associated with chill that it has been, and still is, very difficult, particularly in this latitude, to avoid the suspicion of paludism in any disease associated with recurring rigors; and yet one may safely say that, in the cities of the Atlantic seaboard, the instances of chills and fever due to the malarial parasite are greatly exceeded by those of various other affections. The idea seems firmly ingrained in the mind, and I scarcely pass a week without seeing some instances in which the diagnosis of malaria has been made, simply because the patient has had recurrent chills. The error would not be so unfortunate were it not for the fact that it often causes delay in the adoption of suitable treatment, and may completely blind the physician to the true nature of the case. Perhaps the most frequent mistake is in the chills and fever of tuberculosis. As is well known, these occur at the two extremes of the disease. It is more particularly in the early stages that the mistake is serious, and I have on many occasions known a patient treated persistently for malarial fever without a suspicion having arisen that the trouble depended upon tuberculosis. In all varieties of septicemia the mistake is most frequent. Malaria postpartum, of which one hears not a little, is very often septicemia, and I rarely see a case of abscess of the liver that has not been drenched with quinin, in some instances for months, in the belief that it was a chronic malaria. Frequently pyelitis, pyelonephritis, gall-stones, and empyema are in the same way overlooked, and, even when the diagnosis has been demonstrated, I have often heard from physicians expressions which indicated a lingering idea that after all the septic trouble was only a consequence or a complication.

The profession at large has not yet laid to heart the following rules:

1. *That the diagnosis of the malarial fevers can be made with certainty by the blood-examination.*

2 *That an intermittent fever which resists quinin is not of malarial origin.*

A rich experience during the past nine years warrants the expression of these positive statements.

In the differentiation of the fevers of the South, about which so much discussion has taken place during the past ten years, the study of the changes in the blood must in the future play a most important rôle. The question of the existence of a third type of continued fever, which has been advocated by Guitéras, Baumgarten, and others, cannot be determined without a more complete study than has yet been given to the cases.

When one reads the report of the Proceedings of the Orleans Parish Medical Society, in which for many years the nature of the long-continued fevers of Louisiana has been discussed, the condition really seems to be similar to that in which the profession labored before the differentiation of typhus and typhoid fever. It is interesting to note that in New Orleans at least physicians seem to be coming gradually to the conviction that the long-continued fever which resists quinin is in reality typhoid, a view strongly advocated by Dr. Matas in a short paper in THE MEDICAL NEWS of December 15, 1894.

MALARIA AND VITAL STATISTICS.

The U. S. Census Report for 1890, recently issued, which covers the six years ending May 31, 1890, gives the following number of deaths from malaria, to which I add for comparison those of typhoid fever:

Washington—	Malarial fever,		500;	Typhoid fever,		850.
Baltimore—	"	"	934;	"	"	904
New York—	"	"	2060;	"	"	2031
Brooklyn—	"	"	1413;	"	"	1002

That in Baltimore, New York, and Brooklyn the deaths from malarial fever exceeded those from typhoid will, no doubt, be read with astonishment, particularly by those familiar with the conditions of practice in those cities. Any reasonable physician in Philadelphia or Baltimore will at once acknowledge that a death from malarial fever is a great rarity, while deaths from typhoid fever are only too common. Taking the reports of the large New York hospitals as a basis, one can estimate the degree of reliability of the figures on which the mortuary statistics are prepared. In the last-issued report of the Department of Public Charities and Correction of New York (1894) for the year 1891, the comparative rarity of malarial fever is well indicated by the fact that, of above 15,000 patients admitted to Bellevue Hospital during the year, there were only 15 instances of intermittent malarial fever. It is true that there were 76 cases of typhomalarial fever and only 16 of typhoid in the figures, which is surprising, considering the little stress that has been laid of late years upon typhomalarial fever; but when one turns to the list of deaths and finds that

all the cases of typhoid fever died, 16 in number, it looks as if the diagnosis rested a good deal upon whether the patient recovered or not. In the total number of deaths, 1547, malaria does not appear as accounting for a single one. So also at the Charity Hospital, of 619 deaths not one was caused by malaria.

At the Roosevelt Hospital in the year 1893 there were treated in the medical division 1436 cases, and, so far as one can gather from the report, there does not appear to have been a single case of malaria treated in the wards. Dr. Roosevelt, to whom I wrote on the subject, kindly informs me that from January 1, 1883, to December 31, 1893, inclusive, there have been but two deaths from malaria, both cases of the pernicious form. The total number of deaths in medical cases during this period was 2024, so that the proportion of deaths from malaria to all deaths from disease in the medical division of that hospital during the 11 years was about 1 to 1000.

In the New York Hospital, for 1893, of 1482 medical cases, there were in all 38 cases of malaria, with one death from pernicious fever.

Through the kindness of Dr. Browning I am able to give more extended figures for Brooklyn, a city in which the prevalence of malaria has engaged the attention of the profession for some years. The figures and tables sent to me were prepared by the direction of the Committee of Health, under the supervision of the secretary, Dr. G. S. West. Dr. Browning writes: "One peculiar general feature is that in the last 14 years, while the malaria cases have diminished pretty steadily down to less than one-half, the typhoid cases have fully doubled. During the same period the population has increased fully one-half, and by a small extent by increase in the city's area. Even then the typhoid cases have increased about twice as fast as the population."

He gives the figures for the ten years from 1884 to 1893, inclusive: deaths from typhoid fever, 1543; deaths from malarial fever, 1224. It will be noticed that there is a serious discrepancy between these figures and those in the Government Census for 1890, which deals with the six years ending May 31, 1890, during which time the deaths from malarial fever are stated to be 1413.

Carefully prepared tables of the deaths from typhoid fever, malarial diseases, and typhomalarial fever from 1880 to 1893 inclusive, have also been furnished. The totals for the 14 years are as follows: Typhoid fever, 1898; typhomalarial fever, 1104; and malarial diseases, 2006. In the Transactions and also in the Proceedings of the Medical Society of the County of Kings there are interesting discussions and reports on the prevalence of malaria. With reference to the occurrence of fatal malaria, it is worthy of note that in the reports on malarial fever on Long Island by Dr. Baker and by Dr. W. H. Thayer,[1] while it was acknowledged that intermittents occurred in many parts of Long Island, yet none of the physicians, whose correspondence is given in the papers, mentions, so far as I can gather, a single case of fatal malarial fever, nor do I see one mentioned in the discussion following the reading of the reports. In September, 1893, the members of the Society of the County of Kings again discussed at length the question of malaria in Brooklyn.[2] I have looked carefully through all of the papers there read, and it is certainly a very significant fact that not one of the authors of the papers, and not a physician who discussed the question raised, mentioned the occurrence of fatal forms of malarial fever. In the article by Dr. Hall on types of malaria seen in Brooklyn, in which he quotes the observations of a number of physicians, no mention is made by any of them of fatal forms, and this is a city credited in the bills of mortality with as many deaths from malaria as from typhoid fever! Certain of the writers of the papers seem to have themselves been a little suspicious; thus Dr. Hall remarks that "Carelessness of diagnosis probably affects our ideas of the prevalence of malaria to a considerable extent;" and Dr. Law, in the methods of treatment of malaria in Brooklyn, states that it seems to him a good practice in cases of the remittent type of the disease to give quinin in large doses for two or three days, and then, if the fever is not broken up, to stop and take bearings and search for some inflammatory lesions, or reconsider the possibility of typhoid.

The report from the Brooklyn Hospital gives the following: In 1890, of 608 medical cases admitted there were 18 cases of malaria and no deaths. In 1892, of 742 medical cases admitted there were 27 cases of malaria and one death. In 1893, of 683 medical cases admitted there were 20 cases of malaria and no deaths.

In the report from the Kings County Hospital for the year 1892 there were no deaths from malarial fever in a total of nearly 3000 patients treated with 310 deaths. In the report for the year ending July 31, 1893, there was one death from pernicious malarial fever in a total of 3258 patients treated, with 425 deaths.

In dealing with the statistics of malaria, Brooklyn may be taken as a model, and I have dealt with it partly because of the reputed large death-rate, and partly because the activity of the members of the Medical Society of the County of Kings has furnished most suggestive material, which has been supplemented by the kindness and energy of Dr. Browning.

[1] N. Y. Med. Journ., 1885.

[2] Brooklyn Med. Journ., Jan. 1893.

In localities frequented by the disease, malarial fever kills in such a way that the diagnosis is rarely in doubt. In the acute cases death follows within a few days. In other cases the hemorrhagic features prevail, while the malarial cachexia or the acute exacerbations in the malarial cachexia less frequently prove fatal. The simple intermittents rarely kill, even when protracted. Taking into consideration the statements of physicians in Brooklyn and Long Island, as given in the reports referred to, together with the striking absence of all reference to fatal forms, also the distinctive and readily recognized character of the fatal forms of malaria, one cannot help feeling that in these localities and elsewhere the diagnosis is put down carelessly, and does not represent in any way the incidence of malarial fevers. In the oft-quoted and oft-printed chart of the Michigan State Board of Health, showing the comparative mortality from typhoid fever in sewered and unsewered towns, Brooklyn figures almost at the bottom of the list, having a mortality of 1.5 per 10,000 inhabitants, a mortality which is much more than doubled if we add, as it seems should be done, the deaths due to typhomalarial fever and those due to malarial diseases.

The conclusion of the whole matter may be thus briefly expressed—the mortuary bills dealing with malaria are false, due either to ignorance or to wilful deception on the part of those who make the returns. Malaria is a disease that now rarely kills in the large towns on the Atlantic seaboard, and it behooves the profession to abandon the practice of making a careless diagnosis of the disease in every case of obscure fever which proves fatal, and the Medical Boards should refuse to receive a death-certificate signed malarial fever without more specific details than have heretofore been demanded.

SEVENTEEN CASES OF CHRONIC (RELAPSING) APPENDICITIS, TREATED BY OPERATION.[1]

BY HUNTER McGUIRE, M.D., LL.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.

IT will be seen that 10 of the cases reported were females and 7 males. There were 16 private cases and one operated on in the amphitheater of the University College of Medicine; 15 cases were operated on in St. Luke's Home (my private hospital), and one was operated on in a private house; this last was the fatal case, and the only fatal case of operation for chronic appendicitis that I have had.[2]

The series of cases embraces operations performed in the interval between the attacks, when all or nearly all of the inflammatory symptoms had disappeared—the quiescent stage, as was originally suggested some years ago by Mr. Frederick Treves. There is not included any case of acute or other form of appendicitis.

From the report of my cases it may be seen that I am not always in a great hurry to operate, but that I am inclined to wait for the more acute symptoms to wear off, and operate, if at all, after suppuration has taken place, or during the quiescent stage, between the attacks.

There are some cases of appendicitis so slight that I am satisfied they belong to the general physician and not to the surgeon; very often they are not recognized as appendicular trouble, but are put down as bilious colic, localized petitonitis, kidney-colic, etc. Under rest, purgation, hot applications, rigid diet, leeches, and the very moderate use of opium these cases recover, and, in very many instances, stay well. In some of these cases, if, after the attack, one could look at the appendix and structures around it, he would see evidences of inflammation in the shape of slight thickening, induration, and adhesions. If one will examine subjects in any large dissecting-room he will find frequent specimens of this kind. These slight cases of appendicular trouble are not cases for operation. A man's usefulness is not impaired nor is his life usually shortened by it; indeed, he often gets on through life better than the man with a crippled leg, or the poor fellow who lives for years with a crippled heart. I wish my voice was strong enough, just here, to call a halt to the men who say: "Operate at once—not this afternoon or to-morrow, but now," in all cases when the disease is recognized.

There are cases, however, in which the disease, instead of abating, grows worse, the temperature gets higher, the pulse more rapid, the lump in the iliac region is larger, the belly is more tender, and possibly a rigor comes on. A slight pitting edema in the skin over the region of the appendix is sometimes seen. The fluctuation tells us that pus has formed, and the whole aspect of the case is changed. I know I subject myself to severe criticism when I say that even now I am not in all cases in a hurry to operate. Possibly the disease has been going on for some days, as is often the case, before the consulting surgeon is called; the symptoms are not so urgent, fluctuation not very distinct, and the barrier of lymph containing the pus is probably strong. I am not in a hurry to operate, because a certain proportion of these cases may get well without interference. Recovery is not always impossible, even after some matter is supposed to be present or is actually there. Years ago, when I knew less about the subject than I do now, I have punctured the abscess about the

[1] Read before the Medical Society of Virginia, September, 1895.

[2] I have operated on three other cases of chronic appendicitis, but the records of these cases are too imperfect to justify reporting them. These 3 cases recovered.

appendix with the needle of an aspirator and pumped out some of the pus, and afterward seen the man get well and stay well. One case was that of a Presbyterian preacher in Richmond, whose appendiceal abscess I aspirated several times. He is well and at work now. I do not pretend that this is good surgery, or that I would repeat it at this time; I introduce the fact now to show that recovery may take place after matter has formed. I have seen more than one instance of this, and I have even thought that the violent inflammation rendered the patient free from a second attack. This is certainly not impossible. If a large number of cases of appendicitis are examined it will be found that a large majority of these cases never have a second attack. It is true that delay in operating may end in the barrier being undone and purulent irruption into the peritoneal cavity ensue. I have never seen this occur after the third day. I have, however, seen matter burrow down toward the pelvis and bladder and upward toward the liver. Very often when one operates and opens this abscess he will find it attached to the parietal peritoneum; if so, the operation is simply opening an abscess. The opening should then be made large enough to introduce the finger and gently search for the appendix; and if one can find it or fecal concretions, they are to be removed. If the appendix is fastened by adhesions it should be let alone. The abscess-cavity should be drained with a rubber tube and gauze. If it is found that the abscess is not attached to the parietal peritoneum, I would treat the case, if practicable, as I describe in Case XI.

In acute perforating appendicitis I would operate at once. In such cases one cannot operate too soon. There may often be very violent infection and inflammation producing gangrene and sloughing of the appendix. The peritoneum is speedily involved, and diffuse septic peritonitis quickly comes on. Very often, in these cases, as soon as the peritoneum is opened there escapes a milky fluid thinner than pus, and it is always most imperfectly, if at all, confined by fibrin. These are the frightful cases, and an early operation alone gives a chance for life. It is these cases of acute perforating appendicitis that have induced many surgeons in this country to urge immediate operation in *every case* of appendicitis. I cannot subscribe to this doctrine. I have seen too many of the other kind of cases get well without an operation; but when we have a case in which the symptoms are ushered in with great rapidity, when the pain is atrocious, and the temperature high, the pulse rapid (from 110 to 120), when vomiting is persistent, and constipation insuperable, when the belly is tender, and the right iliac region hard, and, above all, when the patient's face indicates mortal illness; when he looks, indeed, like a man shot with a bullet through the belly; then one may know that perforation, with acute septic peritonitis, is imminent or has already taken place. Operation is then to be done at once, for delay is fatal. Remove the appendix, wash out the belly with warm normal salt-solution, wash it out over and over again, and then drain with strips of iodoform-gauze or tubes, or both. Good washing and free drainage give the only chance for life. These cases are what may be called fulminating appendicitis, or general septic peritoneal infection, and run their course quickly. The whole tale is told usually in 48 hours.

I have gone over, in a very brief and imperfect way, three forms of appendicitis, to distinguish them from the variety presented in the present paper. The cases reported are known as relapsing, or recurrent, or chronic appendicitis, the last name, to my mind, being the most appropriate.

An individual may have an attack of appendicitis more or less severe and the symptoms may gradually subside and disappear, and it is very possible he may never have a second attack; but if the first seizure is at all severe, it is likely that the appendix and parts around it are never entirely restored to their original condition, and at variable intervals of time the attack will recur, with greater or less violence. No one can foretell, from the history of the first attack, what the nature of the second attack will be, or when it will occur. I have seen three years intervene between the first and second seizures, and then a savage attack ensue. Dr. George W. Gay, of Boston, who has written a clever article on the subject, reports an interval in his own case of 17 years between the first and second attacks. But the pathologic changes caused by the first attack may disappear and a second seizure never come on, and a patient is entitled to that chance, if he so decides. But if the attacks are repeated, and especially if the intervals between them are becoming shorter, and the attacks more violent, then the appendix should be removed. The next attack may be fatal, or at least the man becomes a hopeless invalid.

Ever since Escherich discovered the microbe which he called the bacillus coli communis, it has been almost conclusively demonstrated that this bacillus is the genesis of a certain number of maladies, and the chief among them is appendicitis. This microorganism has its domicile in the digestive tract of man and animal, extending from the mouth to the anus. It was for a time regarded as not only inoffensive, but positively useful in the animal economy, but it has been discovered that, under certain circumstances, this microbe may become very virulent and hurtful. Any morbid condition of the bowels makes it virulent; inflammation, obstruction, strangulation, diarrhea, or constipation may render this bacillus virulent. Constipation is a common cause; indeed a very large proportion of

the cases of all kinds of appendicitis that I have seen were subjects of habitual constipation.

The bacillus coli is generally found in cases of appendicitis, alone, or sometimes associated with other pathogenic germs. The pathologic conditions, following one or more attacks of appendicitis, may be partially gathered from the report of my cases. The appendix may be fastened like a strap across the cecum, interfering with the peristalsis of the gut; it may be fixed by adhesions to other parts; it may be bent upon itself and its lumen occluded by kinking; a portion of the canal may be obliterated and closed at its cecal end, and the distal end distended to several times its natural size and filled with mucus or pus, or both; a small abscess may be found around the appendix, walled off strongly by a barrier of well-organized fibrin; or else, it is said, a foreign body may occupy its canal. I have never seen the last; I have seen soft fecal matter lying in the canal, and several times hard dry balls of fecal matter. In one case in Staunton, Va., in which I operated for acute appendicitis on a physician's son, the doctor opened the appendix before I completed the operation, and found what looked like two cherry-stones. Two little, round, smooth balls rattled in a dish as cherry-stones would be expected to do, and the mother stated, at the time, that her son had eaten pickled cherries a few days before. I afterward found, when I mashed the supposed seeds, that they were dry, hard fecal masses. In another patient, a young child, upon whom I operated for acute appendicitis for Dr. Moseley, of Richmond, a small, white, kidney-shaped substance, supposed to be a bean, was found in the discharge; this also proved to be fecal matter and fat. I know, of course, that foreign bodies are found in the appendix, but in the 36 cases of operation in my hands I have never seen one.

It is naturally asked, Is medical treatment in these cases of no avail? I confess, when I recall the pathologic conditions found in my cases, that medical means, to my mind, can be expected to help but little, if at all. In the present state of the science of medicine, one cannot expect them to overcome the difficulties that I have just now stated. But it may be urged that the cases may be only of moderate intensity, and the pathologic changes may be slight. Unfortunately we cannot always tell by the symptoms and duration of the attack how much mischief is done to the parts. An apparently slight and insignificant attack may leave the appendix and parts around it hopelessly crippled and diseased, while an apparently savage attack results in trifling mischief. I have operated after two or three comparatively slight attacks, and found the parts so matted and diseased as to tax all my skill, and only after hard work of an hour and a half completed the task; and I have operated when from severe and lasting symptoms I anticipated great trouble, and found but slight disease, and completed the operation in a few minutes. However, I am not opposed to medical measures. I confess, as I say, when I recall the state of the parts as I have seen them, I cannot feel hopeful of any treatment short of the knife. Prolonged rest in bed, rest not for days but for weeks, a restricted and regulated diet, purgatives, and counter-irritation with iodin and blisters, massage, and an intestinal antiseptic, as, *e. g.*, salol, constitute the chief remedies, and, through them, individuals who have had one attack have escaped a subsequent one. It is only fair to say that persons who have had one attack, and who have not received the foregoing remedies, but followed their usual course of life, have also escaped a second attack. I am frank to say, however, that I believe the former are more likely to escape than the latter.

The first case reported was not one of good surgery. The appendix should have been removed. That the patient got well, and has remained well for several years, is evidence rather of good luck than good surgery. These conditions, as is well known, are sometimes confounded. The case teaches, however, the value of ferrous sulphate in preventing reunion of separated parts, a fact that I have had repeatedly demonstrated to me before and since that time.

Cases V and VII show the hazard of leaving a raw surface, as the stump after castration in women, unprotected. It would be better to paint the raw surface over with the iron spoken of, touch it with a hot iron, or a hood of peritoneum from some neighboring tissue may be used.

Cases II, VI, VIII show the influence tubular and ovarian diseases may have upon the appendix.

Concerning Case XVII, I think it is not too much to say of this, my only fatal case, that he would probably have recovered if the operation had been done in a well-appointed modern hospital.

(To be concluded.)

UNINTERRUPTED ANESTHESIA IN OPERATIONS UPON THE FACE AND MOUTH.[1]

By EDMOND SOUCHON, M.D.,
OF NEW ORLEANS, LA.;
PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY, FELLOW OF THE AMERICAN SURGICAL ASSOCIATION.

ALL surgeons know the trouble, anxiety, and danger of operating upon the face and mouth on account of the necessity of removing the face-piece through which the anesthetic is administered so as to uncover the field of the operation and enable the operater to proceed; soon after the removal of the face-piece the patient recovers from the effects of the anesthetic and the operator has to stop to

[1] Read at the meeting of the Southern Surgical and Gynecological Association at Washington, D. C., on November 12, 1895.

allow the face-piece to be reapplied; and so on during the whole of the operation. All these drawbacks and delays become very much worse when the patient happens to be one of those unfortunates who respond badly to the effects of the anesthetic, or who often wake up quickly from a deep anesthesia and become almost unmanageable. It is a very sorry sight, that of an operation half completed, and an unruly patient bleeding freely and spurting blood all around by the wild movements of his head. His life is then at stake from the impossibility of completely controlling the hemorrhage all the while and of completing the operation in time.

It has been my ill-luck to have once encountered such a case, and the impression was such as to make me determine that henceforth I would control my patient by safe and uninterrupted anesthesia. Junker's inhaler is not equal to such emergencies, because, unless the bulb is pressed very gently, the liquid anesthetic is forced into the pharynx. I therefore devised an apparatus to that end, reducing the pain, the bleeding, the shock, and the duration of the operation to a minimum.

The apparatus was called the *Anesthetizer* or *Anesthetic Injector*, and its description was published in the *Journal of the American Medical Association*. Its feature was that neither the inlet-tube nor the outlet-tube dipped into the liquid, so that it was impossible for any liquid anesthetic to be injected into the patient's pharynx. But its drawback was that ether alone could not be used, because it was too freely diluted with air to have a thorough anesthetic effect. Besides, the mixture of air and chloroform was also rather diluted, and, should a particularly refractory case present itself, there was no positive means of increasing the strength of the dilution at will and as necessity required. These inconveniences have been overcome in the new, improved apparatus. It is an injector, truly, and not an inhaler as we understand it.

In this apparatus the inlet-tube dips into the liquid so that the air in passing out through the outlet-tube is much more charged with the vapors of the anesthetic. But here at once with this dipping of the inlet-tube came two difficulties: First, upon releasing the compression on the bulb, the liquid was aspirated into the bulb; and, second, the liquid anesthetic was thrown through the outlet-tube into the patient's pharynx. It required the utmost care and gentleness to avoid these accidents, and there were cases in which the full power of the apparatus had to be brought to bear to maintain the patient uninterruptedly anesthetized.

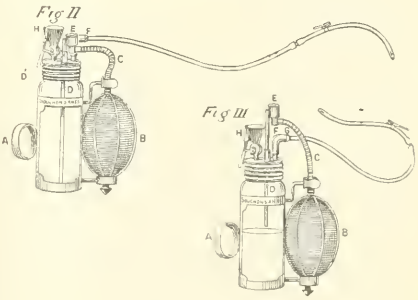
These difficulties, therefore, had to be conquered, and they have been by placing a proper valve on the course of the inlet-tube, and by maintaining a certain distance between the level of the liquid in the bottle and the point of exit of the fixed brass portion of the outlet-tube. That distance must not be more than one-half of the height of the receptacle. It took much experimenting and close observation before this was found out. Diaphragms, perforated tubes, etc., were used, but in vain, as they all failed when the liquid exceeded a certain amount. Now, a certain quantity is necessary, otherwise it would compel a too frequent replenishing. Of course, the size of the rubber bulb is an important factor; if too small, it would not inject a sufficient amount of the anesthetic; if too large, it produced such a splashing in the bottle as to require but a small amount of liquid; otherwise, if too much, the liquid would be injected into the pharynx.

The bulb is $7\frac{1}{2}$ in. in circumference at its middle. The size of the bottle is also to be considered; it is $6\frac{1}{4}$ in. in circumference or $1\frac{5}{8}$ in. in diameter. Therefore the size of the bottle and of the bulb, the amount of liquid in the bottle, together with the distance of the surface of the liquid from the brass and fixed orifice of the outlet-tube, are the correlative factors.

Description of Apparatus. The present improved apparatus is considered perfect in all particulars. It is

Fig I

SOUCHON'S IMPROVED ANESTHETIZER



composed of a glass cylindric receptacle, with a frame supporting a ring, A, for the thumb and a rubber bulb, B, so that it can be worked with one hand. From the

bulb originates a rubber tube, C, wrapped with coiled wire to prevent it from bending; it ends in the inlet-tube, D; just at the point of junction at E is a ball-valve which prevents the liquid from entering the bulb when the pressure upon the latter is released. The inlet-tube extends through the liquid anesthetic to the very bottom; its lower end is bevelled to prevent the orifice from being stopped by coming in contact with the bottom of the receptacle.

This inlet-tube slides up and down through another shorter tube, D^1, so that it can be drawn well up above the level of the liquid anesthetic, thereby diminishing the strength of the vapors injected through the outlet-tube into the pharynx. This feature makes the apparatus thus set an anesthetizer of the first model.

There is a circular line on the receptacle showing how much, and no more, liquid anesthetic should be poured in without running the risk of injecting liquid through the outlet-tube. This line corresponds to the middle of the receptacle from the bottom to the upper surface of the lid. This quantity will suffice to keep a patient anesthetized for nearly two hours with chloroform alone, one hour and a half with a mixture of equal parts of chloroform and ether, and about an hour with ether alone. The receptacle is closed by a metallic lid that screws around its neck; a washer makes it air-tight.

From this lid springs the metallic portion of the outlet-tube, F; it originates directly from the under surface of the lid; it is ½ in. in diameter inside and one and one-half inch in height; after a *very sharp* curve of 90°, it terminates by an orifice of not less than $\frac{3}{16}$ in. Repeated experiments have determined these dimensions; any decrease in them increases the chances of sputtering and of injecting liquid into the throat.

To this metallic portion is attached a rubber tube, 30 in. long, so that the anesthetist can hold himself well out of the way of the operator, leaving more room and play for those directly concerned in the operation. This tube should be sufficiently rigid not to bend too easily; its interior diameter should be $\frac{3}{16}$ in. Its last eight inches are formed by an ordinary rubber catheter, No. 13 English, connected to the main tube by a piece of glass or metallic tubing; this nasal segment can be changed to a smaller one when operating upon children. It is provided with a clasp, seven inches from the extremity; this clasps the nostrils and holds the tube in proper position. The receptacle is readily emptied through the outlet-tube after the operation is over.

The lid is provided with a funnel through which the anesthetic is poured into the receptacle, and through which it can also be emptied after being used. To the edge of the funnel is adapted a clasp, with a long arm that answers for a hook by which the apparatus can be suspended from a buttonhole; the clasp is to catch on to the cloth of the gown when there is no button-hole for the hook. Thus the anesthetist may have both hands free, resting or helping for a while.

Modus Operandi. When the apparatus is to be used it is first filled with the anesthetic up to the circular line; that represents 2½ ounces. The nasal end of the tube is smeared with vaselin. If desirable, an aseptic thin towel in a single thickness can be thrown over the apparatus without interfering with the proper working.

After the patient has been thoroughly anesthetized by any of the ordinary methods, the face-piece is removed, the tube is introduced through the nose until the clasp is reached, a distance of 7 in., and the clasp is made to grasp the nostril and fix the tube; the end of the tube is then in the *lower pharynx*; that is necessary because, if too high up, the patient, breathing through the mouth, would not inhale a sufficient amount of the anesthetic.

The anesthetist places himself to one side or other of the middle of the patient, so as to feel the radial pulse, observe the respiration, and be well out of the way of the operator and his assistants. By compressing the bulb the apparatus is set to work. It injects *only the vapor*, and no liquid anesthetic into the pharynx, *regardless of the force used on the bulb*. The bulb, however, should be compressed gradually, not jerkingly, specially if it causes coughing or recoil of the patient. By compressing the bulb more or less quickly and thoroughly the amount of anesthetic is graduated. As much as possible the compression should take place at the time of each inspiration. This rule compels a closer watch on the respiration.

It takes very little anesthetic to maintain anesthesia when a patient has already been well anesthetized. It is important not to keep on compressing the bulb, if the patient does not re quire it, or if the stage or procedure of the operation is not painful. Much harm is often produced by all methods by unnecessarily prolonged *deep* anesthesia, which harm is often passed under the name of shock, exhaustion, etc.

At times, when the patient expires, a resistance is felt upon pressing the bulb; of course, all force on the bulb should be suspended until it is felt that the resistance has yielded and the patient is about to inspire.

Anesthesia with Chloroform Alone. When chloroform alone is used the effects are at their best, quick, and thorough. Greater care should be exercised when chloroform is used alone. It is then that it would perhaps be prudent to draw the inlet-tube up above the level of the liquid; the dilution is then diminished.

Mixture of Chloroform and Ether. The mixture of equal parts of chloroform and ether is the one I prefer. It has the advantage of the quick and thorough effects of chloroform and the stimulating action of the ether.

Anesthesia with Ether Alone. The use of ether alone in the apparatus at first excites the throat if the patient has been chloroformed, but this soon passes off, and anesthesia is well maintained throughout the operation. Of course, those patients who yield with difficulty to the ordinary method of anesthetization will be more troublesome with ether. It requires more ether, more complete and frequent compressions of the bulb, and a closer observation of the inspirations than when chloroform alone is used. We should remember, however, that ether, especially if used alone, is contraindicated in operations about the face, head, and neck, because of the great congestion which it usually produces.

Proportions of Anesthetic Vapor and Air. Mr. Hermann Fleck, Ph.D., Instructor of Chemistry in the Harrison Chemical Laboratory of the University of Pennsylvania, was kind enough to determine the proportions of anesthetic vapors and air at each compression of the bulb. When the tube is above the level of the *chloroform* the expelled air contains 8.2 per cent. of vapor; when the tube extends through the chloroform, the expelled air contains 11.9 per cent. of vapor, or about one-third more. When the tube is above the level of the *ether* the expelled air contains 18 per cent. of vapor; when the tube extends through the ether

the expelled air contains 37.2 per cent., or double the quantity. It is noticeable that the expelled air is much more charged, about three times more, by passing through ether than when passing through chloroform, and only about twice when the tube does not extend into the anesthetic. In all cases, of course, the dilution after it passes from the outlet-tube and is inhaled is from 4 to 6 times weaker.

Sundry Remarks. The amount of anesthetic consumed is very small, about 1 ounce of chloroform per hour, but 2½ ounces of ether for the same length of time. There is no external evaporation, and this will be greatly appreciated by the operator and his assistants.

The apparatus works very well also when the head is lowered, as in the Rose position.

Should the operation involve the two nasal cavities at the same time when the tube might be in the way, the tube could be introduced through the mouth into the lower pharynx, care being taken to prevent the tube being bitten by using a wedge or gag, or by connecting the end with a metallic tube, or, best, with a disinfected male metallic catheter, which the teeth could not crush.

The end of the flexible tube may be connected with the apex of the face-piece or cone placed over the mouth and nose and the vapor of the anesthetic forced into it. But the face-piece must fit tightly and exclude the air, because the air from the bulb has already diluted the chloroform. For that reason, ether used thus very seldom produces anesthesia.

Anesthesia may be produced from the outset without previously using a face-piece by introducing the tube at once through the nose into the lower pharynx. This does away with all possible nasal reflexes, the effects of which have been so graphically demonstrated by Professor Laborde, the successor of Claude Bernard and Paul Bert at the College de France, in Paris.

The lower end of the bulb is so arranged as to allow it to be connected with a piece of tubing leading to a bag of oxygen, if desired.

For obvious reasons it is important that all connections should be air-tight.

Care should be taken that no bends or kinks form in any part of the tubes, or this will interfere with the proper working of the apparatus.

Sometimes the little ball-valve in the tube becomes adherent to the margin of the orifice inside and the bulb does not empty; by striking on the tube at that point the valve becomes loose again.

The bulb is detachable and may be removed whenever this becomes necessary, that is, when it loses its firmness and elasticity, and when the valves get out of order. This is determined by pressing tightly the tube of the bulb and compressing the bulb; if the air is then expelled it is because the valves are out of order. The manufacturer can supply a new bulb by mail.

Every part of the apparatus can be taken apart to be thoroughly cleaned and sterilized.

The apparatus is most useful also in operations about the head and neck, allowing the operator and his assistants more room, and sparing to all around the unpleasant odor of the anesthetic.

The device has been used in the Charity Hospital of New Orleans by about all the surgeons, Drs. Matas, Delaup, Martin, Bloch, etc., also by Dr. De Roaldes in the Sanitarium. I have used it for Dr. Lange, in New York, in the presence of Drs. Halsted and Fenger, and in the Jefferson Clinic, in Philadelphia, for Drs. Keen and Hearn, in the presence of Drs. Da Costa and Barton. All these surgeons expressed themselves well pleased with the results.

No ill effects have ever resulted from the direct contact of the vapors of the anesthetic with the mucous membrane of the pharynx or larynx.

Conclusions. This apparatus is the *only one* with which there is *no risk of injecting liquid anesthetic in the pharynx regardless of the force applied to the bulb.* Its safety, simplicity, compactness, portability, efficiency, and easy management speak for themselves.

Its use results in a great saving of time, pain, bleeding, and shock to the patient, thereby contributing materially to the saving of life in operations which for the most part are long and bloody, and often bring the patient to death's door. It also provides a great saving of mental strain to the surgeon, who can proceed rapidly and uninterruptedly with the operation.

REPORT OF 111 ADDITIONAL CASES OPERATED UPON WITH THE ANASTOMOSIS-BUTTON.

BY J. B. MURPHY, M.D.,
OF CHICAGO;
PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO AND PRESIDENT OF THE MEDICAL STAFF OF COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXIAN BROTHERS' HOSPITAL; PRESIDENT OF THE NATIONAL ASSOCIATION OF RAILWAY SURGEONS; FELLOW OF THE CHICAGO ACADEMY OF MEDICINE, ETC.

(Concluded from page 538.)

BACON'S OPERATION. This operation was described by Dr. J. B. Bacon,[1] and has been performed twice. The first operation was performed by Dr. Bacon July 8, 1893, for a specific stricture of the rectum. Two years and three months have now elapsed, and there is not only no return of the stricture, but the caliber of the rectum has enlarged since the operation, the infiltration has disappeared, and the rectal walls are now soft and pliable; it is

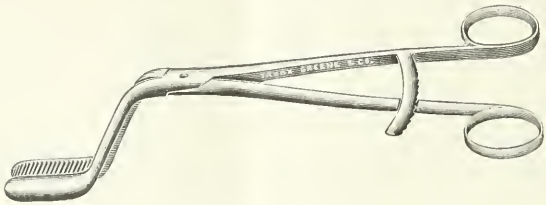
10	 1893	Amer. Med.-Surg. Bulletin.	Schachner, Aug., Louisville, Ky.	Malignant obstruction.	Cholecystenterostomy.	S. S.	D.	Death, 36 hrs.	Operation complicated by tear in intestinal wall, outside of button, which was sutured; liver enlarged and hard.
11	Feb. 19	Pacific Med. Journ., June, 1893.	Rosenstein, Julius, San Francisco, Cal	Common duct obstruction.	Cholecystenterostomy.	.....	D.	Death, 15 days	Post-mortem: Carcinoma of liver; circumscribed abscess around seat of approximation; no union; no peritonitis. It will be noted that the abscess was circumscribed, but it is not clear whether the infection was primary, and prevented adhesions, or secondary, the result of failure of union. As there was no adhesion at seat of approximation, it is fair to presume the infection was primary, otherwise there would be union in some places.
12	1894 Dec. 3	Ann. Surg., xxi, 581.	Shepard, F. J.	Carcinoma of Pancreas.	Cholecystcolostomy.	.....	D.	Hemorrhage 4th day.	Friable wall of gall-bladder cut through by button.

the best result I have ever observed following an operation for stricture of the rectum. Case 148, in this report, was operated upon for a similar condition, with equally gratifying results. The infiltration has almost entirely disappeared, and only four months have elapsed since the operation.

The third case, resection of annular carcinoma of the rectum, also occurred in my practice, and, at the present time, thirteen months after the operation, there are no indications of its return. The fourth case, by von Baracz, of Lemberg, has not been reported in full.

FIG. 1.



Gall-bladder retention-forceps.

RESECTION OF THE RECTUM. This operation has been performed but a very few times by this method, and the number of cases does not warrant us in

FIG. 2.

Murphy button.

making general deductions. The first Kraske operation by this method was performed by Dr. Henry O. Marcy, of Boston, October 16, 1893. The patient

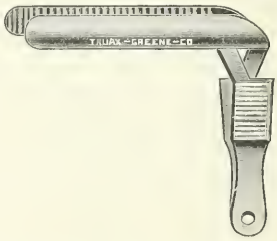
FIG. 3.

Gall-bladder drainage button.

died about one year later from recurrence of the carcinoma. Another case occurred in my own practice, and was one of annular nonmalignant stricture; the operation was performed January 16, 1894; there has been no recurrence of the stricture up to the present time, two years and nine months after the operation.

The objections that have been urged against the button are, first, that the size of the opening made is too small, and that stenosis will follow. Experience shows that contraction does not take place in the cicatrix produced by this method of approximation, when the viscus is in full function. The

FIG. 5.



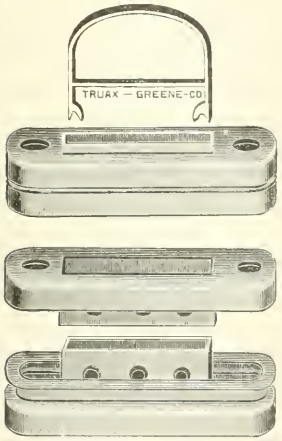
comparative absence of contraction by the button-anastomosis is well illustrated by von Frey (*Beitr. zur klin. Chirurg.*, 1895, xiv). I am convinced that it will not be necessary to employ button No. 4 except in the large intestine, No. 3 being amply large for all small-intestine approximations, and the oblong button may be used in gastro-

FIG. 4.

enterostomy if a larger opening be desired. The second objection is that the button will produce obstruction, as it is a foreign body in the intes-

tinal canal. Experience has so far supported my original claim that it will not produce obstruction, except when there already exists a pathologic diminution of the intestinal caliber. There is one case reported in which the button produced intestinal obstruction and perforation. The doctor reported as follows: The patient had repeated attacks simulating intestinal obstruction, and I feel sure that, should I have another case similar to this, I could easily extract the button and prevent the fatal termination. It has not diminished my enthusiasm for this ideal device in the least. The ease and certainty with which it can be applied discounts all its possible dangers. I have heard of another case, still unreported, of which I lack sufficient details for comment, but it was mentioned as a case of obstruction from the button.

FIG 6.



It is a source of great satisfaction to me to find from this large experience—278 cases—that this accident is likely to be a rare one, since, from a purely theoretic point of view, in the beginning of the use of the button it caused me some misgivings.

The third objection is that the caliber of the button will become occluded. There have been three cases reported in which this accident occurred. The occlusion of the opening of the button should not occur if the precaution is taken to keep the contents of the bowels fluid by mild catharsis—a practice I have always followed.

In experiments on the dog, I find that unless care and judgment are exercised the mesenteric vessels that supply a larger portion of the intestine than it is intended to resect are liable to be ligated. In that case gangrene of the intestinal extremities, instead of adhesion and union, will probably be the result.

The most frequent cause of nonunion and of fistulæ following operations for intestinal anastomosis is infection at the time of the operation.

I would respectfully request the members of the profession to kindly send me reports of their experiences with the anastomosis-button, with sufficient details to permit of their being used in the tabulation.

CLINICAL LECTURE.

A CASE OF PERNICIOUS ANEMIA DUE TO ILEO-COLIC DISEASE.[1]

BY WILLIAM PEPPER, M.D.,
OF PHILADELPHIA;
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

GENTLEMEN: I have the honor to present to you for study to-day a case of chronic disease, the symptoms of which have been to us a subject of keenest interest and a cause of deep anxiety. The patient is a man of fifty-four years, a farmer, whose father died at the age of fifty years of typhoid fever; his mother died at the age of eighty years of causes unknown. He has four brothers living, three in good health, the fourth being troubled, he says, with rheumatism and edema. One brother died of pulmonary tuberculosis, and one sister died of some tumor of the stomach, probably a carcinoma. Our patient had all the ordinary diseases of childhood, since when he has never been confined to his bed and has enjoyed exceptionally good health. Eight years ago he had a slight attack of rheumatism in his shoulder, which, however, never prevented him from doing his work. Eleven months ago he noticed that the slightest exertion made him weak and provoked shortness of breath and palpitation of the heart. He could not walk for any distance without stopping to rest. At the time this occurred the patient was living just the same as theretofore, had the same duties, ate the some food, had no especial care or worry. This condition persisted during the winter. Four months ago his feet began to swell at night, particularly after he had been on his feet a great deal. He was never a hearty eater, but he ate rapidly and did not properly masticate and insalivate his food. In December of last year, before the swelling of the feet appeared, he lost his appetite, his breathing became heavy, and in the morning he would raise dark-brown coffee-colored mucus, and at times he would also expectorate dark matter during the night. For a long while he had had some symptoms of dyspepsia, with occasional attacks of diarrhea, which, however, were probably only the result of his bad habits of eating. For some years he has had to urinate occasionally during the night, but during the last two years he has complained of frequent nocturnal urination. His bowels have always been regular, except for occasional looseness.

From the foregoing symptoms various diseases may be suggested to you. When we heard that carcinoma

[1] Delivered in the Hospital of the University, October, 1895.

was in the family, in connection with his age, loss of flesh, cachectic color, and the raising in the morning of dark mucus like coffee-grounds, we feared he might have carcinoma of the stomach and we examined the stomach and its contents to determine whether there was any neoplasm there. As you see, the color of his abdomen is intensely anemic. The stomach is moderately dilated, the lower margin reaching to 1½ in. below the navel and will contain 2½ pints, but not with the most extreme care could any tumor or hardening or thickening be found anywhere in the gastric area. We washed out his stomach with 7½ pints of distilled water and afterward gave him a test-meal, an hour and a half after which the contents of the stomach were expressed for purposes of analysis. The last portion of the lavage came off clear, in fact all was fairly clear, there being only a slight amount of mucus. The gastric contents were tested for free hydrochloric acid and none was found. The tests also showed some reduction of the digestive juices and impairment of the motor power of the stomach-wall. There is no proof, however, that the pylorus is obstructed. The bowels have been rather loose, and vomiting has been absent. I have told you that free hydrochloric acid was absent and we are trying to learn what that sign means. You will remember that earlier observers considered the absence of free hydrochloric acid after a test-meal, coupled with cachexia and loss of flesh, as almost pathognomonic of gastric carcinoma. Further observations, however, have revealed the fact that free hydrochloric acid is absent under other conditions, such as profound anemia and in atrophy of the glands of the stomach connected with no trace of any malignant disease. A continued persistent absence of free hydrochloric acid is, however, as a sign of carcinoma, of some diagnostic value; but the mere absence of acid without the concomitant symptoms cannot be depended upon to establish the diagnosis.

Here is a man of the requisite age, raising coffee-grounds material, losing flesh, growing weak and progressively cachectic, and with no free hydrochloric acid; but the direct exploration of the stomach fails to show thickening or tumor; nor is there any pyloric obstruction so far as I can judge; no dilatation of marked degree, no visible reversed wave of peristalsis, no vomiting of retained fermenting matters. I do not say that you will always find, when there is malignant disease of the stomach, pain, vomiting from mechanic obstruction, gastrectasis, increasing constipation, or even tumor. There may be a carcinoma, not large, in the posterior wall of the stomach, centrally situated, a mural growth; in such a case food can to a certain extent undergo the process of digestion, be propelled past the pylorus, and in connection with such a lesion the only symptoms may be emaciation, cachexia, and failure of digestive power. Although we must always bear in mind the possibility of such a condition, nevertheless, in the absence of positive diagnostic points, we are not justified in allowing our anxiety and fear to run away with us and lead us to believe that carcinoma exists. On the contrary, we should fight until the last moment against the admission of that fatal diagnosis. We see too much of this yielding to anxiety. This is a diagnosis we should not be forced to make until we can demonstrate it; always give the patient the benefit of the doubt. The moment a doctor would tell me that I had carcinoma, while there were still the shadow of a doubt, unless he could demonstrate it, I would have no further use for that physician. Such a diagnosis paralyzes all one's efforts. You cannot try earnestly to relieve a patient whom you think has carcinoma; all you can attempt to do is to make his last moments painless.

This man also had edema of the feet, increasing pallor of the surface, and frequency of urination, which has been imperative during the night, calling him up often. He was a farmer, accustomed to rising early and exposing himself to all sorts of weather. With such men nephritis is a common affection. Upon examination of the urine, however, we found it normal; 1018, acid, no albumin, no sugar, and no casts. The edema was not the ordinary edema of nephritis, with puffiness about the eyelids; it was more the edema of a weak heart or of poor blood, coming on at night, particularly after extra exertion during the day. There is, however, no sign of organic disease of the heart to explain this.

If this man has no organic disease of the stomach, liver, kidneys, heart, or lungs to explain these signs, where are we to look for the causes of this progressive weakness and malassimilation? The blood at once suggests itself, and we turn with the greatest interest to this examination. A careful examination has given the following results: Red corpuscles, 1,250,000 in the c.mm.—to 25 per cent. of the normal; hemoglobin 20 per cent.—a reduction of 80 per cent., but corresponding closely to the reduction in the red globules; leukocytes 9000. I beg you in particular to note the corresponding reduction of red cells and hemoglobin in this case, and contrast that with the disproportionate oligochromemia seen in chlorosis. The blood showed a high grade of poikilocytosis—ill-formed and poorly shaped red corpuscles. There were also microcytes, minute globules much smaller than the normal red cells and often more intensely colored. Besides these there were large cells, macrocytes; furthermore, nucleated red cells. Here, then, is a blood that presents an oligocythemia and a corresponding oligochromemia, with dwarfed cells, giant cells, misshapen cells, and nucleated cells. Here is evidence that the whole hemic function is profoundly disturbed. The charts you here see illustrate the conditions I have mentioned.

Such a hemic condition corresponds to the condition of the blood in the disease known as progressive pernicious anemia, a disease that has been studied very closely for the past 20 years, but the real origin and causation of which are still obscure.

When progressive pernicious anemia was first recognized, it was regarded as an absolutely fatal disease, coming without cause, like leukemia and carcinoma, and the other great cachexiæ, and running its course to an invariably fatal result. But we have since learned that while there are some cases of pernicious anemia that run the course I have just stated, there are other cases clinically indistinguishable from them that yield to certain forms of treatment. For this reason, while the disease holds for us still the intense scientific interest it has always presented, a deep study of these cases will lead us to practical improvement in differential diagnosis and treatment.

Let us study together the clinical features of this disease and endeavor to find some adequate cause for it. If you have a case of nephritis you may have a high

degree of anemia due to the retention of poisonous substances and to the associated tissue-changes. In a case of carcinoma you have also something to explain the anemia. But progressive pernicious anemia is essential; there is no organic disease or lesion to explain it. The symptoms are that the patients feel themselves becoming gradually weak and weaker, the skin meanwhile assuming a pale, slightly lemon-yellow tinge. The emaciation is very irregular; some patients lose a great deal of flesh, but frequently others lose little or none at all. The feet become puffy when the patients stand or walk. There is dyspnea after slight exertion, palpitation of the heart, hemic murmurs, pulsating vessels, occasionally a venous hum, the pulse-rate often rapid. In the present case there is a soft systolic murmur, best heard at the base of the heart, surely hemic. Patients suffer with attacks of headache and vertigo and complain of ringing in the ears. The muscular weakness and pallor increase progressively. These are the familiar features of the disease. The condition of the stomach varies; digestion is impaired, and in some cases tremendously so. There is a tendency to hemorrhages, the mucous membranes bleed easily, and ecchymoses form in the retina frequently, in the serous membranes, brain, and other organs, sometimes on the skin, hemorrhages probably partly due to arterial degeneration and partly to capillary embolism. As a rule the disease presents but little disturbance of temperature, yet there are not infrequently sharp irregularities, and I have noticed a slow febrile movement as though there were some obscure toxic state of the system causing the variation. Nervous symptoms are not uncommon; paresthesiæ of the extremities, sensation diminished and retarded, the knee-jerks diminished or even lost, and in some cases an almost typical ataxic gait. These symptoms, however, are also found in intense secondary anemias, and post-mortem examinations reveal scattered spots of degeneration in the cord and systemic sclerosis of the posterior columns, secondary lesions due probably to some toxic influence. As the case advances the patients fall into an extraordinary condition of debility, with greatly impaired digestive power. The blood becomes almost watery, general edema appears, intercurrent attacks of diarrhea, hemorrhages, and then death.

During all this time you find that the lymphatic glands have not swollen at all. No evidence of organic disease is given. It is true that the very poor condition of the blood leads to an almost universal fatty degeneration, the result of deficient oxygenation. The heart and liver may thus become very fatty, but you will find no organic lesion to primarily explain the condition. There will be changes in the medulla of the bones, which appear not yellow but a dark-red, a change due partly to a diminution in the normal amount of fat, and partly to an increase in the number of nucleated red blood-corpuscles. But this again is a change not confined to cases of essential pernicious anemia. The spleen in some cases becomes moderately enlarged, in some cases so conspicuously enlarged that some of these cases have been termed splenic anemia; in many cases the size is not altered. We must remember that in some cases there is a great deal of digestive disturbance, and in the post-mortem cases presented for examination there is sometimes almost complete atrophy of the tubules of the stomach. This shows chronic gastritis with proliferation of cells and increase in the connective-tissue of the submucosa which becomes organized into a dense fibrous layer and which surrounds and grasps the gastric tubules, causing their atrophy in the same way that cirrhosis of the liver will produce atrophy of the hepatic cells. Another change constantly found in bodies in which death has resulted from pernicious anemia is the increased deposition of iron in the liver, pancreas, spleen, and kidneys, particularly in the liver, where the iron is deposited in the peripheral zone of the lobule. This points to a destruction of blood somewhere in the body, probably largely in the portal circulation, the products of which are collected in the liver; and corresponding to this the urine frequently contains pathologic urobilin. In addition the urine may contain an excessive amount of indican; and the total nitrogen-elimination is generally increased, this excretion going hand-in-hand with the excessive breaking down of the body-proteids due to the diminished entrance of oxygen to the tissues.

What are we to think of the cases of severe anemia not secondary to nerve-lesions—of the essential anemias, excluding those in which parasites or atrophy of the gastric tubules are found, the cases in which all the post-mortem changes seem effects and not causes? It seems certain that the dwarfed, deformed, and fragmented corpuscles, the hemoglobinemia, the excess of iron and pigment, point to an abnormal hemolysis, and, furthermore, experimental hemolysis has produced in animals a condition resembling pernicious anemia. On the other hand, the malformed macrocytes appear to be a sign of faulty blood-formation; and the nucleated corpuscles look like perverted attempts of the bone-marrow at hemogenesis. If the causes lie in defective hemogenesis, the remoter causes of this defective blood-formation are entirely obscure. But there is clinical and experimental evidence for conditions which can cause increased hemolysis, and these conditions are the formation in and absorption from the alimentary tract of toxic substances, the nature of which is to us as yet entirely unknown. It seems probable that the products of ordinary fermentation cannot produce this condition; the toxins are of more complex origin and nature.

In approaching the treatment of a case of pernicious anemia, you ought always to attempt to ascertain whether the case before you is one of those connected with atrophy of the gastric tubules. In some of these cases the catarrhal symptoms are marked and the power of digestion profoundly reduced; and such cases may properly be called pernicious anemia of gastric origin. You must not expect to find the stomach always dilated in these cases; sometimes the walls of the stomach contract and the organ feels like a narrow transverse thickened band across the upper part of the abdomen. In other cases the gastric symptoms have been slight, but careful investigation will elicit the fact that, although slight, they have been frequent and of many years' standing. This man has always bolted his food, has for years suffered from occasional attacks of gastric irritation and diarrhea, the motor power of his stomach is impaired, his gastric juices much reduced; his stomach contains no free hydrochloric acid; he can take but little food without distress; his debility is so extreme and his anemia so intense, we are forced to fear that atrophy of the tubules has occurred. If the changes in the gastric mucous membrane have not gone too far,

some of these cases respond well to treatment directed to the local conditions; but when the anemia is very intense, treatment directed to the alimentary tract will accomplish little.

There are certain general indications. The patient's blood cannot carry enough oxygen to supply his tissues and he surely has no oxygen to waste in muscular exertion; therefore absolute rest in bed is for some weeks imperative, and almost complete confinement to bed is advisable for a considerable period longer. General massage is an excellent adjuvant and should be consistently employed. Inunctions of cod-liver oil, given once daily, have seemed to me to improve nutrition, and they are being given to this patient.

The gastrointestinal tract demands the most careful diet and treatment, and in these matters each case must be studied for itself. This man's diet consists of finely minced Hamburg steak delicately broiled so that all the juices are retained, dry toast or stale bread, and hot milk with a little coffee in it. In the last few days he has seemed to enjoy eating, and he does not suffer from nausea. However the diet may be modified it must be highly nourishing, given in small quantities and often. Hydrochloric acid is generally indicated, and this man is given a couple of drops after each meal. His bowels have been loose, and we have been washing out his colon daily with warm water and following this with an injection of a weak solution of silver nitrate. Were not his stomach so well behaved with his present diet and treatment I should practise gastric lavage, and cases have been reported in which striking results have followed this procedure.

For the blood we have one drug that exerts over many of these cases a most marvellous influence—arsenic. Under its use some cases recover entirely; others improve greatly, only to relapse. The drug must be pushed to the limit of tolerance, 10, 15, or even 20 drops of Fowler's solution thrice daily, guarded with a little opium to counteract the tendency toward diarrhea. You must watch carefully for constitutional signs of overaction, as puffiness under the eyes and gastrointestinal irritation, and should these appear the dose must be reduced. An irritable stomach does not in itself contraindicate arsenic, as the stomach often improves under its influence. But should the drug aggravate the irritability of the stomach it should be administered hypodermically. Iron rarely does good early in the treatment; when convalescence is well established it may be advantageously combined with the arsenic. Lately bone-marrow (of lambs and calves) has been tried in the form of glycerol extracts, in some cases with reported good results. In extreme cases the hypodermic injection of large amounts of normal saline solution, direct transfusion of blood, and the injection of defibrinated blood have all been resorted to, in some reported cases to good advantage. Treatment must be persevered in for a long time after the blood has been brought back to a good condition; and the patient must be kept under the most careful dietetic and hygenic conditions, and guarded in every way against the all-too-frequent relapse. This man has been under treatment nearly a fortnight. He expresses himself as feeling better; his appetite has improved, he bears the large doses of arsenic well, and his blood has gained 7 per cent. in hemoglobin and 100,000 red cells over the estimation on admission.

ORIGINAL ADDRESS.

SOME REMARKS ON EUROPEAN SURGERY.[1]

By W. W. KEEN, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

THE Dean has requested me to give you a brief statement of some of my observations during the past summer in the course of a short surgical trip in Europe. I would be ungenerous were I not, first of all, to acknowledge the extremely courteous reception, not only in their clinics, but often also in their homes, which I had from all the surgeons whom I saw, whether they were English, French, German, or Swiss.

The time was when European surgeons paid very little attention to American surgical literature, but I found American surgical text-books and American medical journals on the table of almost every surgeon whom I had the pleasure of seeing, and the names of our best surgeons are known as well in Europe as they are at home.

The general impression made upon me by what I saw was that in matters of scientific research and of original investigations Europe is much in advance of us. The length of the course of study, and the support by the government of Pathologic and Bacteriologic Institutes, combine to foster original investigations in scientific subjects much more than with us. Our young men must necessarily earn their living, and as these investigations require a great deal of time and bring little, if any, direct income, there are but few who can devote their time to science, pure and simple. Another thing which fosters this spirit of original investigation is the governmental control of the Universities, at least on the Continent. Governmental control of the Universities has, as a natural result, that a bright young man, who is an assistant to a distinguished surgeon, is sure to have his ability recognized by promotion; first, to the chair of surgery in one of the minor schools, and, if he still shows ability and industry, of promotion to one of the more important schools. In this country we are obliged to depend wholly on private munificence; and such promotion to other schools than the alma mater of the young doctor is the exception rather than the rule. I am glad to say that in the last few years the establishment of a number of laboratories of research by generous donors is beginning to bear fruit. The recent generous appropriation by the Legislature of Pennsylvania to our own hospital will enable us to establish a similar laboratory of instruction and research. Would that it were so with every school in the land! We should not be jealous of each other, for each one profits by the discoveries made in the laboratory of a friendly rival.

But when it comes to practical surgery, whether it be of mechanical means or operative procedures or of careful antisepsis, I believe that American surgeons are quite the equals of their European brethren. In fact, as to antisepsis at least, I think in this country we are more careful, as a rule, than many of the surgeons I have seen abroad.

[1] A *résumé* of a lecture delivered at the Jefferson Medical College, Sept. 27, 1895.

I noticed especially, in the preparation of their patients for operation, that I never saw patients brought into the operating-room disinfected the day before as is our usual American custom. In clinical lectures and demonstrations upon patients, not only were the parts manipulated by the operator, but sometimes also by members of the class, and the disinfection was not done until after this demonstration had been made. Then, however, it was very careful, and especially in the thorough scrubbing with soap and water, followed by alcohol or ether, and then with a sublimate-solution. I was particularly impressed, however, with the fact that most of the surgeons I saw washed their hands for a longer period, I think, than many of our American surgeons. So much so that I made up my mind that whenever I had nothing else specially to do I should employ my time scrubbing my hands. On the other hand, Mr. Horsley told me that he had gone to the opposite extreme and usually prepared his patients for 48 hours, instead of 24, before operation. The field of operation was generally surrounded with towels, which frequently became more or less displaced, and are not as efficient in their protection as large sheets, as we more commonly use in this country.

On the continent the needless exposure of patients in many cases struck me rather unpleasantly. Both women and men were brought in almost, and, in many cases, entirely nude, when it seemed to me not a necessity. We are more careful of the ordinary proprieties of life, it seems to me, in this respect, with no diminution of surgical safety and a great gain to social decorum.

I can scarcely wonder at the frequent deaths from chloroform which one sees so constantly reported in the medical journals abroad. In six weeks I saw six patients within an ace of dying. The rule that my old teacher, Prof. S. D. Gross, always laid down, that chloroform was to be given with plenty of air, seemed to be almost ignored. The chloroform was poured in considerable quantities on a towel or napkin, which was pressed close down on the patient's face, so that he breathed almost absolutely pure vapor of chloroform. In each of the six instances I speak of the operator had to discontinue his operation, and the patients were restored with difficulty by artificial respiration and rhythmic traction of the tongue. Apparatus such as Clover's or Ormsby's, for the administration of any anesthetic, was rarely employed excepting in England.

On my arrival in London Sir William MacCormac very kindly invited me to be present at the examinations for the Royal College of Surgeons, and I was extremely interested in observing their methods, which struck me as decidedly superior to our own. The Court of Examiners consists of ten well-known surgeons, such as Marsh, Morris, Davies-Colley, Anderson, Owen, Howse, Page, McCarthy, Godlee, and Sir William MacCormac, the President. The examinations were held in the examination-hall of the Royal College of Surgeons on the Thames embankment, near the Savoy Hotel They were held at what seemed to me a rather curious hour, from 5 to 10 P.M., with an interval of half an hour for a very simple lunch or supper.

The examiners are divided into five committees of two each, and every one who desires to take his degree in surgery is obliged to pass the Court of Examiners. You will observe that the examiners I have named differ from our own in this respect that they are all active teachers, whereas the Pennsylvania statute forbids any teacher to be an examiner, on the ground, I suppose, of possible favoritism. This is avoided by the Court of Examiners by having no teacher examine students from his own school. Every candidate has to write a thesis on an assigned subject and the theses are divided equally among the five committees, and thus are read and passed upon by two examiners.

The practical character of the examination, however, especially pleased me. For instance, on one evening, in a large room, five healthy men were brought in nude, with the exception of little bathing-tights covering only the pelvis and genitals, and they were placed upon five tables with two examiners at each table. Five students were then admitted and each one assigned to one of the tables. He was then examined carefully as to his knowledge of the normal surgical anatomy of the body. For instance, he was told to "Mark on this man's thigh the course of the femoral artery with a dermatographic pencil," and then was asked, "What is the relation of the vein and nerve to the femoral artery? Point out the borders of Scarpa's triangle. Mark on the skin the line of the carotid artery; the triangles of the neck. If a wound were inflicted here in the middle of the arm, what structures would be divided if the cut went to the bone? Where does the posterior tibial artery run at the ankle-joint, and what is the relation of its neighboring structures? Mark the boundaries of the liver. Mark where the gall-bladder is situated. Indicate the point of bifurcation of the aorta," etc.

After this had been continued for some time, each man was directed to a tray containing a very complete set of surgical instruments, from which the examiner would select, for instance, a lithotrite, and ask him what the instrument was and direct him to show the method of using it. He was obliged to find a trocar and canula, a lithotomy-staff, a grooved director, etc., and to show how they were used. This examination covered perhaps fifteen or twenty of the more important surgical instruments.

Another clinical examination was made in which five patients instead of five healthy men were utilized, and each student in turn was required to examine the patient, obtain his history by questions, examine the tumor, etc., by palpation or other suitable means, and was required to make his diagnosis and give his reasons for the diagnosis, the differential diagnosis, and the treatment. At another stage of the examination, each committee of two had on a table 10 or 15 specimens, dried, or more commonly in jars, from the Hunterian Museum, and the candidate was asked what the specimen was, what was the disease, the symptoms, diagnosis, and especially the pathology of the disease and its treatment.

After the examination was concluded on the second evening that I was there, those who had passed were called in before the entire Court, who rose to receive them, and they were addressed in a few practical pertinent remarks by the President, and their certificates of membership in the College were handed them.

This is the only "Commencement" which is held, if such it can be called, for there is no audience, no music, no flowers, no formal oration, but the occasion is one of the simplest.

The Court of Examiners are elected by the Council

of the Fellows for a period of five years. During the past year four examinations for membership besides two for the Fellowship were held. Of the 79 candidates for Fellowship, 45 were passed, 30 were postponed for reexamination at the end of 6 months and 4 for a year. For the membership 937 candidates were examined, of whom 579 were passed and 378 were postponed. The fees paid by all the candidates, amounting to a little over 1000, were somewhat over $50,000, and the fees paid to the Court of Examiners, as well as the examiners in midwifery, were nearly $30,000. Each of the Court of Examiners in Surgery receives about from $2000 to $2500 a year. The Court of Examiners in Medicine, who are elected by the Royal College of Physicians of London, examined 905 candidates, of whom 521 were passed and 384 were postponed. The Royal College of Physicians also elects, in conjunction with the Royal College of Surgeons, the examiners in midwifery, who passed upon 824 candidates, of whom 558 were passed and 268 were postponed.

You will observe, therefore, that not only are the examinations, in my judgment, more thorough and more complete than ours, but also they are much more severe; the percentage of men who failed being far greater than is usually the case in this country.

In London I had the pleasure of seeing quite a large number of operations by Messrs. Horsley, Howse, Davies-Colley, Barker, Jacobson, Fenwick, and others. I attended also a lecture by Mr. Horsley, in which he demonstrated the very important observations that he has made as to the cause of death in cases of cerebral hemorrhage, tumor, depressed fracture, and gunshot-wounds, as well as of violent concussion of the brain. He has shown unquestionably that such patients die from failure of the *respiration*, and not, as we have hitherto supposed, from failure of the *heart*. This had been already investigated by Duret, Bergmann, and others, but the conclusive proof has been given by Mr. Horsley. A dog was secured to a board after being chloroformed. The pulse was traced on a revolving drum by a pen by means of a canula inserted in an artery. The respirations were similarly marked by another pen. Seconds of time were marked by a third, and the instant when a ball was fired it was also marked upon the same drum by means of a fine wire passing across the muzzle of a pistol, the breaking of which by the ball recorded on the drum the instant of discharge. A ball was then fired through the brain of the dog. The instant that the ball penetrated, the respiration stopped and was very slowly reestablished, but gradually failed and ceased a second time as the blood poured out in the cranial cavity, producing compression.

The experiment was strikingly successful and the practical deduction drawn from it was equally important and should alter the treatment that we have heretofore employed. Usually, after any severe injury to the head, the patient has been stimulated by alcohol with a view to increasing the action of the heart, whereas, as Mr. Horsley has shown in the *Quarterly Medical Journal* for July, 1894, the proper practice would be artificial respiration until, by surgical means, the condition producing the compression has been remedied. As he has shown also in the paper I have mentioned, this means, namely, artificial respiration, has saved more than one patient who who would have died upon the table had it not been used.

The opponents of vivisection will find but little comfort in such practical results in the saving of human life from experimentation upon animals.

The first surgeon whom I saw in Germany was Prof. Krause in Altona, opposite Hamburg, and I found him an enthusiastic, earnest, and able surgeon. I was greatly interested in a number of cases that he showed me, such, for instance, as several of skin-grafting, in which he had grafted not the superficial layer of the skin only as in Thiersch's method, but the entire thickness of the skin. He is very careful, however, to remove all of the fatty tissue from the under surface of the graft. I saw several cases in which he had apparently permanently healed several ulcers of the leg by this method, which certainly deserves a trial at the hands of American surgeons. I saw him also operate upon an inguinal hernia, and he told me that in femoral hernia he had adopted Trendelenburg's method of chiselling off a piece of the pubes and turning it over on a hinge of periosteum, thus closing the femoral ring by bone.

Unfortunately Prof. Krause had no case at the time for removal of the Gasserian ganglion. You know, perhaps, that he and Hartley, of New York, independently and nearly at the same time devised the osteoplastic operation for the removal of the ganglion. He showed me, however, a number of photographs of the specimens which he had removed, which have been published in the *Münchener medicinische Wochenschrift* for this year. The specimens showed a more thorough removal than I had believed possible and more thorough, I think, than most other surgeons have accomplished. The specimens included the entire ganglion with the second and third divisions of the fifth nerve (the ganglion being torn off from the first division at its origin from the ganglion) and the root of the fifth nerve as far back, evidently, as the pons.

It will certainly be my aim hereafter, and I think it should be of surgeons in general, to effect as thorough removal as this. It is accomplished by dividing the second and third divisions of the fifth, seizing them with forceps and by traction tearing out the ganglion and its roots. Of five cases that Krause has operated on all have recovered, and not one of them suffered from any trouble with the eye, though one of them was threatened very seriously for a time with ulceration of the cornea.

Unfortunately Prof. Schede, one of the most brilliant operators in Europe, was incapacitated from operating by reason of an infected finger, but he kindly showed me over his splendid new hospital in Hamburg, one of the most complete that I have ever seen.

In Kiel I was most kindly received by Prof. von Esmarch and his already distinguished first assistant, Dr. Bier.

I was much struck with the systematic means of illustration which Prof. von Esmarch is constantly accumulating, and I do not wonder at the delightful illustrations in his books. A large case with many drawers was filled with water-colored drawings, literally by the hundred, of all sorts of pathologic and surgical cases and specimens.

The number of patients with tuberculous troubles in the hospital at Kiel was extremely large. I think I never saw so many tuberculous patients brought together. Dr. Bier is making a very thorough study of the effects of passive congestion, especially in tuberculosis of joints,

by means of a rubber bandage encircling the limb with sufficient pressure to produce slight congestion.

A number of very interesting operations were performed in his clinic, but I have not time to describe them in detail. In fact, I can only mention to you a very few of the operations and patients that I saw in the course of my little trip.

I was much interested in the cases of goiter which I saw operated upon by Prof. Kocher in Berne, who last spring reported to the German Surgical Society an extremely interesting series of 1000 cases—more than any other surgeon has ever operated upon. He operated upon two and Prof. Roux, of Lausanne, operated upon four in one morning. Prof. Socin, of Basle, operated on another, and I saw also several other glands removed by other surgeons.

The incision that the Continental surgeons now commonly make passes from one side of the neck to the other in a very sharp and rather long curve, with the convexity downward toward the sternum. More frequently they operate without any anesthetic, or by a number of punctures in the skin they deaden the pain of the first incision by means of cocain. The pain did not seem to be at all beyond endurance.[1] These men of large experience are decidedly of the opinion that the dangers of the operation are much lessened by operating without anesthesia. There is much less turgescence of the veins than when an anesthetic is used, none of course from vomiting or cough, and the absence of both of these phenomena after the operation diminishes the danger of complications. Another advantage also is that when the inferior thyroid artery is being dissected and tied, by engaging the patient in a conversation for a few minutes, the possibility of including the recurrent laryngeal nerve in the ligature is avoided, as the altered voice would immediately warn the surgeon of the danger.

In extirpation of goiter the hemorrhage was much less than I have before seen, by reason of the extremely careful hemostasis by means both of very numerous hemostatic forceps and double ligation of the larger vessels before division between the ligatures. Almost invariably the upper part of the tumor was first attacked and the superior laryngeal tied; then the thyroidea ima and then the inferior thyroid vessels. The method of enucleation for cystic growths, which has been so popularized by Socin, is adopted in all cases of cystic tumor suitable for such operation, and is considered preferable to extirpation, as it avoids any possible injury to the recurrent laryngeal, and also avoids the possibility of cachexia strumipriva, by leaving all the gland which is not diseased.

In Heidelberg, Prof. Czerny and his first assistant, Dr. von Beck, were most kind and showed me everything in their power. I saw, among others, an interesting case of actinomycosis of the right iliac fossa, which presumably arose in the appendix, an admirably done suprapubic cystotomy, and a number of other important cases which I have not time to mention.

In Berlin I was greatly interested in the clinics of Prof. von Bergmann and Prof. Bardeleben. The latter has, unfortunately, since died. I was especially interested in seeing a number of patients with fractures of the leg treated by the ambulant method with plaster-of-Paris. In connection with this method I learned one point, as to which I had not been especially careful heretofore, namely, that the foot should be slightly flexed when the plaster is put on, so that the patient walks upon the heel and not on the sole of the foot, thus avoiding either breaking the cast or producing pressure at the ankle.

Unfortunately I have not time to tell you of the many interesting things shown me by Prof. Kraske in Freiburg, Madelung in Strassburg, Championnière, Terrier, Péan, Hartmann, and others in Paris, but with these few illustrations, which I hope may have been of interest, I must close.

[1] Since this lecture was delivered I have operated upon one case with cocain only, and the patient assured me that he suffered but little pain. I was greatly pleased with the method.

CLINICAL MEMORANDA.

A URETHRAL CALCULUS OF LARGE SIZE.

BY P. M. ASHBURN, M.D.,
OF BATAVIA, OHIO.

THE opportunity of observing and operating in the following case I owe to Dr. T. A. Mitchell, of Owensville, Ohio, who had had charge of the case for 2 days before the time of operation, though he was not allowed to operate sooner. I think the case worthy of record because of the very unusual size of the stone. All the works on surgery, five or six in number, to which I have access here, speak of urethral calculi sometimes reaching a large size, but none of them says how large that size may be, or speaks of stones much larger than beans. Whatever may constitute large stones in the urethra, I cannot believe that many, if any, other people would allow a urethral stone to reach the great size of this one. For 30 years the patient had carried the stone in his urethra, and for 30 years had had dribbling of urine. In consequence of this he avoided the society of his fellows to such a degree as to be considered "queer." Still in all that time he never consulted a physician about the trouble, nor in any way sought relief.

He was a large man and by nature a strong one, but the 30 years of pain and worry had worn upon him a good deal, and he looked older than his years, and somewhat cachectic. His name was J. U., 43 years of age, by occupation a stonemason and farmer. His history is as follows:

His father is 75 years old and rheumatic; the mother is 65 years old and feeble. The patient has 6 living brothers, 1 of whom has vesical trouble, and 4 living and healthy sisters. The patient has had no sickness except that under discussion, and no injury except a scald as a small boy. He has been married for 5 years, and has a son 2 years old. When 15 years of age he was one day, while urinating, seized with violent pain in the perineum, and noticed a lump there. As he remembers it, the lump was the size of a cherry. The stream of urine at once stopped, and the patient was in such pain that he had to be carried home. Catheterization was at once performed, and without trouble, but it had to be continued for a month, the boy staying in bed for 2 weeks of the time. After that he always had pain and difficulty in passing urine, and almost constant dribbling of urine. For a voluntary passage he had to

grasp the penis far back and press inward at the sides and downward from above or upward from below.

Three years ago and again 2 months before the last trouble, he had acute attacks of pain in the perineum, with increased difficulty in urination. The attacks subsided, however, without treatment, and the patient kept about his work.

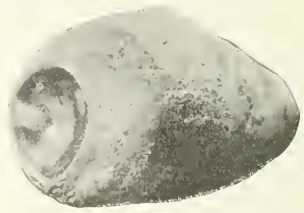
On September 3d, 1895, he again began to have pain in the urethra, with increased difficulty in urination. He continued to work, however, until September 9th, when he consulted Dr. Mitchell, who found a large lump in the perineum, which the use of a sound readily showed to be a large stone. Dr. Mitchell also recognized beginning infiltration of urine in the scrotum. He advised an operation, but the patient ridiculed the idea. The next day, however, he sent for the doctor, who then found the scrotum greatly infiltrated and intensely red and tender. The infiltration and swelling were greatest on the left side of the scrotum and extended along the left spermatic cord in such a way as to excite a suspicion of hernia.

Operation was again advised, and this time consented to, as the patient believed his life to be in immediate danger. The following morning Dr. A. W. Ashburn and myself saw the man in consultation with Dr. Mitchell. He then lay in bed, suffering great pain in the hypogastrium, inguinal regions, and scrotum, trying frequently to pass urine, and being unable to do so. After great effort, however, he did manage to pass a small amount. It was turbid and ammoniacal. The scrotum was much swollen, evidently infiltrated with urine, dusky-red and very tender. Palpation back of the scrotum revealed an indurated mass the size of a goose-egg, which was extremely tender to the touch. A sound introduced into the urethra could only be passed as far as the posterior penile portion, where it gave the clear, loud click of contact with a stone.

The genitals and perineum were at once shaved and cleansed, the patient placed under ether, and put on the table in the lithotomy-position. The stone could then be roughly outlined. The incision, 2 inches long, was then made in the median line of the perineum. Immediately there came a gush of very fetid pus of about an ounce. After its evacuation the incision was deepened and carried immediately to the stone, which was then grasped and easily removed. Back of it lay another and smaller stone, and one or two small fragments.

The large stone lay in the membranous urethra, encroaching on both the bulbous and prostatic portions. The urethra was much thickened and greatly dilated, as can be seen from the description of the stone. After its removal I could easily pass my little finger into the bladder. A free incision was made over the left side of the scrotum and about an ounce of straw-colored fluid ran out of it. Two stitches were then taken in the anterior end of the perineal wound, a catheter passed into the bladder, drainage-tubes into the wounds, and the whole dressed with iodoform gauze, the catheter being brought out through the dressing.

The following day the catheter became occluded and was withdrawn and found to be covered and partly filled with a phosphatic deposit. The second day after operation the wounds were dressed, and looked well. The scrotum, however, was still much swollen. Since that time improvement has taken place steadily, though somewhat retarded by an attack of malarial fever. That, however, yielded to quinin, and the patient is now in good condition, the wound granulating, and the urine, under the use of boric acid, is no longer ammoniacal, but acid and sweet.



The stone, of which an illustration is herewith given, is, I think, about as large as has ever been removed from the urethra. It is 2⅛ in. long and 1¼ in. in diameter. It is white on the outside, very hard, and is shaped and looks much like a potato. It weighs dry 660 grains. At one end of it is a polished surface that corresponds with a similar surface on the smaller stone, which lay against it. This stone is of the same appearance, shaped much like a Lima bean, and weighs dry 60 grains.

INTUBATION OF THE LARYNX IN A CHILD FOURTEEN MONTHS OF AGE, WITH REINTRODUCTION OF THE TUBE, AND RECOVERY.

By MELVIN M. FRANKLIN, B.S., M.D.,
OF PHILADELPHIA.

In looking over records accessible to me, I find that cases of intubation in children under eighteen months of age, with recovery, are exceedingly few, and that the mortality increases greatly as the age diminishes. It is for this reason that I report the following case.

On September 12th, while attending another member of the family affected with diphtheria, my attention was attracted to Stephen B., fourteen months old. I found the pulse-rate accelerated and a slight elevation of temperature, with no other symptoms, except congestion of the tonsils and fauces.

Early the following morning I was summoned in haste to the case, and found the little patient in a precarious condition, with a temperature of 103.8°, a pulse-rate of 160, and all the symptoms of intense dyspnea, with every few minutes a paroxysm of croupy cough, ending in the expectoration of quantities of stringy white membrane. The throat on examination was found to be covered with membrane that could be easily detached, leaving a rough bleeding surface. The mother stated that during the early morning the child's breathing had become more and more labored and the croupiness had greatly increased.

Hastily procuring the necessary assistance and instruments, I introduced a No. 1 tube of O'Dwyer's pattern, and after the operation the symptoms were in a great measure relieved. Two minims of tincture of ferric chlorid, in a mixture, were ordered to be given every hour, the throat sprayed with a 1½ per cent. solution of

papayotin (Merck), and a second mixture to be given every third hour, containing tincture of digitalis and tincture of nux vomica, of each two minims, combined with $\frac{1}{64}$ grain of mercuric chlorid.

As the membrane was still visible on September 18th the tube was not disturbed until the following day, when, on the evening of the 19th (six-and-a-half days after introduction), I removed it, leaving instructions to have the throat sprayed at short intervals. Returning in two hours, the condition of the child was such that a reintroduction of the tube was necessary, and this was followed by immediate relief.

For the second time the tube was allowed to remain for a period of six days, and again, as the temperature was only slightly elevated and no membrane visible, I removed it. After this the breathing was not as free as could be desired, but I allowed the tube to remain out, with instructions to send for me should the child's condition require it, and this proved to be the case a few hours afterward. The tube was with difficulty introduced for the third time, owing to the swollen condition of the parts, but with no less gratifying results. The patient four-and-a-half days later began to refuse nourishment, and the tube was removed for the last time.

The general condition now steadily improved, with the exception of a paralysis of the pharyngeal muscles, permitting liquids to regurgitate through the nose. There also existed a slight nephritis, evinced by albuminous urine, but under hygienic and tonic treatment these complications rapidly disappeared and the child entirely recovered.

1518 North Broad Street.

MEDICAL PROGRESS.

Sudden Death Due to Cardiac Syphiloma.—At a recent meeting of the Clinical Society of London, Duckworth (*British Medical Journal*, No. 1816, p. 974) reported the case of a strongly built man, 35 years old, who, while walking in the street carrying his little boy, suddenly fell down and expired. Only a meager antecedent history was obtained, but there was evidence of old syphilitic disease on the tongue and on the glans penis. A small gumma was found in the left lung. The heart weighed 22 ounces, and was bound by firm adhesions to the pericardium, both at the apex and the base. The ventricles were hypertrophied and dilated; the valves were normal. In the wall of the left ventricle above the apex was a round depression nearly an inch in diameter and covered by long adhesions. This was due to a thinning of the wall, with much endocardial thickening. A large aneurysmal pouch was found behind the posterior cusp of the mitral valve. This appeared from without as a tumor growing from the base of the heart, and completely covering the left auricle. Its walls were half an inch thick, and the pericardium was closely adherent over it. On section the muscle was replaced by tough, fibrous tissue, with foci of gelatinous matter. The endocardium was greatly thickened and fibrous. Microscopic examination proved the formation to be gummatous in nature, with patches of caseation. The smaller vessels showed signs of endarteritis. These appearances were taken to indicate a recent gummatous growth at the base of the left ventricle, and a similar but older one near the apex of that cavity. Investigation showed that in 14 similar cases death occurred quite suddenly in eight. But one case of the whole number was in a woman. The mean age of all the patients was 32 years. Many of the cases appeared to have been previously devoid of urgent symptoms. In some there had been pericardial pain. The valves were usually not involved, and hence murmurs were not to be heard. The ventricles and their septum were the common sites of the growth. The tendency to fatal and sudden syncope was probably attributable in part to endarteritis affecting the coronary vessels and possibly to the formation of embolisms in the branches of the coronary arteries, as a result of the dislodgment of fragments from the interior of aneurysms.

Resection of the Apex of the Lung.—At the recent French Congress of Surgery, Tuffier (*Abeille Médicale*, October 28, 1895, p. 342) presented a man, 29 years old, in whom four years previously he had performed pneumonectomy. At that time the patient presented the signs of tuberculosis localized to the apex of the right lung. An incision was made in the second intercostal space and an extrapleural pneumothorax established by detaching the parietal layer of the pleura over a considerable extent. The apex of the lung at once presented and the diseased area, as large as a nut, together with healthy lung-structure for a distance of 2 cm. in every direction, was excised. The wound was closed without drainage and the patient was up and about on the ninth day. Tubercle-bacilli had been found in the sputum and were also found in the excised tissue. The patient had followed various pursuits in the four years following the operation, but had suffered from no pulmonary disturbance, and physical examination failed to disclose any evidence of return of the disease. It was not contended that similar operative intervention is generally applicable, but it was maintained that exceptionally it is indicated absolutely.

The Relation between Uric-acid Excretion and Leukocytosis.—As the result of experimental and clinical observations, Kühnau (*Zeitschr. für klin. medicin*, B. xxviii, H. 5, 6, p. 534) has found that a group of diseases attended with leukocytosis are characterized also by increased excretion of uric acid. This increase is not to be attributed to the febrile process alone, as it may attend afebrile diseases (cachectic leukocytosis). Rapid subsidence of leukocytosis corresponds with increased elimination of urates. Experimental leukocytosis is attended with increased elimination of urates, which reaches its maximum with the disappearance of the leukocytosis. Increased excretion of uric acid may be induced without the intermediation of leukocytosis by the administration of substances rich in colorless blood-cells (aseptic pus, thymus-infusion). Injections of nuclein induce directly increased elimination of urates, for which the leukocytosis developed at the same time cannot be held responsible. Colorless blood-cells constitute, if not the exclusive, the most important source of uric acid.

The Diagnostic Value of Fluid Discharges from the Ear in Head-injuries.—From a variety of considerations, Miles (*Edinburgh Medical Journal*, No. 485, p. 442) arrives at

the conclusion that, while in the majority of cases in which bleeding and welling-up of cerebro-spinal fluid from the ear are present, a fracture of the middle fossa of the skull exists, these signs are not pathognomonic. The fracture is in many cases, perhaps in most, simply a coincidence. The great bulk of the hemorrhage comes from the vessels of the arachno-pial membrane and of the temporo-sphenoidal lobe of the brain and not from the fractured bone. The path of the discharges is along the sheath of the auditory nerve, through the lamina cribrosa to the vestibule, thence through the middle ear and the ruptured membrane to the external meatus. Excluding the extra risk of sepsis, the prognosis is on the whole better when these signs exist than when they do not.

THERAPEUTIC NOTES.

Anesthesia-Statistics.—GURLT (*Archiv für klinische Chirurgie*, B. li, H. 1, p. 91) tabulates as follows the results of a collective investigation among the members of the German Surgical Society of Berlin into the frequency and fatality of anesthesia induced by various agents and combinations:

Anesthesia with chloroform.

	Cases.	Deaths.
1890–91	22,656	6 = 1 : 3776
1891–92	72,593	31 = 1 : 2341
1892–93	38,495	9 = 1 : 4278
1893–94	33,068	17 = 1 : 1946
1894–95	34,412	25 = 1 : 1376
	201,224	88 = 1 : 2286

Anesthesia with ether.

	Cases.	Deaths.
1890–91	470	...
1891–92	7,968	...
1892–93	6,213	...
1893–94	11,669	2 = 1 : 5834
1894–95	15,821	5 = 1 : 3164
	42,141	7 = 1 : 6020

Anesthesia with chloroform and ether in combination.

	Cases.	Deaths.
1890–91	1,055	...
1891–92	1,854	1 = 1 : 1854
1892–93	1,209	...
1893–94	3,896	...
1894–95	2,148	...
	10,162	1 = 1 : 10,162

Anesthesia with chloroform, ether, and alcohol in combination.

	Cases.	Deaths.

1894–95	1426	...
	8967	2 = 1 : 4483

Anesthesia with pental.

	Cases.	Deaths.
1891–92	219	1 = 1 : 219
1892–93	378	2 = 1 : 189
1894–95	34	...
	631	3 = 1 : 210

Pseudoleukemia Successfully Treated with Arsenic Subcutaneously.—KATZENSTEIN (*Deutsches Archiv für klinische Medicin*, B. 56, H. 1, 2, p. 121) has reported the case of a man, 37 years old, presenting characteristic symptoms of pseudoleukemia in whom a cure was effected by the subcutaneous injection of progressively increasing doses of solution of potassium arsenite. For two months the patient had observed glandular swellings throughout the whole body, and for several weeks a sense of oppressive pain beneath the left costal arch. He suffered also from insomnia, anorexia, and debility; and his appearance was anemic, cachectic, and emaciated. Inguinal, axillary, cervical and other lymphatic glands were enlarged, as was also the spleen. The erythrocytes numbered 4,720,000 to the c.mm., the leukocytes 12,200. The former were free from poikilocytosis and nuclei. Some of the multinuclear leukocytes were eosinophilous. The patient complained beside of intense prurigo. Epistaxis recurred from time to time and the lower extremities were edematous. In the course of six months in the neighborhood of one-hundred injections of solution of potassium arsenite were made in the back on either side of the vertebral column, with the result of effecting disappearance of both objective and subjective symptoms. At first 0.1 c.cm. (♏ⱼss) properly diluted was injected and the dose was gradually increased every third day 0.05 c.cm. (♏ℨ) until 1 c.cm. (♏xv) was injected daily, a free interval being permitted every two weeks. Finally 0.6 c.cm. (♏ix) gradually increased to 1 c.cm. (♏xv) was injected twice daily. Then the doses were gradually reduced until the treatment was discontinued and the patient was dismissed as cured. At the time of report there had been no return of the symptoms for a year. The patient had a previous history of syphilis.

In the Treatment of Herpes Zoster ROBIN (*Bull. Gén. de Thérap.*, October 30, 1895, p. 359) recommends the application on cotton of a powder constituted as follows:

Starch	℥iv.
Zinc oxid	℥j–℈iv.
Camphor	gr. iv–gr. xii.
Opium	gr. iv.—M.

For the accompanying neuralgic pain a pill of the following composition may be administered three or four times a day:

Extract of stramonium Extract of hyoscyamus	of each gr. ⅛.
Extract of belladonna	gr. ⅛.—M.

For Acute Coryza.—

℞.—Chloralis . . . . . gr. x.
Olei ricini . . . . . f℥iv.—M.
S.—Apply to the cleansed nasal mucous membrane.

Practitioner, vol. lv, No. 5.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

POLITICS AND THE INSANE.

UNDER this title Dr. Henry Smith Williams has contributed a popular article to the *North American Review*, in which he makes an indiscriminate attack upon the management of the insane by the "politicians." The tenor of Dr. Williams' article is in accord with that of a species of writing, now rather common, in which there is a tendency to decry anything that is suggestive of "politics." In a country so devoted to politics as our own—one, in fact, whose institutions are essentially founded on popular government, this outcry against everything political has seemed to us illogical and unwise. It is not only dangerous to the country at large, but it sooner or later leads those who indulge in it into reckless misstatements of facts and into a pharisaical condition of mind which unfits them for forming impartial judgments. Dr. Williams' article suggests these thoughts, both by its tone and by its matter.

We are not concerned here, however, with anything that Dr. Williams has written, except his unjust onslaught upon the present management of the Philadelphia Hospital. He has evidently taken no pains to make a personal inspection of the institution or to verify his alleged facts, but has relied largely upon a letter from an unnamed writer, whose statements, to say the least, are highly colored.

These statements are to the effect that the insane in the Philadelphia Hospital are consigned to "wretched, crowded, dark buildings that have been odious and odorous for half a century, with no facilities for out-of-door exercise or occupation;" that "within the buildings the allowance of fresh air equals but a few square feet per patient;" that "all in all, the condition of the insane here is one of the saddest spectacles to be seen in this country;" and that "the politicians have obstinately resisted every effort for improvement." Dr. Williams concludes, from this lurid picture, that the reason the politicians resist efforts at improvement is that the existing system gives them better facilities for patronage than could be hoped for under an improved system. In other words, their motive is to retain the spoils of office.

The exact facts about the present management and condition of the Insane Department of the Philadelphia Hospital are far other than those described in these exaggerated and misleading statements. After the disastrous fire of a few years since the old building for the insane was largely rebuilt and entirely renovated. New wings and additions, including a model kitchen, have since been erected, and the whole atmosphere and appearance of the institution have been changed. So far from this large and commodious group of buildings being "odious and odorous for half a century," it can be said that they are remarkably free from bad odors, and most of them from the burden of all these years. Every one of them has been remodelled, replastered and repainted during the past five years. The new additions, costing $229,000 (more than a quarter of a million dollars), were erected three years ago, and have been pronounced, by competent judges, satisfactory in every way. As to air-space, the ceilings are from 20 to 35 feet high and are not exceeded in any hospital in the State. No ward is overcrowded, and each is well ventilated and heated. All of these facts can be amply verified by personal inspection. This hospital has what no other State hospital has in equal degree, sitting-rooms for day distinct from sleeping-rooms for night. It has a splendid dining-hall, 220 x 100 feet, comfortably seating 1000 persons. It has larger airing-courts than any State hospital, although, of course, it is without much land for farming or trucking. Over 50 per cent. of the patients are usefully employed.

This hospital takes from the dregs of a great city, and its population in consequence is physically much below that of the State hospitals; yet its patients make almost all of their own clothing, for both men and women, and in addition there are shops for making brushes and shoes. Finally amusements are given regularly in a large assembly-room.

The condition of the insane is always a sad spectacle, but it is no sadder at the Philadelphia Hospital to the eye of a true alienist and lover of justice than it is in any gilded asylum in the land.

The "politicians" of Philadelphia, against whom Dr. Williams inveighs, are the members of the present board of Charities and Correction. They are appointed by the Mayor, and represent both political parties. No word of suspicion has ever been whispered against any one of them in either his private or public capacity. They have been taken from the legal and medical professions, and from active business-life in this city, where they are all thoroughly personally known; and few, if any, of them, have been prominently identified with politics. We do not see how a public board could be chosen of more representative and responsible men.

Finally the present superintendent of the Philadelphia Hospital was chosen after a competitive examination under the civil service rules, with the highest average among seven applicants. He has always, according to the medical chief, Dr. Hughes, joined the latter in every move for the improvement of the insane. All appointments and discharges in the insane-department are controlled by the medical chief, and politics is no factor in their cases.

We do not hesitate to say that the Insane Department of the Philadelphia Hospital under its present management compares favorably in cleanliness, hygienic conditions, and general welfare of its patients with any State hospital, and that the authorities, who have had much to contend with, including popular prejudice, are deserving of great credit for what they have accomplished. The truth is, this hospital suffers from a bad reputation which it acquired years ago, before the improved management under the new city constitution made it what it is to-day. Dr. Williams, and others who like him do not take the pains to verify their "facts," simply repeat old calumnies which no longer have a basis.

The Philadelphia Hospital is a great public charity, which for years has been one of the most important centers for teaching and for medical science in this country. Those who criticise it should at least make themselves familiar with the facts.

We should like to ask Dr. Williams what is his remedy for the political control of public hospitals for the insane? Is there any guarantee that boards appointed by the State authorities will be more intelligent and public-spirited than the present Board of Charities and Correction, appointed by the Mayor, and composed of men living here right in our midst? Is not such a board, in fact, more directly under public surveillance than a State board?

The truth is that the faults in our asylums are not so much in the political machinery as in the abuse of it. No dispassionate observer will deny that these abuses have been great in some, even many, instances. But they can be, and even have been, just as great under State as under municipal control. Because these abuses abound in New York and Chicago it does not follow that they occur in Philadelphia, and no upright judge will claim that they do occur at present in the Philadelphia Hospital.

We suggest that the zeal of political reformers should not lead them to misstate facts, and that even the common sense of a mugwump should teach him that public institutions must be under political control.

SERUM-THERAPY AND DIPHTHERIA-ANTITOXIN.

WHILE a great deal has been said of late about the effect of injections of diphtheria-antitoxin, comparatively little study and attention have been bestowed upon the effect of the serum itself when injected into a human being. It is rather strange that so many physicians should have taken it for granted that the serum is inert. If this assumption proves to be without foundation, then we have another and important disturbing factor introduced into the already complex problem of determining the real practical value of the diphtheria-antitoxin treatment.

At a recent meeting of the New York Academy of Medicine an attempt was made to clear up this part of the subject. Dr. Henry Dwight Chapin detailed a series of experiments that he had made on animals with a view of determining the effect, if any, of injections of serum obtained from healthy horses. These experiments prove in a general way that the injection of the horse-serum produces a

moderate reduction in the number of red blood-globules, and causes congestion of the spleen, congestion and cloudy swelling of the kidneys, and sometimes areas of fatty degeneration. Most of the experiments were performed upon rabbits. These results indicate that it is no longer wise to look upon the serum as an inert and harmless substance, and suggest that greater caution should be observed in adopting this treatment. Several observers have noted that the transfusion of the blood of the lower animals into the human subject is followed by a temporary rise of temperature and an acceleration and weakening of the heart's action, and that in addition to a marked destruction of the red blood-cells there have been pathologic changes observed in the kidneys and hemopoietic system. An erythema, similar to that so commonly seen after the administration of the diphtheria-antitoxin, has been known to follow the injection of the plain serum from a healthy horse.

All this would seem to show very clearly that the serum itself is a powerful agent; yet there are not lacking experimental observations opposed to this view. For example, Dr. William H. Park, at the meeting already referred to, said that recently three rabbits had been subjected to experiment. One of them had received injections of plain serum, the second one injections of antitoxin, and the third one had received no treatment, and had been simply kept as a control. The kidneys from these animals had been then sent for examintion to a pathologist of high repute, who, without any knowledge of the particular animals from which the kidneys had been taken, reported that the least changes were found in the kidneys from the rabbit that had received the antitoxin, and the greatest changes in the kidneys of the control-animal. About the same changes were produced by the serum and by the antitoxin in these rabbits.

So much for the part played by the serum alone. To determine the effect of the antitoxin on the kidneys, Dr. William Vissman injected it into a number of healthy rabbits, using an equal number of control-animals. The kidneys from the animals killed 24 hours after the injections were very firm and of a dark-red color. On the cut surface the cortical substance was very much injected, slightly opaque, and a little more prominent than the medullary substance, which was pale. On microscopic examination of fresh sections in 0.6 per cent. salt-solution, the Malpighian bodies and capillaries of the cortex were found to be distended with blood. The epithelial cells of the tubules were filled with refractive granules, obscuring the nuclei, which were only brought into view by the addition of dilute acetic acid. There were no casts found in the tubules. These conditions were present in all of the animals, and, as the time after the administration of the antitoxin increased, the injection of the blood-vessels decreased, and the cloudy swelling became more prominent. Those animals that had received more than one dose of the antitoxin exhibited slight hemorrhages into the tubules.

From these facts Dr. Vissman argues that since the doses administered to the rabbits were about equal to, or a trifle less proportionately than, the doses administered to children in cases of diphtheria, it is reasonable to suppose that approximately the same changes are produced in children when the antitoxin is administered. He also calls attention to a fact, observed and commented upon by Behring, Roux, Biggs, and others, to the effect that the antitoxin has a certain antidotal action when administered with, or very shortly before, the toxin, but that after the toxin has once begun to influence the organism the antitoxin has but little power to neutralize its ill effects. The conclusion that Vissman draws is that as little benefit is to be expected from the antitoxin after the diphtheria has made such progress that it can be diagnosticated, and that since the experiments just quoted indicate that the antitoxin exerts a deleterious influence, and even reduces the power of the organism to resist the inroads of the disease, it is highly probable that, instead of reducing the mortality of diphtheria, the antitoxin has really increased the death-rate.

In a paper on "The Physiological Action of Serum-injections," Dr. William Henry Porter states that as the serum produces a rapid destruction of the blood-cells, and these cannot pass through the body without change or oxidation, it is probable that the chemic properties of the living cells are largely overtaxed. He objects particularly to serum-therapy because all serums and toxins are absolutely unknown quantities. In his opinion, if the statistics of this subject were properly studied, it would be found that the mortality from diphtheria has been raised rather than lowered by the antitoxin-treatment.

But positive and candid as are the foregoing statements, they only seem to excite renewed discussion and controversy. Dr. William H. Park

says that if moderate quantities of serum be injected into animals there will be a moderate reduction in the number of the red blood-cells, but that there will be no broken-down cells, and that after a week or two the original number of red blood-cells will be restored. There is no change in the number of the leukocytes produced by plain serum, but the injection of serum and the antitoxin causes a temporary reduction in the number of the leukocytes. The same changes in the red blood-cells have been noticed in the 800 or more children in New York City who have been treated with the immunizing serum. These children had a slight rise of temperature and a transitory and moderate albuminuria. They have been carefully watched, and in not a single instance has there been any permanent ill effect from the treatment. In drawing deductions from experiments on animals, it should be remembered that the kidneys of rabbits often show granular and fatty changes independently of any experimentation; indeed, Dr. James Ewing says that in an extensive experience in experimentation on rabbits he has found it very difficult to secure rabbits with normal livers, spleens, and kidneys. This observer, having noticed a marked reduction in the number of leukocytes in 55 cases treated with the diphtheria-antitoxin, endeavored to determine whether this was due to the blood-serum or to the antitoxin. He found that when rabbits were injected with normal sheep's serum there was no appreciable decrease in the number of the leukocytes, but that the injection of the antitoxic serum was followed by a decided diminution in their number.

Finally, we may refer to the researches of Dr. J. S. Billings, Jr., at the laboratory of the New York Board of Health. Out of 33 cases of diphtheria treated with the antitoxic serum, a reduction in the number of red blood-cells was noticed in only nine cases, and in but three of these was this diminution at all marked. In a few cases of diphtheria received at the hospital in the latter stages of the disease, the number of the red blood-cells actually increased under the antitoxin-treatment. Five control-cases were treated outside of the hospital without the antitoxin, and in these a decided decrease in the number of the red blood-cells was observed.

We have cited the foregoing array of evidence in order that due weighing may be given it. There can be no doubt, however, that the trend of scientific opinion among those best fitted to judge is that the treatment of diphtheria with the antitoxin has tremendously lessened the average rate of mortality. Despite all adverse facts and criticism, that seems beyond dispute. We may have to modify the details of treatment, and we may at last indeed find that it is "not a specific" or "cure-all," but the fundamental principle is not likely to be overthrown.

EDITORIAL COMMENTS.

More about Antivenene.—This is an age of "Anti's," from Behring's latest discovery back to the respectable "cullud lady" who held "Mas'r Gawge Washington" in her arms, as a tiny girl. The newspaper-"doctors" have taken it up these several years past and we have "Anti-fat," "Anti-korns," and a legion of others. The impulse has now spread into the social and moral realms with deplorable results, and we read of "anti-vaccination" and "anti-vivisection" movements with—unintentionally—comic (or more correctly ridiculous) journals as their champions and mouthpieces.

Antivenene, was described some months ago in the editorial columns of THE NEWS, in connection with Prof. Fraser's discoveries, but a further series of experiments has been continued by Dr. Calmette, pathologist to the French Military Hospital at Saigon, Cochinchina, with some very interesting results which have just been published. The doctor has reached, independently, almost the same conclusions as Prof. Fraser and has further investigated the question of the nature of the immunity produced. He has found that the serum of certain animals naturally possesses a distinct immunizing power against the snake-venom and in occasional individuals of these species this rises to a positive antitoxic power. That this immunity could be readily acquired by certain animals has been known for some time. One such instance is known to us: A bull-terrier in Western Nebraska that was addicted to the pastime of killing rattlesnakes displayed severe toxic symptoms the first time he was bitten, a less violent result the second and third times, and finally no apparent effect from his encounters. From Australia has just been reported a similar series of reactions on the part of a dog, to the poison-spur of the Duck-mole (*Ornithorhynchus*). The immunity, however, popularly supposed to be possessed by the mongoose and the hog was found by Dr. Calmette to be due mainly to the quickness and agility of the former and the thick hide and knife-like hoofs of the latter, although both their serums were highly antagonistic to the action of the venom. In the light of these results it would almost seem as if the widespread popular custom of using "snake-bite" remedies containing the gall-bladder, the flesh, or even the dried venom of the snake had had possibly some crude sort of a rational basis, however slender.

Extending his experiments, Calmette ound that subjects immunized against hydrophobia, tetanus, and abrin (calabar-bean) displayed a high degree of immunity to the venom, and in some cases their serum developed marked antitoxic properties in the same direction. More than this, rabbits that had been inoculated against abrin acquired a high degree of resistance, amounting,

in some cases, to immunity against, not only venom, but also diphtheria, ricin, and even anthrax as well. Another series of experiments showed that in certain cases *the normal serum* of *man* is distinctly antitoxic against diphtheria, as was already known in the case of the horse.

These results form an intensely interesting and suggestive group, and taken altogether would seem to justify the belief that immunity mainly consists in the raising to a high pitch of the *general* resisting-power of the normal serum. If this be the case, may we not hope either that some antitoxin will ultimately be found that will have a protective effect against a whole class of diseases, or that we may discover how to develop this normal immunity, which many of us unquestionably possess already (else the race were long ago extinct), by hygienic means?

—

"Uranalysis" and "Symphyseotomy" Again.—When a badly formed word has once gained vogue, is once actually in current use, there is little use in trying to kill it. There are thousands of such words already in the language that are either laughable or disgusting, or both, according to the standpoint taken. But there they are, and all tilts against them are quixotic. Habit is fate. *Quieta non movere* is a maxim that holds in philosophy as in politics.

But when in cold blood it comes to adding new atrocities, and backing them up with lexicographic or other erudite authority, then, indeed, objection may be interposed. A distinguished physician for whose scientific attainments—other than philologic—we have the most genuine respect, proposed the term *uranalysis* instead of the elder barbarism *urinalysis*. In criticising this "neoplasm" (which as Dr. Parvin would say is an anagram for "pleonasm") we found a most distinguished lexicographic authority arrayed against us, and in favor of *uranalysis*. It seemed to us that the etymologic savagery of *uranalysis* should be glaring without either erudition or pointing out. Not so, however. It came to be a question of authority. In writing to Dr. W. W. Skeat, of Cambridge, England, the undisputed master of English etymology, the author of the great etymologic dictionary, we incidentally mentioned the coinage of the word *uranalysis* and asked him what he thought of it. His characteristic reply was: "I need not say that *uranalysis* means 'analysis of ure;' whatever 'ure' means I do not know."

In the same letter we also asked Mr. Skeat concerning the long-disputed correctness of the spelling of *symphysiotomy*. We have always contended that new words are formed from the *stems* or *roots* of words in older languages. The advocates of *symphyseotomy* based their preference upon the supposition that the word was formed from the Greek genitive, according to the meaning, "the cutting *of* the symphysis." This rule is a manifest error, and besides would require changes in thousands of English words. The φύσις in symphysiotomy, *e. g.*, is the same φύσις whence are derived our words *physiology*, *physiognomy*, *etc.*, *etc. Physiology* is the science (λόγος) of the body (φύσις), and if made up from the genitive should be spelled *physeology*; the same holds of *physiognomy*, etc. In reference to this point we also quote Skeat's conclusive words from his private letter: "It is not the case that Greek compounds are formed from genitives. They are formed from stems. Every Greek scholar knows all about it; it is not a question of 'opinion' at all, but of simple *facts*."

And yet, however much we may hope, we still doubt if we have seen the last of these morbid new-growths.

—

Sterilization in Excelsis.—It has long been a standing joke among bacteriologists that the day would come when the strictest surgical asepsis would be carried out at our dining-tables as well as in our operating-rooms; according to *Truth* (London) the day has already arrived. Pasteur, we are assured, was such a consistent germ-worshipper (or iconoclast?) in every realm, that for the latter years of his life he insisted upon a rigorous process of sterilization of everything that came upon his table. His napkin was taken directly out of a hot-air chamber and brought to him "white-hot." All his bread was either rebaked or toasted for each meal and brought to the table before it had time to cool in a sterilized napkin. His knives, forks, spoons, and plates were freshly scalded just before using, and his dessert-fruit washed in water that had been boiled and then hermetically corked for use. "An antiseptic liqueur ended the repast." We have all used such liqueurs just in that way and enjoyed them without any idea that we were taking a scientific precaution, but now we have a reason for the faith that is in us. We have grave doubts, however, whether the other precautions will ever come into very general use. In this connection the story is related of the distinguished savant that on one occasion, after carefully rinsing in a glass some grapes he was about to partake of, he abstractedly swallowed down the wash-water, dregs and all.

CORRESPONDENCE.

CEPHALHEMATOMA.

To the Editor of THE MEDICAL NEWS,

SIR: I have read with interest the report of a case of "Cephalhematoma with Cerebral Hemorrhage," by Dr. T. W. Keown, in the October 26th issue of the NEWS.

The writer refers to the text-books as regarding "cephalhematoma in infants as due to prolonged labor and mechanical injuries resulting therefrom," describing this form of hemorrhage as "*a particular form of caput succedaneum.*" In all of the text-books I have been able to consult, I have failed to find caput succedaneum and cephalhematoma described as the same condition, or one "a particular form" of the other.

Dunglison says of the former, "A term used for the tumefied *scalp* which first presents in certain cases of labor;" and of cephalhematoma, "a sanguineous tumor sometimes developed between the pericranium and bones of the head of newborn children."

Ashby says a "cephalhematoma is distinct from a caput succedaneum, inasmuch as the latter does not fluctuate, disappears in a day or two, and extends beyond the limit of the parietal bone."

In speaking of caput succedaneum, Cazeaux and Tarnier say: "This tumor, when large, is the result of a slow and painful labor; it is always single; and may be distinguished from the cephalhematoma, with which

it has long been confounded, by the following characters: the caput is irregularly circumscribed, whilst the limits of the cephalhematoma are very distinct; in the former, the hairy scalp is of a well-marked violet color; the tumefaction has an edematous consistence, retaining the impression of the finger, and is not fluctuating, whilst the skin of the latter is colorless, presenting a well-marked fluctuation, occasionally even some pulsations, and its base is limited by a prominent osseous border."

So much for the distinct entity of the two conditions. Now as to the cephalhematomata being due to "prolonged labor and mechanical injuries resulting therefrom," it is a fact that more often than not this condition is noted in children born after perfectly easy, normal, and non-instrumental labors.

The following is a record of four cases of cephalhematoma occurring in 202 cases of childbirth under my observation, of which I have a record:

CASE I was that of a male child, the mother a secundipara. The first stage of labor lasted 3 hours, the second stage 10 minutes. No instruments were used. The position of the child was R. O. A.; the caput succedaneum was very slight and to the left posteriorly. Double cephalhematomata were noted on the second day, over the parietal bones, the left, the larger, measuring 6 x 3 cm.

CASE II.—The woman was a primipara, the child a male. The labor in the first stage lasted 14 hours; in the second stage 1½ hours, aided by the forceps. The caput succedaneum was thick and directly posterior. The position of the child was L. O. A. Double cephalhematomata were noted on seventh day.

CASE III.—The woman was a primipara, the labor in the first stage lasting 6 hours and 45 minutes, in the second stage 37 minutes. The position was L. O. A. The child was a male with the caput thick and directly posterior. A cephalhematoma was situated over the right parietal bone; the time of its appearance was not noted.

CASE IV.—The woman was a sextipara. The labor in the first stage lasted 8 hours, in the second stage 10 minutes; the position was L. O. A. The child was a female with no caput. A cephalhematoma existed over the right parietal bone, and was noted on the third day.

Of these cases, but one could have been considered born after a tedious or instrumental labor.

Semmelweiss[1] is said to have seen a cephalhematoma in a child delivered by Cesarean section.

Ashby divides cephalhematomata into two varieties: 1. A subaponeurotic, or a hemorrhage occurring under the occipitofrontalis aponeurosis and the periosteum; and 2. The subperiosteal.

The case related by Dr. Keown was most likely of both these varieties; had it been a caput succedaneum the tumor would have been found to be jelly-like in consistency, with a few minute hemorrhages scattered through it.

I have thus gone into detail on this subject, because I think the two terms are too often confounded, and a clear idea should be had in regard to the differences between them.

Very truly yours,

HENRY E. TULEY.

111 W. KENTUCKY ST., LOUISVILLE, KY.

NEWS ITEMS.

The Association of Assistant Physicians of Hospitals for the Insane held its second meeting at the Michigan Asylum for the Insane, Kalamazoo, Mich., October 24, 1895. The membership, originally composed of medical officers of the staffs of asylums in Michigan, Illinois, and Iowa, was extended to include the assistant superintendents and assistant physicians of all asylums. The next meeting will be held at the asylum at Independence, Iowa, during May, 1896.

Perforation of the Rectum and Peritoneum.—Dr. Weller Van Hook, 103 State Street, Chicago, will be grateful for reports of cases of perforation of rectum and peritoneum by impalement, to furnish the basis of a collective investigation. An interesting case of this kind was reported in THE NEWS of October 12, 1895.

A Course of Five Lectures on Bacteriology is being delivered by Dr. M. V. Ball, at the Academy of Natural Sciences, Nineteenth and Race Streets, Philadelphia, on Saturdays at 3 P.M. The course began on November 16th and will continue to December 14th, inclusive. There is no charge for attendance.

Pediatrics is the name of a new semimonthly publication to be devoted to the diseases of children. It is owned by Dr. Dillon Brown, of New York, and edited by Dr. George A. Carpenter, of London.

Professor Johannes Gad, of Berlin, has been elected the successor of the late Professor Hering in the Chair of Physiology in the University of Prague and in the directorship of the Physiologic Institute.

Dr. James K. Young has been elected Professor of Orthopedic Surgery in the Philadelphia Polyclinic, and also Clinical Professor of Orthopedic Surgery in the Woman's Medical College.

Dr. Friedrich Miescher, a well-known and able physiologist, and at one time professor of physiology in Basle, died of pulmonary tuberculosis on August 26th, at the age of 51 years.

Dr. H. C. Boenning has been elected Professor of Anatomy and Surgery in the Philadelphia Dental College, in succession to the late Dr. Garrettson.

Two Football Deaths are reported in the daily papers, George Butterworth, of Rochdale, Scotland, and Samuel Steelfox, of Shamokin, Pa.

Dr. Joseph W. Brockbank, of Nicetown, Philadelphia, died of pneumonia on November 7th, at the age of 33 years.

Dr. Robert Battey, the distinguished gynecologist, died at Rome, Ga., on November 8th, at the age of 67 years.

The Texas Sanitarian begins its fifth volume as the *Texas Medical News*.

THE USE OF ANTITOXIC SERUM FOR THE PREVENTION OF DIPHTHERIA.

BY HERMANN M. BIGGS, M.D.,
OF NEW YORK CITY.

GREAT interest was aroused about one year ago by the announcement of the discovery in diphtheria-antitoxin of a specific remedy for the treatment of diphtheria, and there has been but slight abatement of the interest in this agent since that time. Comparatively little attention, however, has been paid to its value in the prevention of diphtheria, and the few reports of its use for this purpose published in Europe have been inconclusive or disappointing.

The antitoxin produced by the New York City Health Department has been employed for the immunization of a large number of children both in public institutions in this city and in private families, under conditions particularly favorable for demonstrating its exact value, and the results have been in many respects very remarkable. It has been employed in public institutions both to control outbreaks of diphtheria and as a routine measure to protect inmates when there was evidence of possible or previous exposure to disease.

Brief reports of the results obtained in the New York Infant Asylum (Dr. Peck) and in the Nursery and Child's Hospital (Dr. Thomas) have already appeared.

The serum employed in all of the cases referred to in this report was produced by the New York Health Department, with the exception of that used at the New York Infant Asylum in January. The amount employed in each case has varied from 50 to 600 antitoxin-units, depending upon the age of the individual. Behring recommended in November last that 150 units should be employed for immunization, but added that in persons already infected and near the end of the incubation-stage, even 600 units might not entirely prevent the disease, as then it became a remedial agent and not a prophylactic.

Unfortunately the period of incubation of diphtheria is not known. It is, however, of short duration and probably does not ordinarily exceed 48 hours. As to the period of protection following the immunizing injections of the antitoxin, Aronson thinks the protection lasts from 3 to 4 weeks; Kossel, from 2 to 3 weeks; while our observation seems to show that it is usually at least 30 days.

EXPERIENCE AT THE NEW YORK INFANT ASYLUM.

From May, 1892, to February 18, 1894, no cases of diphtheria occurred in this institution, which ordinarily has about 400 inmates. From February 18 to September 1, 1894, there were 22 cases of diphtheria and 15 deaths. In September there were 16 cases, and from this time to January 16th (108 days), 107 cases of diphtheria occurred. These were very evenly distributed over this time, about 30 cases developing in each month. In the latter part of October systematic bacteriologic examinations of the throats of the healthy children showed that diphtheria-bacilli were present in so large a number that, in order to isolate these, nearly one-half the inmates were quarantined.

All efforts directed to checking the progress of the epidemic were unattended with success up to the time that the antitoxin was employed for immunization of the inmates. On January 16 and 17, 1895, 224 children were immunized with Behring's antitoxin No. 2. The quantity given to each child varied from 100 to 200 antitoxin-units, according to the age. From this date, January 16th to February 15th, only one case of diphtheria occurred. It appeared on February 3d and was of very mild type. On February 15th, 30 days after the administration of the antitoxin, a second case appeared, and from February 15th to February 28th five more cases developed, one on the 22d, one on the 24th, two on the 25th, one on the 27th. On the latter date, February 27th, the antitoxin was administered again to 245 children. The antitoxin in this instance was that produced in the laboratory of the New York City Health Department, and the dose administered to each child was increased 25 units throughout. No more cases of diphtheria occurred for 31 days.

On March 30th a case of mild diphtheria appeared in one of the children that had been immunized on February 27th. Cultures made from children in the same ward in which this case developed showed that in the throat of six there were typical Loeffler bacilli; each of these six children received then a third dose of 200 units of the same antitoxin on April 3d. Twelve days after this injection one of these children became slightly ill; a small patch of false membrane was found in one tonsil, the maximum temperature (which lasted only about 24 hours) was 100° F., and bacteriologic examination

of the throat-secretions showed typical diphtheria-bacilli.

On April 18th, a child immunized on February 27th developed mild diphtheria complicated with severe bronchopneumonia; this case proved fatal, apparently as a result of the bronchopneumonia. On May 3d, a fourth case, very mild in character, appeared in one of the children immunized February 27th (66 days), and a fifth case, also mild in character, occurred on May 27th, 90 days after the immunization. No further cases developed. During this same period three cases of diphtheria occurred among children not immunized, who had been admitted subsequent to February 27th. Two of these died; none of them received antitoxin.

As contrasted with 107 cases in 108 days before the first immunization, there occurred five cases of mild character in 112 days after the second immunization. Reports from the house-physician, Dr. Peck, to whom I am indebted for these notes, show that, excepting a few mild skin-rashes, no bad effects followed the administration of the antitoxin in any case. Since May 27th the institution has been free from diphtheria.

EXPERIENCE AT THE RECEPTION-HOUSE OF THE NEW YORK JUVENILE ASYLUM.

The inmates vary from 8 to 15 years of age, are admitted and kept under observation in the reception-house for about 3 weeks and are then transferred to the main institution. Admissions average about two daily.

During two months previous to April 13, 1895, there were 12 cases of diphtheria in the house; three occurred during the week immediately preceding April 13th; on that date 27 children were immunized with the antitoxin, each one receiving from 150 to 250 units. On April 27th antitoxin was administered to 10 more, in the throats of 7 of whom diphtheria bacilli were shown to be present. The injections were continued at intervals as new children were admitted. The total number treated was 81. No cases of diphtheria occurred among those immunized, but two cases developed in children admitted about May 1st, who had not been immunized, and a short time later one of the attendants who had not been immunized developed diphtheria. These cases furnish conclusive evidence of the continued presence of infection in the institution.

EXPERIENCE AT BELLEVUE HOSPITAL.

About May 1st, a case of diphtheria developed in a child in Ward 7. On May 7th a second child was taken ill. Both of these children had been in the hospital for more than 2 months, and no diphtheria had occurred in this ward for many months previously. Bacteriologic examination of the throats of 11 children remaining after the second case was removed showed that in 6 diphtheria-bacilli were present; these were immunized, about 200 antitoxin-units being administered to each. No more cases of diphtheria appeared. Three weeks later examination of the throats showed that all were free from diphtheria-bacilli.

EXPERIENCE AT THE NURSERY AND CHILD'S HOSPITAL.[1]

Diphtheria appeared in this institution on January 18th; 46 cases occurred between January 18th and April 18th, of which 15 occurred between April 1st and April 18th, showing that the epidemic was steadily increasing up to the day of immunization. On April 18th, 110 children were immunized with serum furnished by the Health Department, and on April 29th the remainder, 26 in number, were immunized. Of these children, 77 were under one year of age and 59 were between one and four years of age. The dose administered to each varied from 50 to 200 units of antitoxin. Careful observations were made in each case as to the occurrence of albuminuria, elevation of temperature, and remote secondary lesions, with the following result: Four showed faint traces of albumin in the urine, lasting in no case more than 4 days and unattended with any symptoms pointing to disturbance of the kidneys. In 7, rashes occurred 8 or 9 days after the injection; these were not attended with any other symptoms. Immediately after the injection (within 12 hours) some cases showed elevation of temperature, *i. e.*, in 7 cases to 100° F., in 32 cases to 101°, in 16 to 102°, and in 4 to 103°. In all these children, however, the temperature had virtually returned to normal within 24 hours.

The amount of disturbance, as manifested by elevation of temperature, crying, restlessness, etc., seemed to be proportionate to the youth of the children and to the degree of debility. Stronger and older children showed little reaction.

No case of diphtheria occurred in the hospital among the children immunized, but 3 weeks later one of the assistant physicians, who had not been immunized, developed diphtheria, and 5 weeks later one of the nurses became ill. Both of these cases showed well-marked membrane on the tonsils and pharynx and bacteriologic examination demonstrated the presence of diphtheria-bacilli in the throat-secretions.

EXPERIENCE AT THE HOUSE OF RECEPTION OF THE NEW YORK CATHOLIC PROTECTORY.

The reception-house of the New York Catholic Protectory receives the children of destitute parents,

[1] I am indebted to Dr. A. M. Thomas, visiting physician, for these notes.

keeps them for three weeks, and then transfers them to the Protectory proper at Westchester, New York.

On Sunday, July 7, 1895, 2 cases of diphtheria developed in the institution. On the following day 2 more cases appeared, and on Tuesday, July 9th, a fifth case; 5 cases of diphtheria had thus appeared in three days.

On July 9th and 10th, 67 children then in the institution were immunized. The ages of the children ranged from 2½ to 15 years.

The size of the dose was graded as follows:[1]

2½ to 5 years	150 to 300 units.
6 " 10 "	400 units.
11 " 15 "	500 to 600 units.

Each child's temperature was taken morning and evening for two days after the injection. There was in three or four a slight elevation of temperature, which subsided in each within two days. In several instances, an erythematous patch, varying in size from one to four inches in diameter, appeared within two or three days about the needle-puncture. Only one of these caused any discomfort, and this promptly subsided upon the application of a wet 1:60 phenol dressing. Unfortunately it was impossible to secure specimens of urine before the administration of the antitoxin, but after the administration, on July 11th, specimens were obtained from all the children treated. Examinations gave negative results in all but ten cases. In these, more or less albumin was found on one or more examinations and then entirely disappeared. No after-effects, except the albuminuria as described, were observed. Two or three of the children, after about 10 days, showed a few erythematous blotches upon the skin, more or less generally distributed, but these lasted only a few hours. No cases of diphtheria developed after immunization among those treated.

In addition to these 67 children, a few days later one of the attendants and his two children were also immunized. None of these showed albuminuria, local symptoms, or urticaria.

On August 5th, diphtheria developed in a child that had been admitted the day previously. The source of infection was unknown. At this time none of the children was in the house that had been there when the first general immunization was practised.

On August 9th, the physician in charge requested that the new inmates be immunized. Directions were at once given to obtain specimens of urine from all the children for examination before the administration of the antitoxin. On August 10th, the 37 inmates were immunized in the same manner as before. These children averaged older than those previously treated. Most of them were from 11 to 14 years of age, only 7 being under 10 years.

The dosage was graded as follows:

2 years	1 case	200 units.
3 "	1 "	250 "
6 "	1 "	350 "
7 to 12 years	20 cases	400 to 500 units.
13 to 20 "	14 "	500 to 600 "

The injection having been made in the forenoon, most of the children showed temperatures of from 99° to 99.5° the same evening, two or three reaching 100° and one 100.6°. During the two days on which observations were made most of the temperatures subsided to normal, a few remaining at 99°. No cases except those mentioned later showed any constitutional symptoms after the injections.

In only two cases was there any local irritation. In one of these the symptoms promptly subsided without treatment; the other, unfortunately, developed an abscess. This case was a fifteen-year-old boy who had received 600 units, under exactly the same antiseptic precautions as were employed in the other cases; he complained the next day of soreness, pain, and swelling in his thigh. The symptoms increased in spite of the local application of wet phenol dressings; and on August 15th he was removed to the New York Hospital, where a large abscess was evacuated. It is difficult to understand how the infection took place, inasmuch as the children that were injected immediately before and immediately after him in the same manner, and with serum from the same horse, showed no reaction whatever.

In the last group of cases, 37 in number, specimens of urine were obtained before the injections to compare with those taken after the administration of the serum. The results of the examinations are as follows:

	Before immunization. August 9th.		After immunization. Aug 11th.		Aug. 13th.
	Sp.gr.	Albumin.	Sp.gr.	Albumin.	Albumin.
Felice Ferolo,	1022	Trace.	...	Negative.	Negative.
Patrick Donovan,	...	Negative.	1030	Trace.	"
Jos. Dillon,	...	"	...	"	"
Francesca Viria,	...	"	...	5 p. ct.	"
Annie De Borger,	1024	30 p. ct. in vol.	...	60 "	"
Jennie De Borger,	...	Negative.	...	16 "	"

One child showed 30 per cent. in volume of albumin (the urine, after boiling and the addition of nitric acid, was allowed to stand for 24 hours, and the amount then estimated) in the urine before the treatment, and after the injection about 60 per cent. in volume. The urine from the sister of this child showed no albumin before the injection, and 16 per cent. after it. Neither of these children gave the slightest evidence of illness other than the albuminuria at any time, and neither showed any

[1] The doses administered to these children are larger than required and are larger than it is desirable to use.

temperature-reaction. In both of these cases, as in all the others, the albumin had entirely disappeared two days later.

Nine days after the injections, one case developed an urticaria which lasted for 24 hours. No other cases showing skin-rashes were observed.

On August 10th, the day following the immunization, Annie Brady, 12 years old, a sister of the child that developed diphtheria on August 6th, complained of sore-throat, and had a temperature of 101°. She had received the day before 500 units of the antitoxin. When seen on August 10th, she presented the clinical appearance of a mild case of left-sided follicular tonsillitis. Only a few white spots, easily rubbed off, were seen in the mouths of the follicles; no membrane whatever was visible, but a culture demonstrated the presence of Loeffler bacilli. The temperature, 101° on the first day, was at no time thereafter higher than 99°, and within two days the throat presented a perfectly normal appearance. She was kept isolated, and cultures taken every two days up to September 9th all showed the presence of Loeffler bacilli. It is an interesting question as to whether this was a case of simple tonsillitis in which the diphtheria-bacilli chanced to be present in the throat, but were not active, or whether it was one of true diphtheria, so modified by the anticipating effect of 500 units of the antitoxin as to display none of the clinical appearances of the disease.

On August 20th, May Brady, a second sister of the child removed with diphtheria, developed sore-throat, and was promptly isolated. On the 21st, examination disclosed congestion of the whole throat, with a few spots in the mouths of the follicles of the left tonsil. The appearance and symptoms were like those of the preceding case, only still milder. Culture failed to show the presence of Loeffler bacilli. No other cases of diphtheria or sore throat developed.

IMMUNIZATION BY HEALTH-DEPARTMENT INSPECTORS IN INFECTED FAMILIES.

For some months past in families in which diphtheria has occurred, and in which there were other children exposed to infection, the Department Inspectors, acting on their own judgment as to the necessity, have immunized some of these exposed persons. Most of these cases have been among the tenement-house population. A few cases taken at random from the reports of the inspectors illustrate the method:

FAMILY 1.—Five children in family; two cases of diphtheria; the other three children, aged 9, 11, and 13 years, were immunized; no further cases occurred.

FAMILY 2.—Three children in family; one case of diphtheria; two other children, aged 8 and 16 years, immunized, one child had diphtheria-bacilli in the throat at the time. No further cases of diphtheria.

FAMILY 3.—Three children in family; one case of diphtheria, one of the remaining two children immunized; second child, aged 16, not immunized. This child developed diphtheria three weeks later, and was successfully treated with the antitoxin.

Cases like the foregoing might be repeated almost indefinitely; 232 persons had been immunized in this way up to October 1st, and of these, at least 93 (many of the others were not examined bacteriologically before being immunized) had diphtheria-bacilli present in their throats when treated. The cases were kept under observation until the premises had been disinfected, and this was not done until the throats of all were free from bacilli.

	No. of cases immunized.	No. of units of antitoxin administered.	No. of cases of diphtheria developing among those immunized between 1 and 30 days.	No. of cases of diphtheria developing within 24 hours.	No. of cases of diphtheria developing after 30 days.	No. of cases of diphtheria that occurred in the institutions previous to immunization.
New York Infant Asylum (1st immunization)	224	100 to 200	1 mild on the 19th day.	0	6	107 cases in 108 days.
" " " " (2d immunization)	245	125 to 225	1 mild on the 12th day.	0	4	6 cases in 12 days.
Nursery and Child's Hospital	136	50 to 200	0	0	0	46 cases in 90 days.
New York Juvenile Asylum	81	150 to 250	0	0	0	15 cases in 15 days. 12 cases; 3 cases in 2 days.
New York Catholic Protectory	114	150 to 600	0	1	0	5 cases in 3 days.
Bellevue Hospital	11	175 to 225	0	0	0	2 cases in 10 days.
Health Department Inspectors	232	150 to 250	1 mild on the 19th day.	3	3 (1:30, 1:31, 1:55)	One or more cases in more than 90 families.
Total	1043	.....	3	4	13	

Among these 232 persons, three developed membranous croup within 24 hours of the time when they were treated; all recovered. Three others had mild pharyngeal diphtheria, developing one on the 19th, one on the 30th, and one on the 31st day after injection, and one developed a fatal diphtheria on the 55th day.

The cases detailed number altogether 1043; 224 of these were immunized twice; the first time with Behring's serum, and the second time with the New York Health Department serum. In a large percentage of the whole number diphtheria-bacilli were present in the throat when the serum was administered, and all had been exposed to diphtheria under conditions more or less favorable for the transmission of the disease. Among those immunized 3 cases of diphtheria occurred between 1 and 30 days after the treatment; *i. e.*, one on the 12th, one on the 17th, and one on the 19th day, respectively. Twelve cases developed diphtheria later, as follows: On the 30th day, two; 31st day, one; 33d day, one; 37th day, one; 39th day, one; 40th day, two; 42d day, one; 52d day, one; 55th day, one; 66th day, one; 90th day, one. The four cases that developed croup within 24 hours of the injection undoubtedly had the disease at the time of injection. Altogether, therefore, excluding these, 16 cases of diphtheria occurred among 1014 persons—three in from 1 to 30 days, and 13 in from 30 to 110 days after immunization. These cases were all mild, excepting two, one of which proved fatal from diphtheria, and in the other death seemed to be due to bronchopneumonia complicated by a mild diphtheria.

During 90 days preceding immunization, under practically the same conditions, it may be said that more than 225 cases of diphtheria occurred. By the use of the antitoxin it has been possible to stamp out completely diphtheria in four great institutions for the care of children in which it was prevailing in more or less epidemic form. In no instance has there been, so far as can be determined, any serious results from the administration of the remedy for this purpose.

The duration of immunity in many cases is apparently not more than 30 days, but it may be for a much longer period. The doses required to confer immunity are probably between 50 and 300 antitoxin units according to the age of the individual treated.

DIAGNOSIS OF RENAL CALCULUS IN WOMEN.

By HOWARD A. KELLY, M.D.,
OF BALTIMORE, MD.;
PROFESSOR OF GYNECOLOGY IN THE JOHNS HOPKINS UNIVERSITY.

It becomes more and more evident with the increasing frequency of operations upon the kidney that serious errors in the diagnosis of renal calculus are often committed. Not infrequently a patient who has a persistent pain in the lumbar region, blood or pus in the urine, or a retroperitoneal lumbar tumor, is operated upon for calculus of the kidney, and the operation fails to demonstrate the existence of the stone.

I have seen repeated failures where all these signs existed in the same patient and had persisted for a long time.

The presence of pus in the urine is one of the most characteristic signs of calculus in the pelvis of the kidney, but from the mixed urines of the bladder it is impossible to say from which side the pus comes; or, if pain and swelling point distinctly to one side, it cannot be asserted after any ordinary examination that the other side is not affected too.

In so far as pus is diagnostic of the presence of a stone in the kidney, and it is one of the most characteristic factors, though by no means pathognomonic, I have been able to simplify the matter by my method of catheterization of the ureter under a direct inspection, the bladder being distended with air by the posture of the patient. In order to secure a sufficient quantity of urine for satisfactory examination, it is necessary to leave the catheters in the ureters anywhere from a quarter of an hour to several hours. I found that flexible catheters were better for this purpose than the metallic ones that I had been previously using. I therefore had a series of catheters made, 2, 2¼, 2½ mm. in diameter, and 30 cm. (12 in.) long, constructed of woven silk, coated with many layers of shellac, and with a highly polished outer surface. The end of the catheter is blunt and conical, and has a large oval eye 2 cm. back of the extremity. In a warm room the catheter is often too flexible to be introduced into the ureter and it coils in the bladder; this difficulty is overcome by stiffening it with a wire stylet, when the point of the catheter is placed within the ureteral orifice, and then the catheter is simply pulled off the stylet, which is held rigidly as the catheter passes up the ureter. By means of catheters introduced one on either side the urines from the right and left kidneys are collected in separate test-tubes held in two auger-holes bored in a block of wood that is placed in the bed between the patient's legs. The right side must be carefully marked by a piece of string or some other device to prevent confusion.

An analysis of these urines, with the microscopic examination, then shows the presence of pus on one or both sides, and the amount of urea in each indicates the working coefficiency of the kidney.

With the knowledge gained by this sort of examination of the two sides, the operator is posted as to the amount of risk he incurs in operating upon one of the kidneys. He also knows what risk he runs in removing a crippled kidney, if he is tempted to do so by the amount of disease found.

In addition to this indispensable means of diagnosis, I have recently been able to add two other signs of absolute certainty that are applicable in a large number of cases of renal calculi.

FIG. 1.

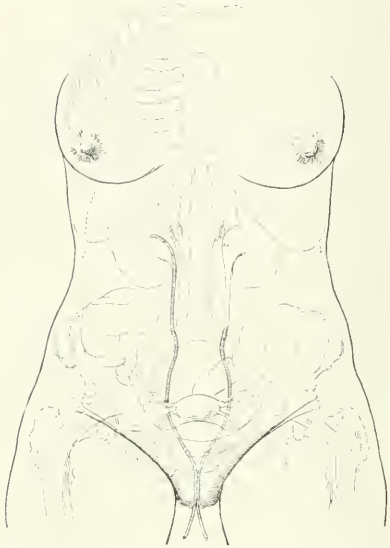

Diagram of ureters and kidneys, with a flexible ureteral catheter introduced just above the superior strait and draining the left kidney; on the right side a flexible renal catheter has been introduced and the extremity lies in the pelvis of the kidney. The ends of both catheters project from the urethra.

For the purpose of this examination I use renal catheters and renal bougies. The renal catheters vary in diameter from 1¾ to 2½ mm., and are 50 cm. (20 in.) long. In all other respects they are like the ureteral catheters already spoken of. The catheter is used in the following way: The ureteral orifice is exposed and the catheter introduced, say No. 2 or 2¼, and pushed gradually on upward until resistance to further advance is felt. In general about from 13 to 17 cm. (6 to 7 in.) of the catheter is left projecting from the urethra. Then taking an air-tight syringe with a tapering metallic point, and connecting it by means of a piece of fine rubber tubing with the end of the catheter, strong suction is exercised. If there is any pus present, this is often brought at once down into the syringe, and begins to flow long before it would naturally without suction. The suction is continued until the renal pelvis is emptied, and the fluid obtained is placed in a conical graduate for careful examination.

In three cases I have been able to diagnosticate the presence of renal calculi by discovering in this fluid a minute, dark-brownish or blackish sediment consisting of little pieces of material about a half-millimeter or less in diameter. On placing these under the microscope and testing them they were found to be composed of uric acid. Their appearance on the surface was mammillated, looking like an aggregation of little masses of rounded stone. On pressing them with a needle-point they were found to be quite coherent, each separate particle bending and breaking under pressure.

The first case in which the diagnosis was made in this way was the following:

CASE I. *Miss S.; several black specks withdrawn from pelvis of kidney by suction. Microscopic and microchemic examination showed them to be masses of uric acid. Operation; renal calculus; recovery.*—The patient, Miss S., aged 29, had spent not less than 10 years in treatment, principally at the various university towns of Europe, where she could secure distinguished counsel. She finally came to me through the courtesy of my friend, Dr. Max Koehler, of Cincinnati. She was of slight build, weighing 106 pounds, and complained of indigestion, a sense of pressure in the abdomen, headache, and irregular bowels. The discomfort she felt in the abdomen was located chiefly on the right side, but no tenderness, pain, or enlargement could be found out by palpation. The urine had also persistently contained pus for 10 years, and on two occasions she had passed some blood. Among others, she had seen Prof. Ultzmann and Prof. Czerny, of Heidelberg, who had diagnosticated a catarrhal pyelitis.

She dated her ailment from a chill taken at a ball, during menstruation, and stated that after this time the urine was affected.

FIG. 2.

Stone found in the pelvis of the right kidney (Case I), diagnosticated by the flexible renal catheter and removed by lumbar section.

On examination, I found the uterus and the pelvic organs normal in size and position. The urine contained pus and a bacillus resembling the colon-bacillus. I placed the woman in the knee-breast position and passed a small speculum into the bladder, and distended it atmospherically, so that all of the bladder-wall could be well seen; this was found to be healthy. I found by catheterizing the uterers separately that the left side secreted normal, clear urine, entirely free from pus; but when the catheter was passed up to the pelvis of the right kidney, 3 or 4 cc. of turbid urine escaped, which under culture developed the colon-bacillus. The fact that there were several cubic centimeters of urine found in the pelvis of the kidney each time showed that there was a stoppage at the juncture of the ureter with the renal pelvis. Ordinarily, in two minutes' time 13 cc. of urine were discharged from the right

kidney, while under normal conditions the flow should not be more than 1 cc. I was never able at any time to trace the source of infection. The final result of the treatment showed that it was not due to any communication with the bowel.

I began treatment by introducing the renal catheter and washing out the pelvis of the kidney, and did this more than 100 times. At first there was some slight improvement, but later the trouble persistently grew worse, the pus increasing in quantity and becoming quite thick. The injections used were at first boric acid; a few times weak solutions of silver nitrate, and, finally, solutions of mercuric chlorid, beginning with a strength of 1 : 100,000, and gradually reduced to 1 : 5000. This was kept up throughout the winter of 1894–95.

On two occasions upon emptying the pelvis of the kidney by strong suction, applied at the end of a catheter by means of an air-tight syringe connected with it by a short piece of thick, rubber tubing, I found in the bottom of the conical glass receiver several minute, black specks not over a half-millimeter in diameter. On putting these under a microscope, they turned out to be little masses of uric acid, holding firmly together, and only crushed with some difficulty by the point of a needle. At no time had any similar pieces been found in the urine passed in the usual way. On the basis of this find, associated with the fact that it was impossible to clear up the urine coming from the pelvis of the kidney, I concluded that the patient had a stone in the pelvis.

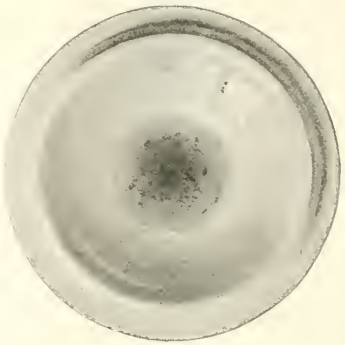
I operated March 30th, removing a small, black, rough, uric-acid calculus, 11 x 16 mm., shown in Fig. 2, natural size. The kidney was brought out through a lumbar incision, the renal pelvis opened posteriorly, and the stone was found lying in the lower part of the pelvis over the ureteral opening. After its removal, the pelvis was closed by suture with catgut. Before closing, the ureter was palpated and found normal down to the pelvic brim. The abdominal incision was closed down to a small opening in the loin left for a gauze-drain.

The patient recovered rapidly, and the urine cleared up completely. When she left my care early in June there was absolutely no pus in it, and, on catheterizing the kidney for a final examination through the bladder and ureter it was proved that clear urine was secreted in the normal manner, and all trace of the stoppage at the junction of the ureter with the pelvis had disappeared.

CASE II. *Malignant disease of the right kidney; hydronephrosis of low grade; bits of renal calculus brought away by suction applied through the renal catheter.*—The patient had a large right kidney, either carcinomatous or sarcomatous. I found upon carrying the renal catheter up into the pelvis that about 10 cc. of clear urine escaped at once, and on putting on strong suction some fine, black granules were brought down which, under the microscope, appeared exactly like those just described in the case of Miss S. The percentage of urea, estimated from urine drawn from the sound side, was 1.7, while in the urine from the diseased side it was only 0.7. The patient's condition did not admit of any operative interference, and nothing was done.

CASE III. *Calculous pyonephrosis; diagnosis made by the renal catheter bringing away pieces of stone; a large piece caught in the eye of the catheter; scratch-marks on the end of the catheter.*—The third case came to me from Chicago, referred for diagnosis by the courtesy of my friends, Dr. N. S. Davis, Jr., and Dr. Fernand Henrotin. The patient was about 46 years of age, and suffered from a persistent pyuria of

FIG. 3.



Sediment drawn down in Case III, August, 1895. The larger masses are tissue-débris. The minute granules are detritus of a calculus.

doubtful origin. I passed a renal catheter into the pelvis of the kidney, and by means of strong suction brought down at once a small quantity of urine mixed with abundant pus. A quantity of fine, granular, amorphous débris shown in the sediment in the figure came down with it, and interspersed with this were some small, blackish particles looking like grains of pepper. (See Fig. 3.) These under the microscope were found to be little, brownish masses of uric acid.

FIG. 4.

FIG. 5.

Fig. 4. Stone caught in eye of catheter. Natural size.
Fig. 5. Free broken-off surface of the same stone, magnified 18 times.

On withdrawing the catheter an irregular piece of stone, a millimeter in diameter, was found wedged in the eye as shown in Fig. 4. On putting this under the microscope, under a low power, one surface was found to be discolored black and to be mammillated, and made up of a number of little rounded elevations set together with shallow sulci

between them. The opposite surface, however, was of an entirely different color, being of a light buff, and it was broken, jagged, and crystalline, with sharp ridges. (See Fig. 5.) It was therefore evident

FIG. 6.

End of catheter hammered down and scratched. Magnified.

that this piece had been freshly broken off and drawn into the eye of the catheter by the suction.

In addition to this conclusive evidence of the existence of a stone in the pelvis of the kidney, I

FIG. 7. FIG. 8. FIG. 9.

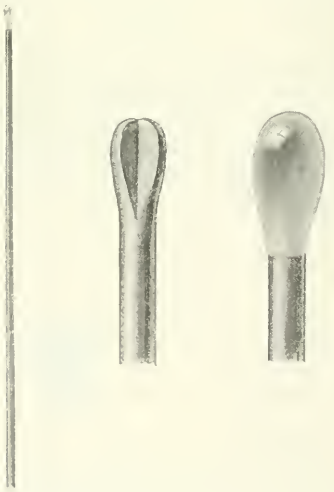


Fig. 7. Rubber bougie tipped with wax. Natural size.

Fig. 8. Hard-rubber bougie, showing groove. Enlarged four times.

Fig 9. Rubber bougie tipped with dental wax. Enlarged four times. The clear spot is the reflection of a window on a smooth surface.

found further confirmatory evidence of the most satisfactory sort upon withdrawing the catheter and putting the end under a weak magnifying power. The smooth, hard, varnished surface was chipped off on one side, and the smooth, round end was hammered down and irregular, as shown in the annexed figure, demonstrating that it had been brought into violent contact with a hard surface.

I had already thought of making a diagnosis in this way. I had made last spring a hard-rubber renal bougie, 2 mm. in diameter, with an olive point, 3 x 2 mm., notched on two sides, the notch running lengthwise; to use this, I melted some dental wax and coated the end of the bougie with it, giving it a smooth, glossy, impressionable point, which is not altered by any kind of contact with the soft tissues, but is easily scratched by a stone. (See Figs. 6, 7, 8, and 9.) I did not happen to have this at hand at this examination, and so made the diagnosis, as stated, with the catheter alone. I expect the bougie to prove more serviceable than the catheter in the future.

This patient has not yet been operated upon, but the diagnostic factors detailed leave no doubt as to the condition in the pelvis of the kidneys.

To recapitulate, I have been able by means of these cases to establish the following points:

1. By renal catheters to demonstrate a unilateral or a bilateral pyelitis and the grade of each.

2. By suction at the outer end of the catheter to bring down bits of stone for microscopic and microchemic examination.

3. The color of these pieces of stone signified a long retention in the pelvis of the kindey.

4. A piece of stone, black and rounded on one side, and light-colored and jagged on the opposite, was evidently broken off from a larger calculus and caught in the eye of the catheter by friction and suction.

5. The bruised end of the catheter was conclusive evidence of violent contact with a hard body.

RECENT EXPERIENCES IN THE SURGERY OF THE HYPERTROPHIED PROSTATE.

BY J. WILLIAM WHITE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF PENNSYLVANIA.

I HAVE so lately reviewed this whole subject (*Annals of Surgery*, July, 1895) that it now seem, worth while merely to bring the existing evidence up to date and submit it to the profession. I am the more interested in doing this for the reason that I am in constant receipt of letters of inquiry from physicians as to the present status of the operation.

I need not recapitulate any of the historic or theoretic portions of the preceding paper, and I have no new facts bearing upon the value of the removal of one testicle in prostatic cases.

If the 3 deaths contained in this series (Kummell Bangs, Keyes) are added to the 20 contained in the previous list, it makes the present known mortality 17.9 per cent., or about what it was before. But

following the plan I then adopted and throwing out the obviously inappropriate cases, those of Bangs and Keyes may be excluded, as the former had pronounced against the operation and the latter says he was "over-persuaded" into its performance. Of the details of Kummell's fatal case I have no information, but if it is included among those in which there was a reasonable expectation of recovery from the operation, it makes 8 deaths in 120 cases, a mortality of 6.2 per cent.

This certainly compares favorably with the mortality-records of all other forms of operative treatment of prostatic hypertrophy, while the degree of relief experienced and the percentage of cases that may fairly be called "cures" are both far in advance of the results obtained by other methods.

To the 111 cases contained in the table already published 24 new cases are to be added.

Case I reported by Lütken in the *Deutsche medicinische Wochenschrift*, January 31, 1895, was inadvertently omitted from my table published in the July *Annals of Surgery*. A man, aged 65 years, had difficulty in passing urine for several years. The catheter had to be used seven or eight times daily, which of late caused great pain and occasionally free hemorrhage. Digital examination revealed a prostate about the size of a hen's egg. As no improvement followed the usual methods of treatment castration was recommended and accepted. Ten days after the operation the left half of the gland was found to have decreased in size. A month later this half had almost disappeared and the other side was about the size of a walnut. Four months later no enlargement of the prostate could be detected. Immediately after the operation the catheter was used less frequently than before, and at the end of ten days was discarded entirely. The patient five months after the operation was perfectly well and could pass a good-sized stream of water. The author prefers this operation to other methods of treatment and even to regular catheterism. No living spermatozoa could be found in the testes, which argues against the view that these organs must be functionally active in order to get shrinking of the prostate after castration.

Case II.—Swain (*British Medical Journal*, January 5, 1895) reported an interesting case which was also accidentally omitted from my table. He operated on a patient 73 years of age with a typical prostatic history. The man had had several attacks of retention; catheterism was becoming increasingly frequent and painful, and when he came under observation was for a time impossible, aspiration above the pubes being employed for two days. Mr. Swain continues the description of the case as follows:

"On the third day I succeeded in passing a metallic prostatic catheter, which traversed the urethra for 9½ inches before the urine began to flow; the considerable depression of the handle which was necessary suggested that the middle lobe, as well as the lateral lobes, was much enlarged. For about ten days his bladder was irrigated night and morning with boric-acid lotion, and, although the urine then contained very little blood and was less fetid, the prostate did not diminish in size, and the patient was getting gradually worse. The kidneys were presumably healthy, as the total amount of urea excreted daily was about normal. After the matter had been fully explained to the patient, I performed double castration on September 11th. In consequence of the decomposition of the urine it was necessary to continue the irrigation of the bladder for three weeks after the operation; but on the seventh day the patient passed a small quantity of water of his own accord, and this gradually increased in amount, so that when the washing out of the bladder was stopped he passed all his urine naturally. Coincidently with this his general condition improved, and the prostate gradually became smaller.

"There was a perceptible diminution in the size of the prostate at the end of the first week after operation, but in the third, fourth, and fifth weeks the increasing atrophy appeared to progress more rapidly. In three weeks after operation the patient began to get about, and in five weeks he was discharged. At this time his general condition had much improved; his urine was normal, he sometimes passed half a pint at a time, but he could not hold his water for more than four or five hours in the daytime. There was no 'residual urine' in the bladder; the prostate was comparatively soft and about the size of a large horse-chestnut. If a catheter was introduced, it passed easily, and urine began to flow along it when a distance of 8 in. from the orifice of the urethra had been reached without any more depression of the handle than is usual.

"I saw the patient on December 11th, 13 weeks after operation, and found that since his discharge he has not once had to use a catheter or to get up at night to pass water, and is now free from any difficulty in emptying his bladder, and the urine is normal in appearance and has no bad odor. On rectal examination, the prostate was felt to be rather smaller and firmer than at the last examination."

Case III.—Dr. Edward Boeckman, of St. Paul, Minnesota, tells me in a letter dated June 24th that three days previously he had performed double castration on an old man who had been entirely dependent upon the use of the catheter for more than a year. He was able to pass urine voluntarily the same night and has had no occasion to use the catheter since.

Case IV.—Dr. Boeckman reported the following case in the *Northwestern Lancet* of June 1, 1895: A farmer, aged 64 years, had complained of difficult urination for two years. At the time he came under observation he was obliged to pass water from every fifteen to thirty minutes. He also had a feeling of fulness in the perineum, constant desire to urinate, discomfort after the act, and dull pains in the lower part of the abdomen. His general health had begun to suffer, he had lost flesh and had a poor appetite. Palpation of the abdomen revealed an enormously distended bladder extending a couple of inches above the umbilicus. Digital examination of the prostate showed that the gland was the size and shape of half a lemon. With a hard catheter

1500 grams of residual urine were withdrawn. The urine was clear, pale, slightly acid, and did not contain albumin. The patient exhibited some degree of general arterio-sclerosis. He was castrated May 20, 1893, and returned to his home six days after the operation. At this time the residual urine was 900 grams and the prostate was beginning to shrink. The patient was examined in January of this year, at which time he looked well and thought himself as hearty in every way as he had ever been. He was obliged to rise a couple of times at night, as had been his habit since he was a child, but he was not bothered in any other way. He was free from all local or constitutional difficulties. The bladder could not be palpated through the abdominal wall; the prostate was considerably diminished in size in all directions, but yet moderately enlarged. The urethra was of normal length; the catheter passed easily. The residual urine measured 400 grams and was normal.

Case V.—Dr. Frank W. Ross, of Elmira, N. Y., has communicated to me the details of the following case, in which he performed castration for enlargement of the prostate, early in May of this year: A man, aged 63, of good habits, had suffered from intermittent retention of urine, requiring the use of the catheter part of the time for three years previously. He had cystitis, residual urine, and a urethritis from the use of the catheter. The patient was placed in bed and the ordinary methods of treatment were adopted, but with little benefit. He was despondent and anxious to have any means employed that offered hope of relief. Double castration was performed, and five days after the operation the patient was able to pass water without the catheter, which was used, however, once a day for a week. No other treatment was employed excepting the administration of potassium citrate. The patient was in the hospital about six weeks. When admitted the prostate was 3 inches in length and hard and firm. When discharged it had decreased one-half in size. The cystitis had been relieved; there had been no retention and no residual urine. The patient was able to pass water naturally and freely and without the least trouble. He was obliged to get up but once or twice during the night, if at all. A letter received from the patient a few days before the date of Dr. Ross' letter states that he considers himself cured.

(To be concluded.)

THE TREATMENT OF ENTERIC FEVER BY SYSTEMATIC COLD BATHING IN THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

Notes based upon Seventy-one Cases observed during a Service of Three Months ending November 1, 1895.

By J. C. WILSON, M.D.,

Attending Physician to the Hospital and Professor of the Practice of Medicine in the Jefferson Medical College, Philadelphia.

When, at the beginning of my term of service, August 1, 1895, I took charge of the wards, they contained a number of convalescent cases of enteric fever, and two cases, admitted a few days previously, still in the mid-course of the attack. Of this number, these two cases only are included in the following statistics.

At the date of the preparation of this paper, November 14, 1895, there remain in the wards of those admitted during my service 17 patients fully convalescent from enteric fever—that is to say, with a normal temperature for ten days or more—and 8 still in the course of the attack. In estimating the mortality-percentages these eight cases are not considered.

Of the 71 cases, 49 were males, 22 females. The ages were: 15 years and under, 8; from 15 to 20 years, 12; from 20 to 25 years, 26; from 25 to 30 years, 16; from 30 to 35 years, 3; over 35 years, 6—total 71. The youngest was 4 years of age; the oldest 69. The greatest number of the cases were admitted during the second week of the attack; a few during the first week, and still fewer during the third week. Of the 71 cases, all but 5 were treated by cold baths, the exceptions being cases to be referred to later, in which the diagnosis was for a time obscure.

The treatment consisted in the administration of one or two laxative doses of calomel to patients admitted prior to the tenth day; a full plunge-bath at a temperature of about 70° F. (21.1° C.) every third hour so long as the axillary temperature continued to rise to 102° F. (38.8° C.); the administration of alcohol in the form of whisky before, during, or immediately after the bath according to the requirements of individual cases. The amount of whisky varied from 4 to 8 or 10 fluidounces in the course of 24 hours. The diet consisted chiefly of milk and broths, and no solid food was given until the temperature had been practically normal for a week. In a few instances, feeble, irregular cardiac action was regarded as an indication for the administration of moderate doses of strychnin. So soon as with a fall of temperature the baths were discontinued, 15-drop doses of dilute hydrochloric acid were administered to patients with coated tongue, and in whom the hunger of convalescence was not present. To those in whom postfebrile anemia was profound the mistura ferri et ammonii acetatis was administered. The majority of the patients, however, with the exception of one or two laxative doses of calomel shortly after admission, received no medicine during the course of the attack or during convalescence.

In the 71 cases relapse occurred in 5 instances, 7 per cent.; three males, two females. Multiple relapses did not occur. Hemorrhage occurred in 5 cases, 7 per cent.; three males, two females. All of these cases recovered.

Intestinal perforation, as established by post-mortem examination, occurred in one case. In

two other cases the diagnosis of perforation was rendered probable by sudden abdominal pain, tenderness, and tympanites, followed by fatal collapse. The patients in these two instances were Russian Jews, and postmortem examination was not permitted. Taking the three cases together, perforation occurred in 4.2 per cent. The conditions in all three cases in which symptoms of perforation showed themselves were such as to preclude surgical intervention.

Left-sided croupous pneumonia with pericarditis occurred in one instance. This patient recovered.

Peripheral neuritis, affecting the lower extremities and attended for some time with distressing pain, occurred in one instance.

A complicating croupous pneumonia with parotid bubo occurred in a single case. This patient still remains in the ward, and is very ill.

A painful arthritis of the right sterno-clavicular articulation with neuritis of the brachial nerve and its branches occurred in one instance.

Furunculosis constituted a troublesome condition during convalescence in several cases. As a rule, the furuncles were distributed on the back, buttocks, arms, and the outer aspect of the thighs. They were usually small and few in number. In some cases, however, there were as many as 15 or 20 furuncles present.

Crops of pustules, circumscribed and symmetrically arranged, developed in four cases during convalescence, on the inner side of both legs just below the knee. They were very painful and tender, but speedily disappeared.

Crural phlebitis developed in two cases.

The diazo-reaction was noted in the urine of eleven cases out of fourteen examined between the tenth and the twenty-second day of the attack. In fifteen additional cases, in which the test was made later than the twenty-second day of the attack, the response did not occur.

As a rule, convalescence was uninterrupted and satisfactory. Patients were usually permitted to return to their homes about the end of the second week after complete defervescence.

The average stay in the house of 42 cases terminating in recovery was 33.5 days.

Five of the cases were of short duration, the history indicating a sickness of less than a week prior to admission, and defervescence being complete in from 5 to 7 days.

Four cases terminated fatally. Deducting the 8 cases with active fever still in the wards, the records show 63 cases with 4 deaths—a general mortality of 6.3 per cent. Of the 4 fatal cases, 2 were not bathed. Of those that recovered 3 were not bathed. Deducting the 5 cases not bathed, we find 58 cases treated by systematic cold bathing with 2 deaths—a mortality of 3.4 per cent.

These facts do not justify generalizations in regard to the results of the treatment. In the series of cases treated by systematic cold bathing at the German Hospital of Philadelphia we find a first group of 40 consecutive cases, without a death; a second of 54 cases, with 1 death; a third of 66 cases, with 7 deaths; a fourth of 66 cases, with 4 deaths; a fifth of 74 cases, with 8 deaths; and a sixth of 108 cases, with 12 deaths.

The fatal cases were as follows:

House No. 1001.—M. E., male, aged 18, Russian, a tailor, was admitted on the 21st day of August, 1895, with a history of irregular fever for five weeks; splenic enlargement; rose-spots not present on admission, but noted two days later; rash abundant and well characterized. The man had 82 baths, which were well borne, reaction being prompt. On the 22d day after admission he suddenly developed signs of perforation with great distention; effacement of liver-dulness; rapid fever-pulse; shallow respiration. He became collapsed, and died in the course of 24 hours.

House No. 1084.—J. T., male, colored, aged 20, a laborer, was admitted September 2, 1895, a walking-case, having been ill two weeks. On admission the temperature was 102° F. It subsequently ranged between 100° and 101.8° F. This patient was not bathed, nor was the diagnosis made. On the second day symptoms of peritonitis developed and death occurred on the fourth day. After death a large number of typhoid ulcers were found in the lower two feet of the ileum. About four inches above the ileocecal valve there was a small circular perforation in the floor of one of the ulcers. The vermiform appendix contained three concretions; one the size of a cherry-stone, the other two the size of grape-seeds. There was no necrosis or ulceration of the mucous membrane of the appendix.

House No. 1141.—J. B., male, a native of Russia, aged 30, a tailor, was admitted September 10, 1895, having been ill two weeks. Abdominal pain and diarrhea were prominent symptoms. The temperature-range was comparatively low, only on three occasions reaching 103°. Twelve baths were administered, each being followed by rather prolonged lowering of temperature. The reaction was not good. Signs of perforation developed on the 20th and death occurred on the following day.

House No. 1395.—A. S., female, Irish, widow, aged 69, a seamstress, was admitted October 19, 1895, having been ill 8 days. There were tenderness and pain in the right side, diarrhea, with thin, yellow stools, and great depression. There were a number of well-characterized rose-spots on the anterior surface of the thorax and abdomen. The temperature on admission was 100.4° F., rising on the following day to 101.2° F. Two days later an apoplectic seizure occurred, with coma, complete relaxation, and rapid rise of temperature to 103.8° F. Death occurred on the 23d.

In the following cases the diagnosis was for a time obscure:

House No. 1265. *Enteric fever, cerebrospinal form.*—R. C., male, aged 4, a Russian, was admitted

October 1, 1895. The patient's parents were immigrants who had been in this country but six weeks. On the voyage hither a younger sister had suffered from some fever and upon their arrival at Philadelphia had been sent to a hospital. The patient had been out of health for some time, with constipation, followed by diarrhea and headache. Four days prior to admission he complained of pain, swelling and tenderness of the belly. On admission there was slight, painful rigidity of the muscles of the back of the neck. There was some spasmodic contraction of the muscles of the arms and hands. Except slight dilatation, there were no pupillary symptoms, no strabismus, no trismus; there was no disease of the ears.

A few hours after admission there was a sudden drop in the patient's temperature from 102° to 95° F. It, however, rapidly rose again. The patient was fretful; he lay on his side, with the limbs flexed. There were manifest evidences of pain upon being disturbed. Ankle-clonus was elicited and the knee-jerks were increased. There was slight albuminuria with hyaline and granular casts. There were one or two herpetic vesicles upon the lips and a few pustules in the occipital region and on the trunk. The tongue was moist, thickly coated with a white, pasty fur; it was red at the tip and edges.

On the third day after admission a crop of typical rose-spots appeared upon the abdomen and chest. The spleen was now made out to be markedly enlarged. About this time there was a rapid amelioration of the nervous symptoms; the reflex phenomena subsided; there was less pain on movement and the case presented the symptoms of a typical enteric fever of moderate severity in childhood. Treatment was by systematic cold baths. Convalescence was retarded by furunculosis.

HOUSE No. 839. *Enteric fever, pulmonary form.*—A. M., female, aged 22, unmarried, a domestic, was admitted August 1, 1895. The patient stated that she was perfectly well until about a week before admission, when an infant in the family in which she was employed died in her lap after a short sickness. She was much shocked, became very weak, and stated that she had been out of her head. The temperature was normal on admission. The woman was very weak and apathetic, with complete loss of appetite; the tongue was coated; the bowels constipated. There was cough, with disseminated small mucous râles on both sides. Two days later the morning temperature rose to 102.3° F.; the evening temperature was 104° F. The tongue was coated and tremulous; the abdomen slightly tympanitic; splenic dulness was somewhat enlarged. Signs of bronchopneumonia developed, being much more marked upon the right than upon the left side. The condition remained much the same, with marked hebetude, irregular fever, and marked physical signs of pulmonary disturbance until the 19th, when intestinal hemorrhage took place. Prior to this, one or two suspicious spots had been noted upon the abdomen. This patient was bathed and made a tedious but satisfactory recovery.

HOUSE No. 855. *Enteric fever, pulmonary form.*—W. T. B., male, aged 33, unmarried, a laborer, was admitted August 2, 1895, having been sent to the hospital by a competent physician as a case of acute diffuse tuberculosis. His illness had developed gradually during the preceding fortnight, with loss of appetite, prostration, severe headache, abdominal cramps, and tenderness. Had had no diarrhea or bleeding at the nose. There had been cough, blood-stained expectoration, rapid loss of flesh, and painful stiffness of the back. Upon admission the temperature was 100° F., the pulse 88, the respiration 28. The face was flushed, the pupils not dilated, the tongue tremulous and coated, the area of splenic dulness not increased. There was abdominal tenderness with pain, but no tympanites. There was marked percussion-dulness over the lower lobe on the right side posteriorly, feeble bronchovesicular respiration, and, upon deep inspiration, a few fine crepitant râles. This patient was very sick for a long time with cough, rusty sputum, marked fever, the temperature running at times as high as 104° F.; there were severe pleural pains on the right side, delirium, and vomiting. Two weeks after admission, for the first time, the area of splenic dulness was found to be increased. A little later the belly became tympanitic, and on the 19th day after admission for the first time the appearance of rose-spots was noted. From this time on the case ran the course of a severe enteric fever with very irregular temperature, the temperature first touching normal August 25th, 23 days after admission, but again rising, and defervescence not being completed until September 3d. This patient was not bathed.

HOUSE No. 1359. *Enteric fever, irregular form, with chills at onset.*—N. S., female, aged 21, unmarried, a dressmaker, was admitted October 14, 1895, on the seventh day of the sickness, which began with headache, pain in the back, and fever. The patient had had previous good health. On the first and second days chills occurred, followed by sweating. The patient took quinin freely prior to admission. The temperature on admission was 103.5° F. the urine normal; examination of the blood revealed no plasmodia. The tongue was dry and red at the edges; there was a good deal of tenderness in the right iliac fossa, with moderate splenic enlargement, and slight tympanites. The bowels were at first constipated; later, there was moderate diarrhea with yellowish stools. There was no eruption.

The attack came on at the close of menstruation, and the pain and tenderness in the lower part of the abdomen on the right side above Poupart's ligament suggested a local inflammatory process, implicating either the right uterine adnexa or the appendix. The patient was not bathed. The pain and tenderness gradually subsided, and the subsequent temperature-range justified the diagnosis of enteric fever.

HOUSE No. 1168.—An obscure case with very irregular temperature, was not systematically bathed, and was removed by his friends against advice. It was subsequently learned that he developed a well-characterized enteric fever.

I desire to express my thanks to Dr. F. A. Packard, who had the kindness to take charge of the service during my temporary absence; to Drs.

Roberts, Nicholson, and Ward Brinton, House-physicians, without whose enthusiastic co-operation the notes could not have been made; and finally to Dr. Starbuck, House-physician, who studied the diazo-reaction.

SEVENTEEN CASES OF CHRONIC (RELAPSING) APPENDICITIS, TREATED BY OPERATION.

By HUNTER McGUIRE, M D., LL.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.

(Concluded from page 566.)

Lastly, a few words about the operation. I make a clean cut straight down on the most prominent part of the swelling, if there is any, or over the supposed site of the appendix, if there is no swelling. I begin near the anterior superior spinous process, and cut inward and slightly downward toward the inner border of the rectus. In fact, the incision is almost transverse. The more nearly transverse it can be made, the better the union afterward, and the less the danger of subsequent hernia. I am afraid of the plan of separating the fibers of the different planes of muscles with retractors and two assistants. The muscles must be injured, repair of bruised parts will be slower, hernia more common, and drainage, if needed, less perfect. The incision is not more than 2 in. long in the skin, and shorter as the cavity is reached. The peritoneum is opened most cautiously, as a piece of omentum, or, more important, a portion of the gut, may be adherent, and in the line of incision. After the belly is opened, Trendelenburg's position is of great assistance. If the appendix is difficult to find, I look for the anterior bundle of longitudinal muscular fibers of the colon, follow this as a guide, and it will usually lead one to the little organ. When found and separated, if attached, a circular cut through the peritoneal coat is made, and the serous membrane stripped down for half-an-inch; a fine silk ligature is tied around the muscular and mucous coats of the little process, and the appendix cut off. The ends of the ligature are cut short. The detached serous membrane is now brought back and stitched or tied over the end of the stump.

Any portion of the omentum that has been adherent and in contact with the appendix is ligated and cut off; no matter how large a portion it is, if it is injured or suspected of being infected, it is removed.

The most difficult part of the operation is to deal with the adhesions. It is very important, if it is possible to do so, that all adhesions should be undone. If they are left untouched, the patient may get well of the operation, but remain an invalid for the rest of his life, liable at any moment to intestinal occlusion, and subject always to tenderness over the abdomen, and to constant gastrointestinal uneasiness.

Iodoform is freely dusted over any injured places in the peritoneum, drainage of gauze introduced if deemed necessary, and the wound closed with a continued fine silk suture for the peritoneum, and silkworm-gut sutures for the muscles, fascia, and skin.

Case I.—Mrs. W. H. B., 30, a patient of Dr. A. G. Taylor, of Chula Depot, Va., was admitted October 11, 1893. She has had repeated attacks of appendicitis; the duration of one attack was 2 weeks. The appendix was found very much enlarged and firmly adherent to the cecum; it lay fastened across the organ like a strap. The adhesions were old and well organized, and their separation was difficult and had to be made with the point of the knife. The appendix was found to be 5½ in. long, and as large as my thumb. After the appendix was separated from the cecum, the raw surfaces were rubbed over with Monsel's solution of ferrous sulphate, and the cavity of the abdomen closed. Recovery was uninterrupted.

Case II.—Mrs. L. B., 42, a patient of Dr. Stuart McGuire, of Richmond, Va., was admitted November 24, 1893. She has had 5 attacks of appendicitis; the last attack was violent, confining her to bed for 3 weeks. The appendix was firmly adherent to the right ovary, which was enlarged and inflamed. Both appendix and ovary were removed, followed by an uninterrupted recovery. In this case the appendix was elongated, its cecal end partially occluded, its free end dilated and distended with gas, and the mucous coat thickened and diseased.

Case III.—Miss L. B., 16, a patient of Dr. J. H. Young, of Burkeville, Va., was admitted November 3, 1893, with a history of one severe and several slight attacks of appendicitis, the last attack being very severe. The appendix was found in its normal position, slightly congested and free from adhesions. It was 6 in. long and ½ in. in diameter. The free extremity was enlarged, the base contracted; it was dense and firm, almost cartilaginous in consistency. The lumen next to the cecum was completely occluded by inflammatory deposit for the distance of an inch, and the mucous membrane which lined the patent portion of the tube was filled with a seromucous fluid. Recovery was uneventful.

Case IV.—Miss A. J., 30, a patient of Dr. H. G. Melvin, of Houston, Va., was admitted December 4, 1893, with a history of several severe attacks of appendicular colic during the past year. The pain was violent, necessitating the use of morphin, lasting sometimes for hours, and on one or two occasions for days. The abdomen was opened and the appendix found at once; it stood up as if made of erectile tissue, and if pressed down would at once fly up in the erect position; its free end was dilated and filled with gas. For an inch from the cecum the little tube was apparently solid. The peritoneal covering was congested. There were no adhesions. The appendix was removed and recovery

was uninterrupted. The operation was simple and quickly performed. The patient remains well.

CASE V.—Mrs. C. R. H., 45, a patient of Dr. C. V. Carrington, of Richmond, Va., was admitted December 27, 1894. An operation was performed on this lady for the removal of both ovaries and tubes 2½ years ago. Six months ago she had her first attack of appendicitis, and every 2 or 3 weeks since that time an attack occurred, each time after a shorter interval, and each time with more intense symptoms. I opened the abdomen and found the appendix swollen and congested and firmly adherent to the stump of the right ovary; it was peeled loose with some difficulty and removed. The appendix was greatly elongated and sharply bent at its cecal attachment. The lining membrane of the appendix showed ulcerative changes, and there was a large amount of mucopurulent secretion in it. She recovered without bad symptoms.

CASE VI.—Mrs. M. B. G., 34, a patient of Dr. James B. McCaw, of Richmond, Va., was admitted December 29, 1894, with a history of griping pains in her right side, the pain continuous, and subject to occasional severe exacerbations, which kept her in bed for days. An examination showed considerable enlargement of the right side; vaginal and rectal examination showed a large lump in the right iliac region. The right ovary was found to contain a dermoid cyst as large as an orange, to which the appendix had grown. The dermoid cyst was removed at the same time, and the woman made an uneventful recovery.

CASE VII.—Mrs. F. B. C., 24, a patient of Dr. Henckel, of Staunton, Va., was admitted December 30, 1894. Two years ago I removed her tubes and ovaries, which were extensively diseased. Six months ago she had her first attack of appendicitis. She has had in all about 5 severe attacks, each time confining her to bed, and requiring the use of morphin. The last attack was attended with great pain, swelling, and fever. The appendix was found attached to the stump of the right ovary; it was sharply bent upon itself and stretched. It was easily separated from its attachments, however, and brought out for inspection. It was found congested, red, and swollen, and after its removal was seen to contain several hard fecal masses. Recovery was uninterrupted.

CASE VIII.—Mrs. F. J. T., 48, a patient of Dr. Harrison, of Richmond, Va., was admitted January 9, 1895, with an ovarian tumor of several years' standing, but, as for a long time it gave her no trouble, she declined operative interference. Suddenly, however, and without any explanation, she began to suffer great pain in the right groin; the pain was continuous. Occasionally, however, she would have a sharp attack, which confined her to bed. On opening the abdomen, the first thing I saw was the appendix running across the face of the tumor like a little snake. It was firmly adherent and almost impossible of detachment without bursting it or the tumor. I removed it, however, and at the same time the ovarian tumor was taken away. Her recovery was complete.

CASE IX.—Miss N. T. S., 16, a patient of Dr. Stuart McGuire, of Richmond, Va., was admitted March 20, 1895, having had several attacks of acute appendicitis during the past year, but as 3 or 4 months had passed and no return of the trouble appeared, her parents sent her to Washington City to school. While there she had a pretty severe attack. Her parents brought her back after the attack subsided, and I deemed it best, after examination, to remove the appendix. The abdomen was opened, the appendix found closely adherent to the cecum, going transversely across the organ, and somewhat constricting the lumen of the bowel. It was peeled loose after a great deal of trouble and removed. A small opening was made in the cecum in detaching this appendix, which was closed with fine silk sutures. Recovery was uninterrupted.

CASE X.—Mrs. E. B. B., 35, a patient of Dr. R. E. Franklin, of Richmond, Va., was admitted March 29, 1895, having suffered for the last 6 months. The pain was usually confined to the right iliac region, but occasionally extended all over the abdomen. Her last attack kept her in bed for weeks, during which time she had fever, great pain, loss of appetite, and constipation difficult to overcome, and her life was thought to be in great danger by her attending physician and by myself, who saw her in consultation. The abdomen was opened and the appendix was found doubled on itself and fastened to the cecum; it was dense and firm in consistency and of unusual length. The omentum was closely adherent to the cecum and appendix; after separating the omental adhesions a large slice of the omentum was ligated and removed. An adherent coil of the intestine was also released. The appendix was removed and found full of fecal matter. The patient recovered without a bad symptom.

CASE XI.—Mr. G. H. G., 17, a patient of Dr. W. L. Drewry, of Wakefield, Va., was entered in December, 1893, with a history of several attacks of chronic relapsing appendicitis, the last one only a short time ago. This was very severe, and he was obliged to take a good deal of opium. I operated on him and came down, after the abdomen was opened, upon the omentum, slightly adherent to the parietal peritoneum. By palpation I could feel through the thin piece of omentum an abscess-cavity. Before opening this I stitched the surface of the omentum to the parietal peritoneum, so as to keep the cavity from the contents of the abscess. After carefully packing gauze around the edges of the opening I carried the knife through the omentum into the abscess-cavity; following it with my finger, I found the detached appendix, which was easily removed, along with one or two hard small fecal lumps. The cavity was then washed out carefully, a drainage-tube of rubber introduced, and the wound closed. Recovery was uneventful.

CASE XII.—Mr. W. C. B., 27, a patient of Dr. Keister, of South Boston, Va., was admitted April 6, 1895, having had 14 attacks of appendicitis, each more and more severe than the preceding one. I examined him some months ago and advised an operation, but he declined. Three weeks ago he had a very severe attack, attended with the usual

symptoms. I opened the abdomen and found the omentum covering the cecum adherent to that organ, and difficult to detach. After separation a portion of the omentum was ligated and cut away. Several points of adherent bowel were separated. The appendix was fastened to the cecum for the greater portion of its length and was detached with difficulty. It was found after removal to be filled with foul-smelling pus. The parts about the cecum looked dirty, brown, and friable. Gauze-drainage was used and the cavity closed. The drainage was permitted to stay for 3 days and then removed. Recovery followed without any bad symptoms. The operation in this case lasted 75 minutes.

Case XIII.—Mr. C. R., 30, a patient of Dr. Lewis Wheat, of Richmond, Va., was entered April 25, 1895. He had had three attacks of appendicitis, the last one very severe, keeping him in bed for 3 weeks. I saw him at this time in consultation with Dr. Wheat, and advised him not to have the operation done until the fever and acute symptoms had disappeared. I operated April 25th, 6 weeks after the subsidence of the last acute attack, and found very extensive adhesions, the omentum being fastened to the cecum. The adhesions were hard to break up. I found three points of adherent coils of intestine, which were separated with great care, and took a good deal of time. The appendix was fastened tightly to the cecum, and in detaching it I made a hole in the bowel about ½ in. long and ¼ in. wide. This was immediately sewed up with fine silk, and the appendix removed. It was found after removal to be closed at its cecal end; it contained a large quantity of bodies like boiled rice, but no pus. Gauze-drainage was inserted. The next morning the man was doing so well that the House-surgeon removed the gauze-drainage, although the discharge had been very free. As soon as the gauze was removed he began to get worse, and his temperature went up to 101°. That night, fortunately, I was able to replace the gauze and re-establish the drainage. The improvement was immediate, and his recovery after that was uneventful.

Case XIV.—Mr. H. B. L., 21, a patient of Dr. David Lucas, of Quinton, Va., was entered March 22, 1895, having had 10 attacks of appendicitis, each successive one becoming more and more violent. I opened the abdomen March 24th, found the appendix with great difficulty, underneath the cecum, which organ was adherent to the iliac fossa, and had to be detached. The appendix, when found, was adherent for ¾ in. of its free end to the peritoneum covering the iliac vessels; it was closed for about 1 in. of its cecal portion; the free end of it was bulbous, swollen, dilated, and filled with dirty, foul-smelling pus. Around the appendix in the iliac fossa was deposited quite a quantity of stuff, which looked like boiled custard, probably about an ounce of it in all in that region. This was scraped out, curetted, and the cavity dusted thickly with iodoform. Gauze-drainage was freely used in this case, being allowed to remain for 3½ days. Recovery was uneventful.

Case XV.—Mr. A. A. M., 28, a telegraph-operator, a patient of Dr. C. V. Robinson, of Petersburg, Va., was entered February 4, 1895. He had had repeated attacks of appendicitis in the last two years, the last ones being very severe, attended by vomiting, pain, fever, etc. The operation was performed February 5th. The omentum was fastened to the cecum and to the anterior abdominal wall; it was detached without great difficulty, however, and the detached portion ligated and removed. The appendix was found upon the inner side of the cecum, imbedded in a mass of inflammatory deposit. The adhesions were difficult to break, and at one time I was almost on the point of abandoning the attempt to find the appendix. When, however, the adhesions were completely removed, the appendix was found enlarged, swollen, perforated at its extremity, and so rotten that it was with great difficulty it could be handled and tied off. On the inner side of the cecum, at the site occupied by the appendix, was a cavity filled with some boiled-custard-like material. This was scooped out, the cavity-wall curetted and covered with iodoform. Gauze-drainage was used very freely, and the wound closed. It was impossible, in this case, to cover over the stump of the appendix with peritoneum as I usually do. The gauze-drainage was permitted to remain for 3 days, when it was removed, and the man recovered without any untoward symptoms. On June 5th, 4 months after the operation, an abscess formed in the abdominal wall; not in the cavity of the belly. This abscess was opened and drained by Drs. Budd and Robinson. The man came to see me August 1st quite well again.

Case XVI.—Mr. G. M., 29, a bookkeeper, a patient of Dr. Lewis Harvie, of Danville, Va., was entered June 15, 1895, having had repeated attacks of appendicitis, which began about 18 months ago, and recurred every 2 or 3 months. One attack kept him in bed for 6 weeks. I operated June 18th, making the incision in the usual way, and found that the swelling was due to distention of a portion of the cecum. The appendix was small, fastened like a strap to the cecum, and intimately blended with the bowel. I removed it in the usual way, stripping it loose from the cecum, although it was difficult to do, and I was compelled sometimes to use the point of the knife. Gauze-drainage was used. The man recovered without a bad symptom.

Case XVII.—Mr. J. H., 28, a patient of Drs. Austin and McChestney, of Lewisburg, W. Va., had had repeated attacks of appendicitis, requiring the free use of morphin to stop the pain. His general health had been impaired by the attacks. The most severe one was in the spring of last year, which confined him to bed for some time. He was never free from pain, and there was tenderness on pressure over the region of the appendix. I operated June 25, 1895, finding the adhesions very extensive, and the omentum fastened to the bowel at many places. The appendix was distended and enlarged, filled with mucopus, and its walls studded with numerous small, dark points. The operation was an exceedingly difficult one; the appendix was hidden under a mass of adhesions, which were old and well organized, and it was not until I had separated a great many of the adhesions that I was able to find the

appendix at all. Gauze-drainage was used, and the patient did well for 24 hours. His temperature the morning after the operation was 99°. About 2 o'clock on the second day his temperature rose to 101°, at 4, 102°, at 5, 103°. Dr. Stuart McGuire had given him 5 gr. of calomel that morning, and afterward magnesium sulphate, both of which, however, were rejected. Enemata were used, the long rectal tube was employed, but all failed to move his bowels. The next day Dr. Stuart McGuire cut the stitches and opened the wound, found a pint or more of bloody serum in the cavity, the small intestine distended with gas, and a small piece of the omentum which I had detached was fastened to the bowel in the neighborhood. These were all broken loose, the abdomen flushed out, and a great many drains of sterilized gauze were inserted. The patient rallied well, and an hour later was apparently better than before this secondary operation; about dark, however, he began to fail, and died at 10.20 that night from septic peritonitis.

HEMIFACIAL ATROPHY.

BY JAMES HENDRIE LLOYD, M.D.,
OF PHILADELPHIA;
NEUROLOGIST TO THE PHILADELPHIA HOSPITAL; PHYSICIAN TO THE METHODIST EPISCOPAL HOSPITAL AND TO THE HOME FOR CRIPPLED CHILDREN.

A RARE disease is, or should be, something more than a mere pathologic curiosity. Such a disease always has its practical relationships. It is not reserved for the specialist alone, who knows how to diagnosticate it and may, or may not, know how to treat it. It is only too likely to fall to the lot of other practitioners, and it then imposes obligations and responsibilities upon them which a fair general acquaintance with it would do much to lighten. One of the evils of the increasing tendency to specialism is that it directs the attention of the general physician away from anything that looks a little strange and unduly interesting.

Another tendency at present is to regard only those diseases as *practical* that admit of ready and successful treatment. Those who take this view seem to forget that the science of diagnosis underlies the whole practice of medicine, and that the province of the physician is more frequently to know than to do.

Some such considerations as the foregoing must serve as an apology for presenting a brief statement of a rare, incurable disease, with a photograph of a patient afflicted with it, in a medical journal which aims especially to minister to the practical needs of the profession.

Hemifacial atrophy was apparently first described by Parry in 1835. The latest writer on the subject, Collins,[1] says that it is still a rare disease and that in an extended search of the literature he had been able to find only a few more than one hundred cases reported. The number of patients photographed is doubtless much smaller; and as the disease lends itself particularly well to photography, cases so presented are much increased in value.

The practical relationships of this disease are in no way better shown than by its etiology. Collins, from a study of reported cases, gives as real or apparent causes the following: local injury, such as pressure or blows on the head or face; local lesions, such as abscess behind the ear, inflammation of the lachrymal sac, and inflammation of a submaxillary gland resulting from a sore-throat; the infectious diseases, such as influenza, erysipelas, scarlatina, and typhoid fever. Hemifacial atrophy has been found associated also with such diseases as hysteria, epilepsy, locomotor ataxia, insanity, multiple sclerosis, and syringomyelia. It has occurred also in association with somewhat similar trophic lesions in other parts of the body, as scleroderma; and with some skin-diseases, as pityriasis rubra. Some of these alleged causes are perhaps open to doubt; but it seems probable that local traumata and other local lesions may be in some cases the starting points of the affection. Lewin found a traumatic history in 14 out of 68 cases, and Mendel a peripheral origin in 19 out of 86 cases (quoted by Sachs).[1]

Hemifacial atrophy occurs more frequently in females than in males. It is most common in early adult life, although cases occur in childhood and in old age.

This disease, as its name indicates, is characterized by an atrophy of one side of the face. The exact location and extent of this wasting, as well as the accompanying symptoms, differ widely. Without exception, however, so far as I know, the disease does not extend across the median line. It usually begins as a circumscribed spot or patch, from which the pigment either disappears or in which it is altered, and in which the skin becomes notably thinned. From this, as from a center, the disease spreads. Not only the skin, but also the subcutaneous tissues and even the bones are soon involved. The muscular tissue is not, as a rule, so completely involved; but this rule varies. In some cases the muscles are wasted, in others they are the seats of tonic and clonic contractions. As the disease advances, great deformity results. The bones of the forehead and face may become extensively wasted, and this wasting may be so sharply demarcated at the median line that the patient presents almost the appearance of having received a saber-cut. The atrophy causes a scar-like tissue, which in some cases is bound to the bone beneath.

Tactile sensation is usually not involved; neither is the thermal or the pain-sense. In some cases neu-

[1] A Text-book of Nervous Diseases by American Authors, edited by F. X. Dercum, 1895.

[1] The Medical Record, March 15, 1890.

ralgic pains have occurred. Thus Courtet[1] observed severe pain both before the onset of the disease and after its establishment. It was not unlike toothache, and was apparently caused by carious teeth.

The special senses, as a rule, are not affected. Exceptions are reported by Bannister (quoted by Mills),[2] who observed loss of taste, with atrophy of one side of the tongue. The ear-drum has been noted to be diseased in one case.

The muscles of mastication have been observed to be affected with both clonic and tonic spasms (Courtet, Sachs, and others). A veritable trismus, holding the jaw firmly, has occurred temporarily in some cases. Fibrillary contractions are occasionally seen.

In some cases the eye seems to be withdrawn into the socket (enophthalmia).

Other parts may be affected, as one nerve of the arm. This observation is a very rare one. The hard and soft palate, the uvula, and the gums of the affected side may be involved.

The hair of the affected region usually falls out. It may, in some instances, change color. The contrast in the growth of the beard on the two sides is sometimes very great. When the atrophy affects the scalp an area of alopecia is the result. This area is usually sharply demarcated.

Thesebaceous glands are atrophied with the skin. Sweating, as a rule, is not affected. Contraction of the pupil, variations in the normal surface-temperature, and even hyperidrosis are indications of involvement of the sympathetic nerve.

The disease is sometimes very slow in its course. It may be confined for years to one comparatively limited region, and does not by any means always involve the whole of one side of the face, or, at least, does not do this until very late in its course.

In the case which I report the disease is still in a comparatively early stage. As shown in the photograph, the lesion is limited to the forehead and upper and lateral parts of the nose.

A. S., a young Swedish woman, aged about 25, first noticed a white patch near the bridge of the nose several years before her case was brought to my notice. This patch gradually spread upward until it reached and finally invaded the hairy scalp.

The skin of this area was atrophied, the true skin almost destroyed, and the epidermis left as a dead-white, lifeless-looking, and shrivelled integument. The fat and connective tissue were also gone, and the bone was deeply atrophied—one might almost say eroded. The resulting lesion, confined strictly to one side, but extending quite up to the median line, had the appearance of a cleft, or, as it has been called, a saber-stroke. Where it involved the hairy scalp the hair had fallen out, leaving the unsightly lesion still more conspicuous (see figure). The disease had extended downward to one side of the nose, where it was as yet quite superficial, not involving the bone, and hence not appearing plainly in the photograph. It tended to spread also laterally on the forehead. There was no pain, itching, or subjective sense of any kind in the affected area. Neither was there anesthesia or analgesia. Sweating was apparently not increased.

All the other symptoms detailed earlier in this paper were absent—the disease being still of comparatively recent origin, and hence confined to a comparatively limited area, it is, perhaps, better depicted in the photograph than it can be by word.

In this case there was no known cause. The patient had received no local injury, nor had she had any local inflammation or lesion of any kind to which the disease could be ascribed. The affection was very slowly progressive, and during the six months that it was under my observation it yielded in no way to treatment. This treatment in fact was only empiric, for I know of nothing that has any power over the disease.

The diagnosis of hemifacial atrophy is usually not difficult. The disease is to be distinguished especially from the morphea of the dermatologists. This latter is apparently also a trophoneurosis, but it does not involve the bone. It is probably closely related to hemifacial atrophy, and some reported cases of it are apparently identical with the disease described here.

The prognosis of hemifacial atrophy is entirely unfavorable. Many writers, apparently following older examples, speak of the disease as not endangering life, and seem to wish to derive from this fact some element of comfort for their patients. This is cold comfort, however, as the patients naturally are much dismayed at the inveterate and disfiguring disease which marks them so terribly for life.

It is of some practical importance, perhaps, con-

[1] Gaz. Heb. de Méd., 1876, p. 195.
[2] Pepper's Syst. of Med., vol. v.

sidering that hemifacial atrophy may follow surgical lesions, to emphasize the fact that in any unfortunate case in which it thus happens no responsibility can attach to the practitioner who has treated the primary lesion.

This disease is probably a true trophoneurosis. In the few autopsies that have been made (that especially of Mendel) the trigeminal nerve has been found involved in an inflammatory or degenerative process. The pathology has given rise to much speculation, which this is hardly the place to recapitulate at length.

In conclusion, I may say that I have used the term *hemifacial* atrophy as rather more accurate than *hemiatrophy* of the face, a term which is used by many writers.

CLINICAL LECTURE.

SOME PHASES OF SYPHILIS OF THE BRAIN.

A Clinical Lecture delivered at the Philadelphia Hospital.

By CHARLES K. MILLS, M.D.,
NEUROLOGIST TO THE HOSPITAL; PROFESSOR OF MENTAL DISEASES AND OF MEDICAL JURISPRUDENCE IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

Gentlemen: Many diseases that are usually considered under other special heads are really syphilitic in origin. Encephalic and spinal tumors, arteritis and thrombosis of both cerebral and spinal arteries, hemorrhages, which are frequently the result of rupture of vessels weakened by syphilitic disease; and finally meningitis, encephalitis, and myelitis, and both meningoencephalitis and meningomyelitis, may all be syphilitic affections. Syphilis needs to be considered separately for certain practical reasons, one of the most important of which is that the lesions of syphilis are frequently not only multiple, but are of different pathologic types in the same case, and hence give a symptom-picture that has a stamp of its own. It is possible that a single gumma may be the only intracranial lesion, but this is a rare occurrence. Not only do we have in nervous syphilis lesions diverse in their pathologic characteristics, but frequently the disease shows a tendency to arrange itself under certain peculiar clinical types. The best method of considering syphilis of the nervous system is probably one that presents a series of such clinical types that occur with considerable frequency, and which can be related with comparative accuracy to lesions of a definite character. Most of the attempts to classify syphilitic diseases of the nervous system have been confusing and lacking in some essential features. Mickle, for instance, gives: (1) cerebrospinal; (2) hereditary; (3) spinal; (4) tabetic; (5) convulsive; (6) neuralgic. Here is a strange admixture of anatomic, etiologic, pathologic, and semeiologic factors as the bases of a single classification. Others, like H. C. Wood, after discussion of several clinical types—epilepsy, paralyses, cerebral and cranial, apoplectic and comatose attacks, and episodes of somnolence—abandon classes entirely for the study of special symptoms.

In approaching the subject of nervous syphilis, the first great general subdivision which should be made of cases as they present themselves in ordinary practice is into the affections directly due to the continuing action of the specific virus, and those which are the more or less remote consequence of this virus. These two classes constitute Fournier's *specific* or *syphilitic* and *parasyphilitic* diseases. The parasyphilitic diseases are affections that are the issue of syphilis, but are not its first and most direct results.

Fournier's distinction is one to be especially borne in mind in connection with the degenerative diseases or affections showing arrest of development, and in which a history of acquired or inherited syphilis is present. "The *specific* group arise from the specific action, processes, and lesions of syphilis. The *parasyphilitic* have origin in syphilis, are products of its action, under its influence, and without it in all probability would not be present; but although thus proceeding originally from syphilis are not of a syphilitic (specific) nature. As parasyphilitic, Fournier classes, for acquired syphilis: pigmentary syphilid; acute hysteroneurasthenia of the secondary stage and later neurasthenic symptoms; tabes; general paralysis; a special form of epilepsy; and of muscular atrophy. For hereditary syphilis: many general or partial dystrophies and organic malformations (*e.g.*, dental); physical or mental developmental defects, infantile types; cachexia; rickets; hydrocephalus; some cases of true epilepsy; certainly juvenile tabes and general paralysis." (Mickle.) To most of the diseases of the parasyphilitic class no allusion will be made in this lecture, although the wards of this hospital abound in illustrations. Their relation to syphilis needs separate and special consideration.

Let me at the outset, however, say a few words about syphilitic neurasthenia and syphilitic hysteria, typical cases of which have been described by Fournier, Kowalewsky, and Dercum. Typical cases of this category do not present marked ophthalmoscopic changes, nor any evidence of focal nervous disease, although aphasias and palsies are sometimes present. A syphilitic neurasthenic or hysteric is a patient who, with a clear history of syphilis, presents all the characteristics or some of the characteristics of a case of grave hysteria or neurasthenia. The affection may be primarily due to the effect of the syphilitic virus upon the blood; but sometimes it is the result of prolonged antisyphilitic treatment, or it may be dependent upon the psychic shock and depression largely caused by the knowledge of infection; or the changes that have taken place in the vessel-walls and in the nerve-tissues through the action of the poison—although these two last classes might as well be placed under some other head.

The cases now to be shown will be presented in the briefest possible manner in pursuance of my intention to give simply a bird's-eye view of some phases of syphilis of the brain illustrated by clinical cases. It will be understood that in these cases careful studies with detailed records have been made, but that time will permit me to present little more than the baldest outlines. The case with which I shall begin the series that will be used to illustrate these lectures was first supposed to be a case of hysteria in the male. The patient was sent to the ophthalmologic department of the hospital to have his fields of vision tested for the reversions and contractions so often present in grave hysteria.

CASE I. *Case supposed to be one of hysteria or neurasthenia; ophthalmoscopic examination shows neuritis and perivasculitis; other evidences of cranial-nerve disease and cerebral involvement.*—The patient, P. L., has a clear history of syphilis. He had fallen into a peculiar mental state and presented evidences of general nervous and muscular weakness. On ophthalmoscopic examination, Dr. C. A. Oliver found a most interesting condition of neuritis with perivasculitis. His report is as follows: Marks of old plastic iritis are present, and most pronounced in the left eye. The ophthalmoscope shows a low grade of neuroretinitis, with perivasculitis on both sides and a broad hemorrhage in the right retina. Vision is normal, and the fields of vision are also normal. There is no motor disturbance. On the blackboard is a picture in colors, drawn by Miss M. Washington, the artist, from actual observation of this patient's eyes with the ophthalmoscope. This case is a striking illustration of the possibility of obtaining, by an examination of the eyes, an idea of the pathologic processes probably going on in and around the vessels of the brain. Similar conditions to those visible in the vessels, vessel-walls, and perivascular spaces of the fundus are probably present in the brain. The revelations of the ophthalmoscope led to a closer examination for other symptoms. The patient has a scarcely-perceptible awkwardness of articulation, the right side of his face droops slightly, but his tongue deviates very decidedly to the right. Mentally his condition is one of slight apathy with timidity and apprehension, with also a lack in his powers of attention. At times he is decidedly emotional.

The case is certainly not one of neurasthenia or hysteria pure and simple, although the functional weaknesses and disturbances may be due in part, at least, to the effects of the specific virus. Here are the clearest evidences of cranial-nerve disease and of some cerebral involvement, probably chiefly cortical and prefrontal. My main purpose in presenting this patient is to call attention to the fact that in some cases supposed to be instances of syphilitic neurasthenia and hysteria, signs of organic disease can, on close scrutiny, be found.

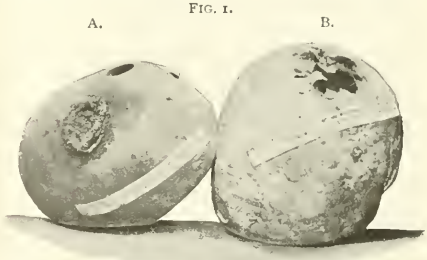
The best general classification of syphilitic (true specific) diseases of the nervous system is into *encephalic* or *intracranial*, *encephalospinal*, and *peripheral-spinal* (lesions of spinal nerves). Any one of the subdivisions of the nervous system may be separately affected; any two or more parts may be attacked at the same time, or all may simultaneously be the seat of active specific disease. The difficulties of subclassification are great. In the present lecture only encephalic syphilis will be considered, and chiefly those forms of it in which cranial-nerve disease is present, either alone or associated with disease of other parts of the brain.

Considering the subject from the pathologic side, perhaps no better practical classification has been made than that of Bramwell, who divides encephalic syphilitic lesions into (1) intracranial nodes with or without meningitis; (2) gummata; (3) lesions of the large or medium-sized bloodvessels, chiefly obliterative endarteritis; (4) diseases of the minute vessels, in many instances periarteritis rather than endarteritis; (5) localized encephalitis in the neighborhood of gummata and meningeal lesions; (6) inflammation of the intracranial portions of the peripheral nerves; and (7) meningeal inflammations without gummatous deposits(?). Almost every one of these classes of lesions will be illustrated by our cases.

Swellings or nodes due to syphilitic disease of the periosteum, or both the periosteum and the bone, may give rise to symptoms that simulate closely those of meningitis or tumor, and indeed meningitis, tumor, or softening due to vessel-disease may be associated with such nodes. These are often extracranial, and it is by no means uncommon to find intracranial nodes present in the same case with the extracranial swellings. The prominent symptom will usually be headache with evidences of pressure and irritation according to the site of the lesion. When such nodes are prefrontal and large, somnolence and mental hebetude may be marked. Paresis or affections of the special senses may be present. Occasionally these periosteal swellings are situated along the course of the cranial nerves or around their foramens of exit, and thus may give rise to cranial-nerve palsies, anesthesias, and neuralgias. As syphilitic nodes, either intracranial or extracranial, when efficiently treated, have a more favorable prognosis than some of the varieties of encephalic syphilis, it is important to bear in mind the probability of their existence. They sometimes melt away under active treatment with mercury and the iodids.

In the present lecture I have not the opportunity of showing any cases which I believe to be illustrations of syphilitic osseous or periosteal disease, although such cases are often found in the nervous wards of the hospital. I exhibit, however, two specimens (Fig. 1) from

FIG. 1.



Two specimens of syphilitic bone-disease: A, ossifying periostitis; B, greatly thickened and necrosed calvarium.

the Pathologic Museum. One of these is from a patient who was for many months under my care. Syphilitic periostitis, ostitis, and necrosis finally caused the large irregular opening seen in this calvarium. The nervous system of this patient was also attacked in various other ways by the specific virus. The other is a specimen of syphilitic ossifying periostitis. While some cases of periosteal and osseous syphilis are amenable to early and active treatment, this specimen shows the permanent ravages that may be produced by such diseases.

The next cases, some of which I will present in groups, illustrate some of the most frequent clinical types seen in this hospital.

In the first place, encephalic cases are seen in which for a long time, or perhaps even until a fatal issue results, *only one or two dominating symptoms*, such as *headache*, *somnolence*, etc., are present.

Case II. *Headache, vomiting, and emaciation; double optic neuritis, but no motor or sensory symptoms.*—This patient is a German, 30 years old, with an uncertain past history. His present illness dates back three months. He began to suffer with great pain in the head, had no appetite, and after a few days was attacked with nausea and vomiting, which continued for one or two weeks. He had no paralytic or sensory symptoms. The only symptoms to which attention was attracted until the ophthalmoscope was used were headache, nausea, and vomiting, except that the man was neurasthenic and had lost flesh. I show you upon the blackboard another beautiful illustration in colors, drawn by Miss Washington, of the optic neuritis present in this case, and I append the notes of Dr. Oliver's examination. Neuroretinitis is present on both sides, older on the left, atrophic changes appearing in many places. This disc is swollen so as to project far into the vitreous, —5 D., as measured by the ophthalmoscope and by actual measurement 1.33 mm. Numerous hemorrhages are seen, some old, but for the most part new, extending along the main trunks of the retinal arteries and veins. Pupils partly dilated and irides sluggish to light. Vision is good.

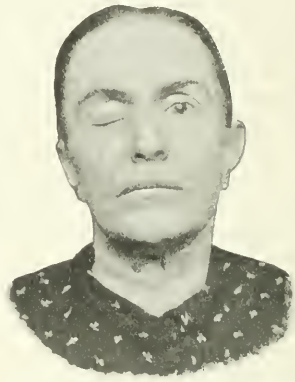
It is probable that this patient has a gumma situated in one of the so-called latent regions of the brain, as, *e.g.*, the right temporal lobe. The growth might be located in the prefrontal region, although the patient does not present with any decisiveness the psychic phenomena of lesions in this locality. He has made great improvement under the use of potassium iodid in large doses.

Case III. *Mental weakness, epilepsy, and polyuria.*—This patient is introduced simply to show that in typical cases of syphilitic disease a single symptom like polyuria may be the most prominent feature, or there may be one of two or three features in the symptomatology of the case. He has suffered for a long time from polyuria. He has also a clear history of syphilis and of subsequent convulsive seizures. He is 37 years old. He had a chancre in 1881, and four years later had an eruption, probably syphilitic. He has been somewhat weak mentally since 1888. Ordinary happenings do not leave any impression upon him. In 1890 he had a fit for the first time. When first affected he had four or five a week, but at present he averages one every two or three weeks. He bites his tongue in the seizures. He complains of great thirst and voids urine almost every half-hour day and night. In this case some local lesion of the pons may have caused the polyuria, while more diffuse lesions and secondary degeneration have induced the epilepsy and mild dementia.

In a certain rather large percentage of cases of intracranial syphilis, *affections of the cranial nerves* are the chief or only phenomena. In the first place, I say that they are *the chief* phenomena because in not a few of these cases casual observation or close investigation will show that other parts of the encephalon have been attacked by the disease. I have the opportunity of presenting an unusual series of cases illustrating the occurrence of these cranial-nerve affections, either alone or with symptoms showing implication of other regions than the base of the brain. The first case of this series is one in which marked disease of the cortex and of at least one of the cranial nerves is present at the same time. This is a somewhat frequent clinical combination in encephalic syphilis.

Case IV. *Oculomotor paralysis with evidences of meningeal and cortical disease.*—This patient, M. F., is a woman, 45 years old, who has had no living children, but who has had three stillbirths. Her present illness has been attributed to a sunstroke, and this may well be true, and yet the case be one of intracranial syphilis, for excessive heat, traumatisms, and various other causes may light up the lurking syphilitic fire. On admission she was much deranged and papers were made out to send her to the insane-department, but the mental symptoms clearing up somewhat under specific and sedative treatment, she was admitted to the nervous wards. Her first attack came on with dizziness. About five months before admission she saw double and her right eye was closed by drooping of the upper lid. Just before admission she had a convulsive seizure. Her present condition is one of oculomotor paralysis (Fig. 2), with a slight

Fig. 2.



Right oculomotor paralysis, facial paresis, and meningocortical disease.

paresis of the right side of the face, some hesitation of speech, mild dementia, and a tendency to undue emotionality.

In succession I shall next present a case of third-nerve disease with multiple vascular and meningeal lesions, with the record of the autopsy; a case of paralysis of the abducens and of the iris; a case in which all the cranial nerves from the fifth to the ninth are conjointly involved; and a case in which only the seventh and eighth nerves are implicated. I believe that the origin of each of these cases was syphilis, although it is not possible in at least one of them to obtain a clear history of the infection.

Case V. *Right oculomotor paralysis with paresis of left leg, and mental symptoms; long apoplectic period preceding death; autopsy showing fibroid meningitis, diffuse endarteritis, multiple thrombosis, and localized softenings.*—I show you now a specimen from a patient who was brought before the class during my lectures last year. She was 29 years old and had a previous history of dissipation. She had had sore throat, an eruption probably syphilitic, and had lost most of her hair. Her clinical history was that of headache; of an attack in which she lost for a time the use of her left leg; and

also of complete right oculomotor paralysis. Later she became irritable, slightly demented and apathetic, and finally stuporous.

Her eyes were carefully examined by Dr. Oliver, who found on the right side complete ptosis, and all movements of the ball lost, except outward movements and a slight rolling motion upward and outward. The appearances presented by this patient with the paralyzed eye closed from the ptosis and held open are shown in Figs. 3

Fig. 3.

Oculomotor paralysis, showing ptosis. The case proved to be one of gummatous meningitis, endarteritis, and thrombosis of the internal carotid. The right third nerve was bound down by exudate.

Fig. 4.

Oculomotor paralysis: the eye held open. Same patient as Fig. 3.

and 4. The pupil of this eye was 4 mm. in diameter and immobile; both optic discs were gray. The patient died after a long apoplectic period in which she was comatose most of the time, and during which she had one slight convulsive seizure. The third-nerve paralysis on the right deepened; on the left the pupil became somewhat contracted and fixed. The following interesting conditions were found at the autopsy: The right internal carotid was free until within 2 or 3 mm. of the point where it penetrated the dura, where a plug, flesh-colored and well organized, was found in the artery. The right postcommunicant was reduced in size and the right precerebral was also very small; the left precerebral was very large, as was also the left postcommunicant. On the right side of the chiasm and the beginning of the optic nerve was a dense mass surrounding the internal carotid, and adherent to the optic nerve and third nerve; the mass lay in the beginning of the fissure of Sylvius, which it fairly obliterated. The left internal carotid also contained a clot about the position at which it joined the precerebral, the medicerebral, and the postcommunicant. The clot also extended into the medi-

Fig. 5.

Drawing showing the lesions present in Case V (illustrated in Figs. 3 and 4); a, right third nerve adherent to fibroid mass; b, right internal carotid plugged by a thrombus; c, fibroid mass filling the Sylvian fossa and extending backward to the crus; d, chiasm; e, left internal carotid containing recently organized thrombus; f, left third nerve; g, left postcommunicant at junction with postcerebral; h, basilar giving off postcerebral.

cerebral artery about half an inch. The cerebellum, pons, and oblongata showed nothing abnormal. The head of the caudatum and lenticula were softened, the material in the softened cavity being liquid and about the color of pus.

Later I expect to have a full report made of the microscopic examination of this specimen. The gross appearances are well indicated in Fig. 5, which is a drawing made by Miss Washington from the actual specimen and from a photograph of it. This specimen shows a localized gummatous meningitis with fibroid change, associated with syphilitic endarteritis, thrombi forming toward the last. The third-nerve paralysis and the paresis of the left leg are readily explained by the lesion extending from the Sylvian fissure to the crus. The softening of the striatum was due to syphilis of the vessels and thrombosis. The disease of the vessels was chronic and not limited to the base of the brain. This case affords a beautiful illustration of a comparatively common form of encephalic syphilis with lesions diverse both in character and position. It is very probable that similiar lesions are present in Case IV.

(To be concluded.)

MEDICAL PROGRESS.

Unsuccessful Esophagostomy for Cicatricial Stricture.—At a recent meeting of the Philadelphia County Medical Society, ROBERTS reported the case of a boy, 3½ years old, who, three months before coming under observation, had swallowed a solution of lye, which resulted in stricture of the esophagus. It was said that a month previously a rubber catheter could be passed through the contracted portion of the gullet. The child was greatly emaciated and very weak. An attempt was made to pass a flexible catheter down the esophagus, but even the smallest was arrested by a constriction at its upper part. A whalebone filiform bougie, such as is used in urethral surgery, was without much difficulty, however, pushed downward and apparently passed through the contracted portion of the tube.

As the child was evidently starving to death, it was determined to operate upon him. At first gastrotomy was considered. The bougie passed down the esophagus from the mouth would, it was thought, enable a strong ligature to be drawn from the stomach upward through the stricture. This would have been used to cut the stricture, as in Abbe's string-saw method. Careful examination of the patient, however, showed that the contraction was situated at a point sufficiently high to enable the esophagus to be opened below it. Accordingly esophagotomy was performed by making an incision along the anterior edge of the left sterno-mastoid muscle. The esophagus was opened a little below the level of the cricoid cartilage and a No. 12 soft-rubber catheter introduced into the stomach. The edges of the esophageal wound were then stitched to the skin and the catheter allowed to remain for the introduction of liquid food into the stomach. There was some difficulty in identifying the esophagus, which was necessarily small; because of the character of the lesion and the position of the thyroid gland. The left lobe of the thyroid gland extended to a higher level than the top of the larynx.

About half an inch above the first esophageal incision a second opening was made into the esophagus above the seat of constriction, and a rubber catheter passed upward into the mouth. Between these two openings the esophageal walls were largely cicatricial. An endeavor was made to dilate or lay open this portion of the tube, but was not successful. The point of a pair of forceps, introduced into what seemed the caliber of the esophagus, when forced upward passed backward behind the wall of the pharynx. The condition of the child was so bad as to render undesirable the prolongation of the etherization in order to lay open or cut away the cicatricial tissue, and it was accordingly determined to postpone further operation until the child could be nourished for a few days through the catheter used to convey liquid food into the stomach. The catheter that had been introduced into the portion of the esophagus above the stricture, and which protruded from the mouth, was withdrawn.

The child was fed on peptonized milk and stimulants in small quantities, but did not seem to rally well. On the tenth day a purpuric spot about four inches in diameter appeared upon the abdomen. This subcutaneous hemorrhage increased, the child became weaker, and died on the sixteenth day. It was impossible to keep the seat of operation aseptic, because food and mucus contaminated the wounded surfaces, notwithstanding the greatest care. Frequent washing of the part with mild antiseptic solutions was therefore maintained. The post-mortem examination showed that about three inches of the esophageal walls were almost entirely destroyed by suppuration. This rendered it difficult to preserve the connection between the upper and lower portions during removal of the specimen. The bodies of the vertebræ at this point were exposed, and the inter-vertebral cartilages loose. Some of them could have been easily removed by picking them out with forceps. The spaces between the loosened cartilages and the bones were filled with dark, foul-smelling pus. There was an area of consolidation about the root of the right lung posteriorly; incision into this portion of the lung showed it to contain material similar in appearance and of the same odor as that in the region of the wound.

—

Patent Ventricular Septum in a Man of Twenty-nine.—At the last meeting of the American Pediatric Society, JACOBI (*Archives of Pediatrics*, vol. xii, No. 11, p. 835) presented a Russian, twenty-nine years old, who three years previously had been seized suddenly with illness, manifested by dyspnea, palpitation, frequency and feebleness of pulse, and lividity. A loud cardiac murmur was heard whose character could not be made out, and the size of the heart was found to be fairly normal. The patient gave a history of blueness of the lips and nails for a period of twelve or fourteen years. Relief followed the administration of digitalis and later also of potassium iodid. Several attacks of similar character had occurred in the interval. The finger-nails were not only blue but also clubbed, and the toe-nails presented a similar appearance. The superficial veins were prominent but not dilated. Jugular pulse could not be detected. The area of cardiac dulness was little if at all increased. The cardiac impulse was strong. A loud murmur, largely systolic, but partly diastolic, could be heard over and about the ensiform cartilage. A diagnosis was made of tricuspid incompetency, with patent interventricular septum and probably congenital stenosis of the pulmonary artery. The symptoms were again mitigated by means of digitalis and potassium iodid and the murmur became musical in character. Later pulmonary hemorrhages occurred, with transient elevation

of temperature and pain over the left ear. In the further progress of the case supraorbital neuralgia, occasional twitching of the left side of the face, aphasia, paralysis of the right side of the face and of the right hand, and rigidity of the neck were successively noticed. After death the heart was found to be slightly enlarged. The normal pulmonary artery arose from the body of the right ventricle; the conus arteriosus was absent. The caliber of the aorta was small, and the innominate, left carotid, and the subclavians were also small and arose from the ascending aorta. A small artery arose close to the left carotid, proceeding upward and probably representing a vertebral. The left ventricle was small; the right large, with eccentric hypertrophy. The ventricular septum was defective in its upper part, the opening readily admitting two fingers. The foramen ovale was closed. The duct of Botal was not appreciable. The tricuspid valve was much thickened and roughened. There was no evidence of recent disease. The brain was soft on the left side, normal on the right. The posterior horn of the left lateral ventricle contained a quantity of pus, and the cavity communicated with an abscess extending to the upper posterior part of the temporosphenoidal lobe, but not perforating the surface of the brain.

The Transitory Derangement of Consciousness of Epilepsy.—As the result of a study of the derangement of consciousness observed in various epileptic conditions, Siemerling (*Berliner klinische Wochenschrift*, 1895, Nos. 42, 43) maintains that a dreamy state of consciousness, rather than total or partial amnesia, constitutes the most significant feature of the epileptic psychoses. Various gradations exist among the individual varieties of the so-called acute and chronic epileptic psychoses. Epileptic or epileptoid conditions and psychoses must be considered as symptomatic of cerebral disease. States of transitory confusion are characterized by the occurrence of apparently orderly, indifferent, and inconspicuous manifestations, side by side with unusual, unexpected actions often of a violent character. Epileptic psychoses are always preceded by epileptic or epileptoid antecedents. Epileptoid conditions are more common than is generally believed, particularly vertiginous attacks. In the absence of epileptic or epileptoid symptoms the diagnosis must be based on other manifestations, such as amnesia, likeness of attacks, peculiarity of conduct, and of hallucinations.

The Surgical Treatment of Infectious Cholangitis and Cholecystitis.—Terrier (*Progrès Médical*, 1895, No. 43, p. 257) maintains that when the biliary passages are the seat of inflammatory conditions occasioning pronounced febrile manifestations celiotomy is indicated for the purpose of effecting cholecystostomy. By this means the condition of the biliary tract can be determined, calculi present removed, and means of exit for the bile provided.

THERAPEUTIC NOTES.

The Treatment of Pneumonia with Inhalations of Large Doses of Amyl Nitrite.—Hayem (*Wiener medizin. Blätter*, 1895, No. 43, p. 682) reports the employment of amyl nitrite in large doses by inhalation in the treatment of both pneumonia and pulmonary tuberculosis. The results were more favorable in the former than in the latter condition. Tuberculous patients can inhale the vapor from a suitable receptacle. Pneumonia-patients used compresses, upon which fifteen drops of the pure drug were dropped and the compress held close to the nose and mouth, deep inspirations being made the while. When this quantity has evaporated the amount is repeated again, and perhaps twice or even thrice. In this way fifty drops may be employed in the course of five hours. The physiologic phenomena of flushing, pulsation, pressure, respiratory and circulatory acceleration, cough, dyspnea, etc., soon disappear and leave no bad effects. The treatment is continuous throughout the illness and for a few days beyond defervescence. The dosage must depend upon individual tolerance. Other therapeutic measures are not contraindicated. It is not contended that amyl nitrite thus used shortens the duration of the disease or affects the temperature-curve, although it mitigates the symptoms referable to the lungs. The effect is attributed to an influence upon the pulmonary circulation.

Parachlorphenol for Laryngeal Tuberculosis.—As the outcome of a clinical study, Spengler (*Archives des Sciences Biologiques*, T. 4, No. 1, p. 1) has reached the conclusion that parachlorphenol applied directly to the larynx or in a 10 per cent. solution in glycerin in the form of a spray will induce cauterization of tuberculous ulcers, superficial and deep, as well as resorption of tuberculous infiltration, without engendering evidence of irritative reaction. Solutions of parachlorphenol in glycerin have a local anesthetic effect upon tuberculous lesions, lasting for several hours. Parachlorphenol has the advantage over lactic acid and operative measures that it may be employed in all forms and all degrees of laryngeal tuberculosis up to the last hours of life. The drug exerts also a favorable action upon lupus involving the mucous membranes, and may here effect a perfect cure. It possesses most energetic disinfectant activity toward the tubercle-bacillus both in pure culture and in sputum.

Strontium Carbonate as a Dentrifice.—Métral (*Bull. Gén. de Thérap.*, October 30, 1895, p. 360) speaks highly of the use of strontium carbonate as a dentrifice. He has employed the following formulæ:

Strontium carbonate } Flowers of sulphur }	āā	℥iv.
Essence of rose		gtt. vj.—M.

To be triturated and used as a powder.

Strontium carbonate	℥iss.
Flowers of sulphur	gr. xlv.
Medicinal soap	℥viss.
Essence of rose	gtt. vj.
Mucilage of gum arabic and glycerin sufficient to make a paste.	

For Chronic Eczema.—

R.—Liquor carbonis detergent.	♏xx.
Hydrarg. ammoniat	gr. xx.
Ung. zinci oxidi	f ℥ss.
Vaselin.	f ℥ss.—M.

S.—Apply topically.

PHILADELPHIA.

SATURDAY, NOVEMBER 30, 1895.

UNLICENSED ANTIVIVISECTION.

IT appears evident to us that vivisection, and with it some of the best interests of scientific medicine, are now running one of the peculiar risks that arise from the constitution of modern society—the appeal to public opinion. This is always the last resort of those whose reasons are not so strong as their passions and prejudices; whose native wits are more at home in controversy than in discussion; and whose consciences, apparently, must have a million keepers.

The latest acute phase of the vivisection-question cropped out at Minneapolis at the recent meeting of the American Humane Association. The position taken there was noteworthy for two reasons: because, first, it exhibited a bad method; and because, second, it ignored the true ethical question involved.

We think that the method adopted by Dr. Leffingwell and by the special committee was bad because its aim was to appeal this question to popular prejudice. Their tone, and, in fact, their exact language, conveyed a threat which was intended to intimidate their opponents by holding up to them the bogie of social tyranny. Dr. Leffingwell's paper and the committee's report have both reached us through the columns of a daily newspaper, to which they were telegraphed in full from the scene of the meeting. The paper itself is a not very brilliant example of special pleading. In diplomatic language it gives the lie to a committee of Harvard professors, whose names and work are well known in all the scientific world. Dr. Leffingwell is not content to attempt to refute men who in their special fields are eminently able to take care of themselves; therefore, he charges them directly with falsehood. The merits of this style of warfare are generally well understood. The body of the paper is composed of disjointed quotations from scientific reports, each quotation seldom more than a few lines in length, embodying merely some technical description of a vivisection-experiment. The object of the experiment, the care and conscientiousness with which it was done in each instance, and the results obtained, can, of course, be in nowise determined from such garbled and mutilated data. The whole object is simply to bring out in bold relief some of the more or less shocking features of the experiments. This is not done for the benefit of scientific men, because such men would pay no heed to such unfair presentations of experiments; but it is done too evidently in order to catch the eye and harrow up the sensibilities of lay readers. The paper, in our judgment, is a very strong argument, not against vivisection, as its writer intended, but against making the question an instrument for popular agitation.

We have made these strictures deliberately and in spite of the fact that the Committee's report embodies the results of an appeal to two-thousand physicians, clergymen, writers, and educators in the States of New York and Massachusetts. This appeal does not alter the fact for us, that the obvious intention is to catch the popular eye and to win popular favor. About the personality of these two-thousand individuals we have but limited means of knowing anything, and about their special fitness for forming a judgment on the subject of vivisection we know but little. But, taking even physicians at large, we need only point out the fact that the large majority of them have absolutely no practical acquaintance with the methods of, and even with the necessity for, vivisection. It is even a well-known fact that some physicians bitterly oppose vivisection with all the prejudice of professed agitators. The opinion of one specialist—like Pasteur, or Ferrier, or Welch—is worth more than the opinions of all the

average respectable practitioners, "of fifteen years' experience," in New York or Massachusetts. To attempt to settle such a scientific question by merely counting noses is trivial. Unfortunately, it is not without precedent that members of the medical profession have opposed scientific progress. The use of anesthesia in obstetrics was opposed, and its introduction delayed, by eminent professors in Philadelphia, one of whom gravely argued that it would defeat the scriptural plan, according to which women should bear children in agony. Even to-day physicians are found who deny the very existence of hydrophobia or the infectiousness of tubercle.

As for our friends, the clergy, although on the whole they have given some very sensible answers, it is not to them as a body that we look for light to illumine the pathway of science. And as for educators and writers, they are of all known species and varieties. What particular varieties of them were appealed to by the Humane Committee, and how much they know about the needs of modern scientific medicine, in no way appears.

It may be worth while to note, however, that the answers obtained by the Committee were on the whole favorable to vivisection under certain conditions and restrictions. While we do not attach much importance to these results, it is but fair to say that in the main they exhibit a degree of enlightenment that is encouraging to scientists and must be discouraging to the antivivisectionists. The vast majority of the replies are against the total abolition of this necessary adjunct to science.

We should note also that Dr. Leffingwell himself disclaims that he is an antivivisectionist. His methods and spirit, however, are such that we doubt not that the antivivisectionists will have no difficulty in recognizing him as one of their own.

The futility of an appeal to public opinion for the settlement of such a strictly scientific subject is clearly shown in the replies obtained by the Humane Committee. The majority of these replies are in favor of "vivisection when restricted by utility" and "vivisection when without pain." These expressions are in fact euphemistic. They are well-intended, no doubt, and indicate a disposition in those who use them to be liberal-minded; but practically they offer no solution for the difficulties and objectionable features of vivisection. The utility of an experiment can be determined alone by the investigator and by critics trained in his own special field—not by clergymen, writers, and educators, or even by the average physician. Vivisection without pain is, we fear, an ideal far yet from attainment. It is folly for scientists to claim that it is yet practicable in all cases. Such a claim puts them in a false position, of which their opponents take immediate advantage, as shown in Dr. Leffingwell's paper. It raises a standard to which the scientist cannot attain, but by which agitators and fanatics will aim to control him. It is better to acknowledge that vivisection means pain in many instances, and to claim that the degree of this must be left to the humanity and skill of the operator. It cannot be measured out by public opinion. The question of the right to inflict pain is included in the larger ethical question of the right to take animal life.

The impractical note in the report of the committee comes out still more clearly in its recommendation that this humane association by its local societies should demand the right to enter every laboratory and witness the experiments in vivisection. The main objection to this is not in the inconvenience to and interference with scientific workers that it entails, but in the recognition of the right of irresponsible persons, without special training or fitness, most of whom have already imbibed and even expressed a prejudice against vivisection, assuming to themselves inquisitorial duties, and arrogating to themselves the privilege of sitting in judgment for the public benefit upon the thing which they have already condemned. We do not presume to speak for all the experimental scientists of this country, but, if they shall agree to this proposition, we can only say that they will exhibit a degree of kindness and amiability that would fit them pre-eminently for the trying work of vivisection. The best work even in our hospitals could not endure such a test of ignorance without grave risk of misrepresentation and defeat.

The true ethical question that is involved in vivisection is practically ignored in the paper and report from Minneapolis. It has been stated so often that it can gain nothing from being stated again, and yet in this connection it can never be stated too frequently. We observe, by the way, a rather uniform reticence on this question by those who oppose vivisection. They either ignore it as beneath them or they studiously avoid it as too far above them, we know not which. This question, in brief, is that of the right of mankind, who claim and constantly exercise the right to chase, trap, catch, maim, and slaughter all forms of animal life

for sport, for food, for clothing, or for avoiding nuisances; also to use animal life for the demonstration of scientific truths. We are content here, without discussion, to state merely our belief that the one right is inseparable from the other.

Of the immense importance, nay absolute necessity, of vivisection for the progress of medical science there can be no question. Obstructionists, who, like Dr. Leffingwell, minimize the results obtained (as in the treatment of tetanus), present a mental attitude which is simply fatal to all progress. Such obstructionists have stood to oppose every inch of progress, not only in the scientific but in the political and religious world. For them one objection is magnified so as to obstruct their mental horizon in all directions. They are mentally and morally myopic.

The position assumed by this journal has always been in favor of proper legal restrictions upon the practice of vivisection. We doubt, for instance, its utility, or its desirability, for general didactic purposes. We are content, however, to leave the control of this question, in all its difficult details, to the proper law-making powers, guided by the advice and experience of experts who are qualified to state and to demonstrate the needs of their respective specialties. We do not believe that it can or should be settled by popular agitation or by an appeal to "clergymen, educators, and writers," or even to a general vote of the medical profession; although of the result of the last there can be no doubt.

A QUESTION OF CONSCIENCE.

DR. ARABELLA KENEALY, a woman-doctor—or, more accurately, a female physician—has popped a question of conscience into the masculine ear of the British practitioner which has stirred up quite a lot of the moral instincts for which the insular branch of the Anglo-Saxon race is noted. This question is a syphilitic one—or, to be more elegant, it is a question pertaining to syphilis. Dr. Kenealy shows plainly that she thinks that she is well grounded in the gospel of syphilis; and her child-like faith in the prevalent doctrines of the syphilographers is much better schooled than is her moral sense as a plain British subject. It seems that this question took its rise in a crisis in Dr. Kenealy's professional life which was about as follows:

The doctor was called to see "the wreck of a young woman" who was threatened with an abortion. The threatened abortion was, or would be, the sixth. Only one child had been born living to the patient, and this child was "typical," *i. e.*, syphilitic. The doctor, retiring to the library to write a prescription for a mercurial that was sagely intended to check the abortion, encountered this unhealthy child in an interview which was almost as long as a column of the *British Medical Journal*, in which the adventure is told. So impressed was she with the undesirability of adding another such child to that household that she rashly tore up her prescription and decided, not in this exact language, but yet literally, to let Nature rip. Dr. Kenealy's acquaintance with Nature in all her moods—especially her destructive mood toward all things syphilitic—is not the least remarkable of her accomplishments. "Nature," for Dr. Kenealy, is a distinct personality, aflame with a divine wrath against syphilis and syphilographers and syphilotherapeutists—Nature, she says, "is abhorrent of syphilis, and, in a spasm of anger, thrusts the abhorred thing from out of its mother's womb." Hence for Dr. Kenealy to give mercury in order to abort an abortion, and to save a small life "from rushing headlong into a sphere for which it was not yet equipped," was unnatural, sophistic, and diabolic. Acting, therefore, on this cue from Nature, Dr. Kenealy, apparently without even taking farewell of her patient, left the library and went home thinking.

The subsequent history of the patient and her embryo is not given; but Dr. Kenealy, like every true Briton who has a grievance, or else because her conscience did not preserve its equilibrium, rushed into print to invoke the aid of her older colleagues in solving this "problem of intricate differentiation." One would think that the proper place to solve this problem would have been at the patient's bedside instead of in the columns of our esteemed contemporary; but leaving this thought aside, especially as we have not had an opportunity to reach the patient's bedside, and would probably now be too late, let us enter briefly into consultation even at this inconvenient time and distance.

First, let us note and commend Dr. Kenealy's optimism in obstetrics. Her patient was in such a risky condition from a threatened abortion that she had been obliged to have the "foot of her bed raised" and to sip "iced lemon-water." These heroic remedies (which apparently are more serviceable in Britain than they are in America) were supplemented by Dr. Kenealy in ways not men-

tioned; neither are the patient's symptoms described. Nevertheless, the danger being temporarily averted, the doctor turned confidently to mercury as a reliable remedy to complete the cure—to clinch the embryo, as it were, anew. This is a power that we confess we did not know that mercury has. When the embryo, already four months developed, is almost thrown off, and the mother, with the foot of her bed elevated, has to sip iced lemon-water, we should not have supposed that mercury, even in the hands of a syphilographer, would have the power or the time so to renovate embryonal and placental tissue as to render a further mishap impossible. It seems to us that Dr. Kenealy has given herself useless concern about this matter. Her casuistry is as far astray as her therapeutics. If mercury has not the power that Dr. Kenealy attributes to it, we should say that her conscience has bled in vain.

But the question raised by Dr. Kenealy is one of casuistry, not of therapeutics. The doctor had, according to her own innocent belief, an infallible remedy in mercury against a half-finished abortion. There was no doubt about that. She wrote the prescription for it in the library. The question for her simply was, Should she use this infallible remedy? Dr. Kenealy decided not—and there she made a fatal error which neither her candor nor her rhetoric can condone. In the midst of all her confusion of thought as to the action of mercury, the pathology of embryonal syphilis, the causation of Mongolian idiocy, the importance of iced lemon-water in abortion, and the personal likes and dislikes of her tutelary goddess "Nature;" in the midst of all these there stands out clearly the glaring sin of omission of which Dr. Kenealy was guilty. For we hold it to be an axiom of medical ethics that the physician ought never to withhold a remedy, unless for the patient's good. It is not for him, or her, to judge the mystery that lies in the untold future; to cast a horoscope for the unborn infant and to condemn it to infamy under the sign of Mercury!

For, we ask, what guarantee had Dr. Kenealy that this particular infant could not be saved and made healthy and useful? What were the wishes of this embryo's parents on the subject? They were not even asked. The father, in fact, does not appear on the scene. It was probably lucky for him that he did not meet Dr. Kenealy. Have no syphilitic children ever survived and flourished? In fact, what evidence had the doctor that this child *was* syphilitic? She gives but little. A succession of abortions is not a sufficient evidence of syphilis to justify a physician in snapping his fingers at a poor imperilled embryo and bidding it go the way of its predecessors. If Dr. Kenealy's logic is followed to its just conclusion, the penalty for all syphilis will soon be death—and not confined to the embryo. Dr. Kenealy will not only expose suspected children on the mountain-tops, but she will be exterminating their fathers and mothers in the market-places, if she is not checked.

With reference to Mongolian idiocy also Dr. Kenealy has rather bold and original ideas. She tells us that the effect of syphilis is to retard evolution in such a way that from Caucasian parents an offspring characteristically Mongolian results. We did not know before that Mongolian idiocy was subject to such a sweeping elucidation. In this exceedingly rare type of idiocy the "Mongolian" feature is but a superficial resemblance; the child is still a Caucasian, not a "maimed Mongolian." And to what extent this type is due to syphilis is still, as in the case of all idiocy, a somewhat obscure question.

We fear that Dr. Kenealy may find the practice of obstetrics too much involved in casuistry to permit her to become a good midwife, and we suggest that she try some other branch of medical science—for instance, pathology.

EDITORIAL COMMENTS.

Phonography in Medicine.—We have on several occasions referred to the utility to medical men of a knowledge of phonography and its practical application to the exigencies of a busy and active existence. Many of these points, and others as well, are brought out clearly and forcibly in an interesting address recently delivered by the distinguished neurologist, Dr. W. R. Gowers, before the Society of Medical Phonographers, and reprinted in the *British Medical Journal* of October 5, 1895. The Society was organized in December, 1894, with a membership of 60, which by September, 1895, had increased to 175, and it issues a monthly journal containing in shorthand reports of clinical lectures, original articles, and the like. In the course of his address Dr. Gowers pointed out that the current method of writing is not only cumbersome but laborious. Every movement of speech requires for its representation several different movements of the hand. Writing can be made easy and simple by having the movements of the hand that symbolize each movement of speech and its resulting sound the fewest compatible with secure and ready perception by the eye. This is the fundamental basis of shorthand. Written records form an important factor in medical

advance, and much time can be saved, much expenditure of energy spared, and fuller as well as more careful observation made possible by the adoption of means that simplify this process and render its execution easier. The use of shorthand is not restricted to the making of records, but it may be applied to all the purposes for which ordinary writing is employed. Especially useful to the student is the art of phonography. By this means he can make a perfect epitome of his lectures, and at the same time keep his mind engaged upon the subject in hand. It were best if the knowledge of shorthand were acquired before entrance upon the medical education, and Dr. Gowers proposes that shorthand should be an extra mark-bearing subject in the preliminary examinations. He does not believe that the practice of making shorthand-notes has a deleterious influence upon the faculty of memory, but holds rather that, properly used, shorthand involves the retention of a greater amount of knowledge by the memory.

A Hahnemann Statue.—An esteemed contemporary remarks that "Germany has never ventured to erect a statue to Hahnemann." Literally speaking this is true, yet there is in Germany a statue to the man who discovered "the inner, monstrous, chronic miasm—psora, the only true fundamental cause and producer of innumerable diseases which figure under the names of hysteria, rachitis, scoliosis, cancer, jaundice, amenorrhea, hemoptysis, asthma, impotence, migraine, deafness, cataract, etc." (*Organon der Heilkunst*, Section 80. This work, be it remembered, is still used as a text-book in homeopathic medical schools.) Our contemporary has evidently never encountered in his wanderings abroad, a life-size, bronze statue "to the memory of Samuel Hahnemann." It is placed in an inconspicuous corner in Leipsic and is considered a good representation of the great potentizer. With reference to the position of the figure a Viennese wit propounded a rather neat conundrum: "Warum sitzt Hahnemann?" Answer: "Weil er für die Homeopathie nicht stehen kann."

As to the success of the Hahnemannians in raising money for their statue in America, there is one aspect of the matter not sufficiently emphasized. Both the monument and the money-raising are made a standing advertisement. The honor or principle involved is purely figurative or assumed.

Medical Education.—The following certificate was sent a railway company by a legally qualified physician:

July 31, 1895.

Owing to the request of the —— Company I hereby certify, that I found Mr. —— several years ago in a dying condition in the office, suffering from an ulcer and chronic catarrh of the stomach. Since that time I attended Mr. —— for catarrh of the stomach, the bowels and the liver, and rheumatism of the joints. Last October the blood was so bad that he lost his memory, and his sight was so impaired that he saw everything on 2 different places; this condition of the brain ceased as soon as I cured his kidney-trouble! These diseases are not due to alcoholic use, he did not drink liquors in all the time I attended him, as this caused a rushing of blood to the brain.

Epistaxis through the Eyes.—Dr. M. A. Veeder, of Lyons, N. Y., writes that he has lately had a case of epistaxis in which, as soon as the lower part of the nostrils had been plugged by the aid of cotton and astringents, the blood found its way into both eyes by the lacrimal ducts and continued to flow quite profusely for nearly half an hour, trickling down over both cheeks in quite a stream at times. Have similar cases been met in practice?

Zoolatry is a new word coined by an English Jesuit professor to describe the attitude of certain antivivisectionists, and "which," in the opinion of the *British Medical Journal*, "exactly expresses the state of mind of the antivivisection fanatic, who makes the feelings of animals the object of a tender regard which he is far from showing for those of men."

NEWS ITEMS.

The Revival of the Index Medicus.—The following additional subscribers are announced by the Philadelphia Committee for the revival of the *Index Medicus*:

Dr. William S. Halsted, Baltimore.
Medical Exchange Club, Chicago.
Dr. John E. Owens, Chicago.
Dr. O. L. Schmidt, Chicago.
Dr. F. Forchheimer, Cincinnati.
Cleveland Medical Society.
Sir T. Grainger Stewart, Edinburgh.
Free Public Library, Newark, N. J.
Philadelphia Neurological Society.
Dr. Lewis S. Somers, Philadelphia.
Reynolds Library, Rochester.
Dr S. C. Busey, Washington, D. C.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one-hundred-and-eighty dollars, will be made on July 14, 1896, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but must not have been published, and must be received by Dr. Charles W. Dulles, the Secretary of the College, on or before May 1, 1896.

Each essay must be sent without signature, but must be plainly marked with a motto, and be accompanied by a sealed envelop having on its outside the motto of the paper and within it the name and address of the author.

It is a condition of the competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

Dr. Francis Peyre Porcher, LL.D., a well-known physician and botanist, died at Charleston, S. C., on November 19th. He was at one time Professor of Materia Medica and Therapeutics in the South Carolina Medical College, and was the author of *Resources of the Southern Fields and Forests, Medical, Economical, and Agricultural.*

Dr. J. Abbott Cantrell has been appointed Dermatologist to the Frederick Douglass Memorial Hospital.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVII. SATURDAY, DECEMBER 7, 1895. No. 23.

ORIGINAL ARTICLES.

THE HEART IN ANEMIA.[1]

BY DELANCEY ROCHESTER, M.D.,

OF BUFFALO, N.Y.,

ADJUNCT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, MEDICAL DEPARTMENT UNIVERSITY OF BUFFALO; VISITING PHYSICIAN, ERIE COUNTY HOSPITAL; ASSISTANT VISITING PHYSICIAN BUFFALO GENERAL HOSPITAL.

I HAVE chosen as my subject the heart in anemia, because I believe that not infrequently through the mismanagement of anemic cases organic deformity of the heart occurs, and, on the other hand, that sometimes the presence of an anemic bruit has given rise to a diagnosis of organic deformity and consequent false prognosis.

Let us consider briefly the symptoms of anemia referable to the heart, the signs to be found by physical examination, the condition of the heart as revealed by autopsy in cases of pernicious anemia and in some of the severe secondary anemias, and let us then see if we can fit the two together in such a way as to obtain a rational explanation of the symptoms and signs, and to formulate methods of treatment suitable to the conditions revealed by careful study of the case.

The symptoms of anemia referable to the heart may be said to be shortness of breath, palpitation and pain in the precordial region upon physical exertion or emotional excitement of any sort. All of these symptoms may be present in a given case, singly or together, at different periods in its history. When we make a physical examination of an anemic patient we generally note upon inspection a marked pulsation in the epigastrium and precordium, often *more* marked in the epigastrium; the apex-beat is generally in its normal position, or occasionally a little below and to the left; percussion gives a normal area of cardiac dulness or one slightly increased transversely; auscultation reveals a forceful beat of the apex against the chest-wall, a first sound short in duration and lacking the normal booming quality, accompanied by a loud, soft, blowing murmur; sometimes there is no first sound at all, its place being entirely taken by the murmur; the second sound is sharp and valvular in quality, the pulmonary being considerably accentuated as compared to the aortic.

With the exception of Laennec, Guttman, and, in one case, Strümpell, all observers whose works I have been able to consult agree that the anemic heart-murmur is systolic in time, and the majority of these observers agree that it is basic in situation. According to different observers the point where this murmur is heard with greatest intensity is over the pulmonary orifice, *i. e.*, in the second left intercostal space close to the sternum, over the aortic orifice, *i. e.*, in the second right intercostal space close to the sternum, at the apex of the heart, in the tricuspid area; in fact, as Roberts says, it "has usually the position of a pulmonary systolic murmur—it may, however, be situated over the aorta or be heard at all the orifices."

Balfour, of Edinburgh, agrees with other observers that the anemic heart-murmur is systolic in time and basic in situation, but he places its point of greatest intensity, not over the aortic or pulmonary orifice, "but" (I quote from his book) "actually about one-inch-and-a-half or rather more to the left of the pulmonary area, and in the same plane immediately over the part where the appendix of the left auricle pops up from behind just to the left of the pulmonary artery."

Another clinical observation, originally made by Hanford, I believe, is worthy of note, namely, that in the large majority of cases, in which the murmur is basic in situation, its intensity is much greater when the patient lies flat on the back than in the upright position; indeed, in some cases the murmur is audible only when the patient lies down, disappearing entirely when the upright position is again assumed.

So much for the symptoms and signs of anemia that may be referred directly to the heart as their source. Let us now turn our attention to the morbid anatomy of the heart in such cases. False conclusions are liable to be drawn from too small a number of observations, and therefore, as I have seen but one autopsy in a case of pernicious anemia, and that not in my own practice, my personal experience is of no value in the matter. In this case, however, there was fatty degeneration of the myocardium with dilatation of the left ventricle.

In his masterly article on diseases of the blood in the *American Textbook of the Theory and Practice of Medicine*, Osler says, in regard to the morbid anatomy of the heart in leukemia, "the serous membranes (pericardial and endocardial) not infrequently present ecchymoses, and leukemic growths may ex-

[1] Read by title at the meeting of the New York State Medical Association, October 16, 1895.

ist there as well as on the peritoneum. The cavities of the heart are, as a rule, dilated and the myocardium soft; if the papillary muscles be teased out a moderate grade of fatty change is evident."

The changes in the heart in progressive pernicious anemia are stated by the same author as follows: "The heart-muscle is very pale, light yellow in color, and shows in fresh teased preparations the most intense fatty degeneration. The walls of the ventricles are remarkably lax and flaccid and the cavities contain light-colored blood."

In regard to the morbid anatomy of chlorosis the same author says: "Few cases die directly from the disease and the pathologic findings in those which have come to autopsy have been by no means constant. Rokitansky in 1846 pointed out certain instances of incurable chlorosis due to anomalies of the bloodvessels and genital organs. Virchow described a congenital hypoplasia of the vascular system found in several autopsies on chlorotic patients. The aorta and all its branches were of small caliber and thinner than normal; the elasticity of the vessels, however, appeared to be increased. The heart is at times dilated and the left ventricle hypertrophied." I will not quote others, as they all agree essentially and the quotations given represent the latest and best observations on the subject.

To sum up, we may say that we have in the heart, according to the degree and character of the anemia, the following morbid conditions present: Laxness and flaccidity of the myocardium with some dilatation of the cavities and some hypertrophy of the left ventricle, fatty degeneration varying from a mild degree of degeneration of some of the fibers of the musculæ papillares to the severe grade of degeneration seen in progressive pernicious anemia.

The shortness of breath, the palpitation, the pain, the increased area of cardiac dulness, and the murmurs are the symptoms and signs that it behooves us to explain from our pathologic findings. The first four are easy of explanation and there is essentially no difference of opinion among observers in regard to them. The shortness of breath and the palpitation are both due to the effort on the part of nature to supply sufficient oxygen to the organism by increasing the rapidity of the stream which is so poor in the oxygen-carrier, hemoglobin; the pain is probably the cry of starved nerves for more or better food; the slight increase in area of cardiac dulness observed in some cases is undoubtedly due to the mild degree of dilatation and hypertrophy that has been observed.

The most interesting point, and the one about which there is more difference of opinion among competent observers, is the mode of production—the mechanism—of the anemic murmurs. When fluid is driven with a certain amount of velocity through a constricted opening into a larger space beyond, a sound is produced that has been shown by careful experiments to depend upon the vibrations of what have been termed fluid veins, produced at a greater or less distance from the orifice according to its size and the velocity with which the fluid is propelled. In the case of heart-murmurs dependent upon organic lesions of the valves—whether the murmur is direct or regurgitant—the sound is produced in this way, the blood being propelled with a certain velocity through a constricted opening into a larger space beyond. The sonorous vibrations of these fluid veins are transmitted to the surrounding blood, to the walls of the containing vessel, and thence, through whatever medium may intervene, to the ear of the listener. This is beyond doubt the true explanation of the mechanism of heart-murmurs dependent upon valvular diseases.

We have seen that by different competent observers the cardiac murmurs of anemia have been located at the aortic, the pulmonary, the mitral, and the tricuspid areas, and in the area described by Balfour in the second left intercostal space to the left of the pulmonary area. For the most part these murmurs have been systolic in time, though a few diastolic murmurs have been described. Is there any rational manner in which we can explain the production of these murmurs which will satisfy all these observations, for we obviously have no right to doubt the diagnostic power of any observer unless we have proof of the inaccuracy of his observations.

First, then, how is this murmur produced at the aortic orifice? In a healthy individual by the ventricular systole a certain amount of blood of a definite weight is driven with definite velocity against the semilunar valves, pressing them flat against the walls of the artery. Evidently if the weight of the blood is reduced below a certain limit, though the velocity remains the same or even be slightly increased, the semilunar valves will hang out into the lumen of the vessel and thus produce a constricted opening with a larger space—the cavity of the artery, beyond—all that is needed to produce the fluid veins of Savant and the consequent sonorous vibrations resulting in the murmur. A similar line of reasoning would apply to the production of the murmur at the pulmonary orifice. Before leaving the base of the heart we have the observation of Hanford, which has been confirmed by us all, that in a certain number of cases the basic murmur is increased in intensity when the patient lies down. Hanford's own explanation is that when the patient lies down, owing to the lax and flabby condition of its walls, the whole heart *falls upward* and presses upon the larger vessels, thus producing a constriction and the necessary mechanic condition for the

production of a murmur; that when the patient assumes the upright position the heart *drops down* again and the murmur disappears, or only so much remains as may be due to the obstruction produced by the hanging out of the valves as I have suggested. Personally I am not quite satisfied with this explanation of Hanford's, but I have not as yet anything more rational to offer in its place.

Now how about the murmurs heard at the mitral and tricuspid areas? As they are systolic in time, they must be regurgitant in character.

We have learned that in the morbid anatomy of anemia there is a lax and flaccid condition of the muscular fibers and often some fatty degeneration; that when there is fatty degeneration, it is more marked in the musculæ papillares to which the chordæ tendineæ are attached, and is not infrequently limited to those structures. We have found that with this laxness and flaccidity of the walls there is developed a certain amount of dilatation of the cavities, producing a dilatation of the auriculoventricular orifices and a consequent insufficiency of the valves, resulting in regurgitation. This is the explanation given by Dr. Balfour of the mitral regurgitation observed by him. This would require a considerable dilatation of the ventricle, more than we have any right to premise from the size of the heart as shown by percussion. Another and, to me, more rational method of explaining this regurgitation—one long ago brought forward by Walshe, of Dublin—is through the fatty degeneration and consequent weakening of the musculæ papillares to such an extent as to allow the auriculoventricular valves to yield to the pressure of the blood during the ventricular systole and permit the regurgitation to take place. As for the murmur heard in the area described by Balfour we must remember that he says it is "about one-inch-and-a-half or rather more to the left of the pulmonary area and in the same plane immediately over the part where the appendix of the left auricle pops up from behind just to the left of the pulmonary artery." It is a well-known fact that sometimes a mitral regurgitant murmur is heard with greatest distinctness at this point, the sound being conducted better "along the course of the regurgitating blood, the fluid veins producing sonorous vibrations louder at the point of impingement than at that of origin." From these observations he concludes that the heart-murmur of anemia is one of mitral regurgitation. We have just shown how mitral regurgitation may occur in anemia, and thus the murmur heard in Balfour's area is accounted for.

In those rare cases, such as Strümpell's case of pernicious anemia, in which a diastolic murmur occurs, the dilatation of the ventricle has probably proceeded so far as to dilate the aortic orifice and so allow regurgitation to take place at that point.

Thus, we see, we have a rational explanation of the mode of production of anemic heart-murmurs which is applicable to all cases, and is none other than that which holds in the case of organic murmurs, namely: An obstruction to the onflow of the blood, causing at one point a narrowing of the lumen of the vessel through which it passes, thus producing the fluid veins already referred to.

The arterial murmur heard in the carotids in a certain number of cases is synchronous with the cardiac systole, and is, in my opinion, merely a transmission along the current of blood of the cardiac murmur arising at the aortic orifice. The venous murmur, however, is a continuous humming sound, and so cannot be referred for its origin to the cardiac murmur, which is necessarily intermittent, as it occurs only with the systole. It must, therefore, originate in the vein itself, and here we find a cause for it. The external jugular vein is attached to the clavicle, the lower part of the vein being thus kept constantly extended, and not permitted to collapse down upon the blood; just above this somewhat enlarged chamber of the vein is a pair of valves; owing to the relaxed condition of the walls of the vein found in anemic individuals and the lack of weight of the blood necessary to keep them in place, it is highly probable that these valves hang out into the lumen of the vessel and produce the necessary obstruction for the formation of the fluid veins of Savant and their sonorous vibration. The continuousness of the sound is probably due to the fact that the velocity of the blood-current is much more constant, though not so great as in the arteries.

To sum up, we have the following facts before us: First, that when fluid is forced at a certain velocity through a constricted opening into a larger space beyond, at a certain distance from the orifice, its particles are thrown into sonorous vibration; second, that in certain diseased states of the cardiac valves, we have beyond a doubt the necessary conditions for the production of such sound, and the presence of the sound; third, that when there is no such diseased state of the valves, but when, from the impoverished state of the blood and certain changes in the myocardium, we should expect the healthy valves to be placed in such a position as to produce the constriction mentioned, we find the murmur, the indication that such constriction exists, present; therefore, I think we are justified in concluding that the valves are in that position, especially as the murmur can be satisfactorily accounted for in no other manner.

What practical conclusions as to the management of our cases can we draw from the facts before us? I think we are justified in the following: If the murmur is heard only at the aortic or pulmonary

orifice and is systolic in time, it is probable that the condition of the blood is the chief factor in its production and that the cardiac muscle is still in fair shape; if, however, the pulmonary second sound is considerably accentuated as compared to the aortic, there is probably already some change produced in the myocardium of a degenerative character; if the murmur is heard with greatest intensity at the apex, or in Balfour's area, or over the tricuspid valve, there is already present marked change in the myocardium; if there is a diastolic murmur the condition is most serious. The relative strength of the aortic and pulmonary second sounds is a pretty fair index of the strength of the heart; the more the pulmonary is accentuated the weaker is the heart.

The treatment of anemia may be summed up briefly as follows: Keeping the bowels, skin, and kidneys active; a careful supervision of the diet; regularity in eating; the internal administration of iron and arsenic in varying proportions according to the relative proportion in the blood of the hemoglobin and the red corpuscles; the inhalation of pure oxygen-gas; exercise, passive or active, according to the condition of the heart; the administration of the tincture of nux vomica in increasing doses to strengthen the cardiac action.

I think that we are all agreed that exercise is important for anemic individuals, but I think it of the utmost importance that the condition of the heart should be the index to the character and amount of exercise. The heart in an anemic individual is just in the condition in which too great or too prolonged exercise may cause a dilatation that will produce a permanent mitral insufficiency or possibly a worse condition. Therefore, in those cases in which the physical examination shows aortic or tricuspid regurgitation, and in most of those in which mitral regurgitation is revealed, rest in bed for a more or less prolonged period, according to the effect produced, is indicated. The necessary exercise should be supplied by massage and muscular movements given by one thoroughly competent.

The slow, deep inhalation of pure oxygen-gas is of the utmost importance in these cases in that it supplies the oxygen and conduces to full expansion of the lungs, thus improving the circulation and increasing the strength of the cardiac action. The administration of tincture of nux vomica in gradually increasing doses is of great value in increasing the vigor of the myocardium.

The chief point I wish to urge is the careful examination of the heart in all cases of anemia, the ocation of the origin of the cardiac murmur or murmurs that may be present, and the regulation of the character and amount of exercise according to the findings of the physical examination.

RECENT EXPERIENCES IN THE SURGERY OF THE HYPERTROPHIED PROSTATE.

BY J. WILLIAM WHITE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF PENNSYLVANIA.

(Concluded from page 598).

CASE VI.—Dr. H. G. Wetherill, of Trenton, N. J., has been kind enough to send me the following facts as to a case operated upon June 13, 1895: The man was 73 years of age and had depended upon the use of the catheter for a year. He had an enormous prostate, measuring 3½ by 2½ in. He was able to pass about three ounces of urine in 24 hours, and was drawing 60 ounces by the catheter. Thirty-six hours after double castration he passed three ounces of urine at one effort and about 12 ounces on the second day after the operation. On the twelfth day he passed 10 ounces of urine freely and without pain on rising in the morning. The catheter was then introduced and the bladder was found to be practically empty. Both of the testes were cystic and there was a hydrocele on either side. The patient was delighted with the result of the operation.

CASE VII.—I am indebted to Dr. B. M. Ricketts, of Cincinnati, Ohio, for the following report: One month ago I performed double castration upon a patient aged 79 years. The operation was done with cocain-anesthesia, 1 gr. being used, and occupied seven minutes. The patient passed about 6 ounces of pus daily for one week previous to the operation, at which time the average period between the successive acts of micturition was twenty-two minutes. At the time of the report the pus had disappeared; the patient urinated about once every hour; the general health had also improved.

CASE VIII.—Dr. J. C. Reeves, Jr., of Dayton, Ohio, has very kindly sent me the following report: A man, aged 72 years, had had a high grade of diabetes for some years, difficulty in passing water for over four years, and was entirely dependent upon the use of the catheter for four months, during which time urine was passed from every half-hour to two hours, the act being accompanied by considerable distress; the urine was clear. By rectal examination the prostate seemed to reach almost to the sides of the pelvis. Double castration was performed under cocain-anesthesia, without giving the patient any pain. The only systemic effect of the drug that was noticed was slight talkativeness. The patient passed from observation, but at the end of ten weeks it was reported that he was still obliged to use the catheter two or three times a day, although a portion of the urine was passed without it. On the day of this report (July 21, 1895) half a pint was passed voluntarily at one effort. The patient's general condition is improving.

CASE IX was operated upon by Dr. A. H. Levings, of Milwaukee, and is reported in THE MEDICAL NEWS, August 17, 1895. J. B., aged 77 years, was obliged to resort to the use of the catheter eighteen years ago on account of an enlarged prostate. For thirteen years he was entirely dependent upon this instrument. Five years ago, as instrumentation be-

came almost impossible, a suprapubic cystotomy was performed and an artificial urethra established.

The condition seemed satisfactory for three or four years, when he began to complain of pain. The cystitis grew worse, and repeated rectal examination established the fact that the prostate was constantly increasing in size, until the time of the operation, when it was as large as a cocoanut. Castration was performed May 14, 1895. On June 20th, 36 days later, the patient passed a small stream of urine, the first time for 18 years. He has continued to do this every day; the size of the stream is increasing, and for the week preceding the report he has used the suprapubic opening night and morning only when the bladder was irrigated. The prostate had diminished in size about one-half, the cystitis was much improved and the severe pains had practically disappeared.

CASE X was operated on by Dr. A. H. Levings. The man was 51 years old, and had been dependent upon the use of the catheter since December, 1894. About the middle of December the right testicle became inflamed and suppurated; two weeks later the left one became similarly affected. Upon entering the hospital there were two ounces of residual urine, which was ammoniacal and contained a considerable quantity of pus; both lobes of the prostate were very decidedly enlarged. The disease of the testicles was thought to be tuberculous. Both were removed with the view of reducing the size of the prostate. Two weeks after the operation the patient was walking about the hospital almost wholly free from pain; the urine had become acid and almost clear, the catheter was no longer necessary, and the residual urine had entirely disappeared. At the end of 25 days the left prostatic lobe was scarcely to be felt, while the right was much reduced in size. The patient was discharged in excellent condition.

CASE XI was operated upon by Dr. H. O. Walker, of Detroit. The patient was 65 years of age; he had had symptoms of prostatic obstruction for eight years, namely, frequent micturition, frequent use of the catheter, a large amount of residual urine loaded with pus. Rectal examination revealed a very much enlarged prostate. As the man had run the gauntlet of treatment by catheterization, irrigation, and medication without benefit, both testicles were removed on February 10, 1895. He was shown to the class in two weeks, at which time he was able to retain his urine for from four to nine hours; the catheter was discarded after the ninth day. The pain had all disappeared and there was but little pus in the urine. The patient was able to pass urine without much effort, and the prostate had appreciably diminished in size.

CASES XII to XIX, inclusive.—The *British Medical Journal* of August 17, 1895, contains an abstract of a paper by Kummell, in the *Berliner Klinik* of August, 1895, in which 8 cases are reported upon which the operation of castration had been performed by the author on account of prostatic hypertrophy. The operation was followed by considerable relief in all the cases. One patient, aged 77, died from exhaustion four weeks after the operation. In two cases the function of the bladder was restored in spite of considerable weakness of the detrusor. In the author's opinion the treatment of hypertrophy of the prostate by double castration compares favorably with other operative measures in being simpler in performance and less dangerous.

CASE XX.—The following case is reported by R. Church in the *New Zealand Medical Journal* for July, 1895: The man, aged 62, consulted the author 18 months before the present report, on account of great pain and difficulty in passing urine. He stated that he had been treated previously for this trouble. The symptoms commenced 7 years before, and had gradually increased in severity, until at the present time "life was a misery to him." For a few years back he had occasionally used the catheter, but of late he had been unable to pass it without excruciating pain and sometimes hemorrhage. There was a slight cystitis; the prostate was greatly enlarged. Washing out of the bladder and careful use of a coudée catheter improved the condition for a time. The patient's condition on February 11th was described as one of agony. He had lost all appetite and had decreased in weight 2 stone 7 lbs. Sleep came only in snatches. The pain was so intolerable that he resorted to chlorodyne, taking 40 drops at a time. Double castration was performed February 18th. At the end of the first week the gland was appreciably smaller as measured by the catheter and by rectal touch. The pain was but trifling; the patient was at times able to urinate without the catheter. At the end of the second week the prostate was one-third smaller, with still further improvement of the symptoms. At the end of the third week it was reduced to one-half of its former size, the symptoms still improving. March 18th the gland was only slightly larger than normal. The patient was able to sleep about four hours at a time during the night; appetite was restored; the weight was increased; there was practically no pain, but still some slight atony of the bladder, necessitating the occasional use of a catheter, which could be passed, however, without pain. Instead of brooding over his trouble he interests himself in his business affairs. Mentally and physically he is a better man. The author states that to all intents and purposes the patient is cured.

CASE XXI.—In a discussion upon the treatment of prostatic hypertrophy before the Massachusetts Medical Society, June 11, 1895,[1] Dr. L. Bolton Bangs, of New York City, referred to a case which he was asked to see in consultation. The patient was 64 years of age and had all the evidences of prostatic obstruction. He was straining in a most agonizing manner to expel a few drams of purulent urine every two hours. He had a cachectic appearance and an overdistended bladder. Dr. Bangs was asked if the case was a proper one for castration. He replied in the negative, because the patient's kidneys were evidently affected. Nevertheless, castration was performed, the patient dying a week later.

CASE XXII.—In the same discussion Dr. Edward L. Keyes mentioned the case of a man, aged 65

[1] Boston Medical and Surgical Journal, August 2, 1895.

years, apparently in good health. Many years before he had had a suppurating testicle. The speaker had also seen the patient a number of times at long intervals with slight attacks of recurrent prostatic suppuration, with a mild catarrhal cystitis, causing vesical spasm, but never laying him up. He came back in another of these attacks, when he said he was rather tired of them, and asked to have the testicles removed. Dr. Keyes was anxious to adopt other methods of treatment, and if possible relieve the catarrhal disturbance before operation. Being overpersuaded by the patient, however, he finally yielded, and removed both testes under cocain-anesthesia. The symptoms increased gradually, and it was advised that the bladder be drained. The patient and family objected, however, and the patient died in the fifth week after the operation. No autopsy was allowed. Examination before death failed to reveal either a stone, a tumor, or ulceration in the bladder. Nothing could be found but a moderately enlarged prostate and a moderate amount of catarrhal cystitis in the prostatic sinus.

CASE XXIII.—At the same meeting Dr. Abner Post, of Boston, described the case of a man, aged 76 years, who was under observation two weeks, during which time he was catheterized by an attendant five times in 24 hours, although he was constantly begging for the use of the catheter. His pain and discomfort were very great; he was a feeble old man, was confined to bed, and complained a great deal of his head. He kept informing the attendants that he should go crazy if he did not have relief from his bladder-trouble. Treatment in bed, with careful systematic catheterization and washing of the bladder, for his urine was purulent, failed to give him relief, and at the end of 16 days, in spite of a general febrile condition, Dr. Post performed the operation of castration, although without any great hopes of relief. At the end of three weeks the patient was able to pass as much as five ounces of urine at a time. Although there is still some residual urine, he has to be catheterized only once daily. His mental condition has changed wonderfully for the better.

CASE XXIV.—A second case reported by Dr. Post is the following: A man aged 59 years, with a prostate very much enlarged, and a distinct bar at the end of the bladder, was obliged to pass water every hour. He had six ounces of residual urine, and he asked to have the operation done. He was kept under observation for a fortnight when the operation was performed. The intervals of urination have increased from 2 to 3½ hours. There is something like one-half the former amount of residual urine, but a good deal of the pain and discomfort has disappeared. The prostate does not seem to have undergone much diminution in size.

CASE XXV.—Mr. H. W. M. Kendall reports (*British Medical Journal*, Sept. 28, 1895) the case of a man, aged 82, an old Hungarian, who had suffered for some years from retention of urine and cystitis, necessitating the almost incessant use of catheters. For six years past he had been unable to leave his cottage, and when admitted to hospital was in a miserable condition, getting no rest night or day from the pain and distress caused by the continual desire to micturate, the bladder being intolerant of urine about every 15 minutes. The urine was in a stinking condition, viscid, and ropy. Rectal examination showed an immensely enlarged prostate, the finger not being long enough to reach its boundaries. On April 18th, after a preliminary hypodermic injection of a quarter of a grain of morphin, the operation was performed under chloroform, as described in the *British Medical Journal* of January 5th, the testicles being removed through a median incision in the lower part of the scrotum. Immediate relief was obtained, the patient retaining his urine four hours, and passing it without pain.

One or two attacks of cystitis recurred, requiring irrigation of the bladder occasionally, and convalescence was retarded by an acute attack of hysteria. The man was discharged early in July, quite free from all his troubles, having gained rapidly in weight and strength, and, according to his own statement, as well as he was 30 years ago. He can now walk three or four miles and only complains of being always hungry. Before his discharge examination by the rectum showed that though the prostate had diminished considerably in size, it had by no means disappeared, as described in some previous cases.

CASE XXVI.—Dr. Thomas S. K. Morton, of Philadelphia, has been good enough to send me a report of the following case: M. W., aged 71 years, was admitted to the Pennsylvania Hospital August 25, 1895. There was given a history of increasing difficulty in micturition extending over a considerable time and culminating in total retention. Attempts by a physician to relieve the bladder failed of their purpose, but originated alarming hemorrhage. Subsequently the man was removed to the hospital. Upon admission it was found that he was still bleeding and had a greatly distended bladder. Ordinary instruments failed to pass the prostate, but finally a vertebrated catheter of large size gained admission and drew off the urine. Then it was proved by rectal examination that an enormously hypertrophied prostate existed. It was as large as an orange and exceedingly soft in consistency. The urine was black with decomposed blood, ammoniacal, and contained much pus and detritus. Hemorrhage ceased after catheterization, but recurred upon each subsequent introduction of the instrument. The difficulties attending the withdrawal of urine constantly increased until it became apparent that operative interference must be resorted to or the man would speedily perish. It was decided, if consent could be secured, to perform castration, and if this failed to do a cystotomy later. The experimental nature of the proposed operation having been explained, written consent of the patient and some of his relatives was secured. The testicles were removed August 28th. Although catheterization had to be continued, bleeding ceased almost immediately after the operation, and the urine began to clear up and become less decomposed. On August 30th the urine had become entirely clear of blood, pus, and odor, and two days later was and has since continued to be normal. On the second day after the operation the man began

to pass a portion of his urine. This amount steadily increased until a week later the catheter was discontinued and there was no residual urine. Examination of the prostate by the rectum at this time demonstrated its reduction in size to that of a hen's egg and in consistency to that of the normal gland. The change was quite surprising. Following this the man passed through a period of partial incontinence which was ascribed to weakened sphincteric action. But this slowly improved, so that in three weeks from the time of the operation the action of the bladder was normal.

On October 28th the man was in excellent health and could not sufficiently express the extent of relief that the castration has afforded him. He urinated from four to six times a day, had no distress whatever, and passed normal urine. The prostate was much smaller than when examined two weeks after the operation, and has become very dense in structure, as well as perfectly insensitive. Owing to the patient repeatedly removing the dressings, both wounds suppurated, but no harm resulted.

CASE XXVII.—Dr. J. T. Stewart and Dr. Francis L. Haynes, of Los Angeles, have kindly sent me this memorandum of a case recently operated on: "This patient, aged 65, was suffering great agony on account of inability to pass urine. His prostate was enormously enlarged. During the past year the difficulty of voiding urine increased until for a month life had become a burden. After a consultation it was decided to castrate him, and the operation was performed. In a few days the pain subsided and he began to pass his urine easily. He left the hospital with his wounds healed a week from the day of operation. The case was examined by the leading surgeons of this city, and they are following the case with us. Now, one month later, he voids urine like a boy."

As to the permanence of the good effects thus produced, all the evidence that has reached me justifies the belief that serious relapses will be very rare or altogether unknown. Nothing of the kind has occurred in any of my own patients. I have seen some cases and heard of others in which there were days or weeks during which some of the symptoms (especially the vesical irritability) were worse than at previous periods. Occasionally the degree of relief experienced is so slight as to be disappointing. It must be understood that we do not yet know enough to select accurately and without a certain percentage of error the cases in which there is not a reasonable hope of improvement.

A further report of the case described by Bryson in the *New York Medical Journal* of April 27, 1895 (Case VI of my earlier table), appears in the same journal of August 3d, and illustrates this point. The article concludes as follows:

A man, aged 74 years, shows first evidences of beginning prostatism at the age of 56 years, which slowly increase during the succeeding 11 years until the tidal urine reaches 12 ounces, while the residual is 3 ounces (dilatation of the bladder from obstructive prostatic overgrowth). He rises thrice at night. In the following 6 years the residual urine increases to 6 ounces. The tidal diminishes to about 2½ ounces and the diurnal and nocturnal frequency increases to 18 and 6, respectively, with marked diminution of detrusor energy (evidences of increasing obstruction, with thickening and degeneration of the bladder-walls). Cystitis and a mild pyelonephritis develop. Two separate attempts to enter on catheter-life fail on account of increased irritation, difficulty in entering the bladder and aggravation of cystitis; dilatation of the heart and pulmonary emphysema supervene. All unfavorable symptoms increasing, castration is done for relief.

Demonstrable Results. Marked and satisfactory diminution in the size of the enlarged prostate, without change in frequency of urination day or night, without alteration of tidal, but with slight decrease of residual urine. Pyuria, bacteriuria, and pyelonephritis remain practically the same. In a few words, the double orchidectomy has caused an almost complete atrophy of the prostate gland without effecting any change in a chronically inflamed and degenerated bladder and equally without curing or even benefiting a chronic pyelonephritis from extension.

But, on the other hand, as I have said, relapse in the sense of the return or recurrence of the overgrowth has not yet been reported, and in no case among those who have been benefited physically by the operation and who have been restored to good general health have there been any consecutive phenomena, either mental or physical, which could be attributed to the castration. I am now constantly asked whether any change in voice or in manner, any diminution of mental energy, any sudden putting on of flesh, any alteration of figure, or, in other words, any appearance of "eunuchism" is to be expected. I can only say that, so far as I know, nothing of the sort has occurred and that I believe it to be in the highest degree improbable and unlikely that it will occur.

A personal communication received from Dr. Francis L. Haynes, Los Angeles, dated August 7, 1895, states that the first patient whom he castrated for enlargement of the prostate, and who was the first case operated on in this way in America, has remained in the favorable condition described in my paper in the July *Annals of Surgery*. The operation was performed December 12, 1893; the condition of the patient in August, 1895, was as follows: "The urine is passed normally without the use of the catheter; the man is obliged to rise once at night. He has passed 9 hours without voiding urine, but the average is five times daily. There are two drams of residual urine, which is perfectly normal. The patient feels well. Examination with the vesical sound indicates that the prostate has nearly disappeared. Digital examination by the rectum shows that the large lateral prostatic masses that were present before the operation have entirely disappeared, so that nothing can be felt ex-

cept normal bladder-wall, which is, however, a little thickened. The patient's mind is in excellent condition. He says: 'It is a good operation and everybody with my disease should go through it.'"

This is the oldest case of which I have recent information.

Excision of the Vas Deferens. In July I reported the effect of ligation or section of the vas deferens in seven dogs that had been killed at various periods afterward. After giving the details, I said that, while there were comparatively few changes in the testicles themselves, there was nevertheless a constant loss of weight in the prostate in every dog that died after 8 days. Even at 10 days this loss was perceptible. In dogs which were kept for 52 days the atrophic changes were unmistakable, and they were to be found in nearly every section. I added: "If these results are reliable it will certainly be worth while to investigate still further the effect of obliterating the vas, although outside of these experiments there would seem to be every theoretic reason to agree with Griffiths who says 'With regard to the suggestion made by Mr. Reginald Harrison of the division of the vas deferens in cases of enlarged prostate, I have not sufficient experience to arrive at a conclusion; but, seeing that obliteration of the vas deferens has so little effect upon the structure and secretion of the testis, it must be doubtful whether the operation will suffice to influence the enlargement of the prostate.' Possibly I have wounded other structures in exposing and tying the vas, but I was very careful and the operation is easy. It may well be that the whole effect upon the prostate caused by the removal of the testicles is exerted through the medium of the nervous system. It would be easy to make a strong argument in favor of this view, basing it on well-known physiologic facts. And it may also be that in tying or cutting the vas certain nerves, more potential than others, are included or are themselves divided. In the dog they are all small and difficult of recognition without an extensive dissection. I wanted to tie or divide the nervous constituents of the cord alone and in a separate series of experiments, but the difficulty of finding them all and of avoiding damage to other structures was so great that I gave up the idea after some trials. Still, I should think it feasible and hope to make the attempt at some future time. Dr. King, of Toronto, has, in two experiments on dogs, had results from dividing the vas precisely similar to those I have detailed, a fact which increases my confidence in my own experiments."

In the summary of that paper I said with reference to this subject: "My experiments on dogs have shown in nearly every case in which the vas deferens was tied or divided on both sides, that, without much change in the testicles, there were beginning atrophy and considerable loss of weight of the prostate. These experiments need repetition and confirmation, as the absence of corresponding testicular change seems to make the results somewhat anomalous. It is possible that the inclusion or severance of small but important nerves may account for the effect on the prostate."

There is now additional evidence to offer. Pavone records in *Il Policlinico*, June 1, 1895, the result of his experiments on dogs with regard to the effects of removing the testes or the vas deferens alone. He finds that bilateral excision of the vas deferens in dogs brings about the same atrophy of the prostate as castration. Drawings of the microscopic appearance of the prostate glands after castration and excision of the vasa deferentia, respectively, show that practically the same changes occur after both operations. The author, therefore, recommends excision of the vasa deferentia for prostatic hypertrophy in preference to castration, as being a simpler operation, and giving equally good therapeutic results.

Isnard, in the *Centralblatt für Chirurgie*, 1895, No. 28, reports two cases in which he performed division and ligation of the vasa deferentia for enlarged prostate. The first operation was performed in 1894. The patient died of marasmus two months later. At the autopsy he was found to have had carcinoma of the prostate, and consequently no benefit could have been expected to follow the operation.

On May 1, 1895, he performed his second operation, on a man, 72 years of age, who had suffered for the past year from the result of prostatic hypertrophy, in combating which all the usual methods of treatment had been useless. The patient was presented before the Medical Academy on June 14th, entirely cured. Retention of urine and incontinence had entirely disappeared. During the night the patient was able to retain his urine seven hours. It is now clear and normal, while formerly it was purulent, and from time to time mixed with blood. The prostate which before operation was as large as half a nut, can now scarcely be felt by examination per rectum.

Dr. E. E. King, of Toronto, sends me the following details of a case in which he excised 2½ in. of each vas deferens. The man was 65 years of age, and was in great distress from the results of prostatic enlargement. The patient stated that five days after the operation the relief that he had experienced since its performance had already fully repaid him. The middle lobe was the most enlarged. The gland was very hard. The effort that had formerly been required to start the stream was at the time of report practically absent.

Dr. F. Tilden Brown, of New York, has furnished me with the details of a case in which he applied double ligatures to both vasa deferentia for enlargement of the prostate in a man of 70, who was wholly dependent upon the catheter, not being able

to pass a drop of urine voluntarily during the three weeks he was under observation in the hospital. The operation was done with cocain-anesthesia. On the second day after the operation he began to pass a few drops of urine. At the date of Dr. Brown's letter, 2½ months after the operation, the patient was perfectly comfortable. Urine was passed on an average of four-hour intervals, and but for the advice of the author the catheter would have been dispensed with. The residual urine averages a little more than one-half the quantity passed at a voluntary effort. Before operation the catheter was inserted 9½ in. before drawing urine, and at the present time 8½ in.

Chalot reports the following case in *L'Independence Médicale*, November 6, 1895. A man, aged 64, had been troubled with moderate symptoms of enlargement of the prostate for 15 years, and with decided symptoms for two years. He had been addicted to the use of liquor and to sexual excesses; he had never had gonorrhea. He was obliged to pass urine frequently, especially at night, but without feeling relieved. The stream was small and intermittent. The length of the urethra measured 26 centimeters. The urine was clear usually, but was sometimes a little blood-stained at the end of micturition. Rectal examination showed the transverse diameter of the prostrate to be about 5 cm. The gland was uniformly enlarged. There was neither calculus nor tumor of the bladder.

On February 28, 1895, Chalot resected 1 cm. of each vas deferens after having applied double ligatures of fine silk. Two months later the patient was in good spirits, his appetite was good, he had gained in weight, and micturition was about normal; he urinated 3 or 4 times a day and twice during the night. The testicles were sensibly smaller, but not as much as the author had been led to believe from the published observations. Their consistence had scarcely increased, as had been noted by Isnardi. Rectal examination showed the prostate to have decreased one-half in volume.

In July, Chalot heard that the patient had frequent and complete erections, and that he indulged in sexual intercourse. The general condition was excellent; the urine was passed naturally and freely.

Guyon reported to the French Association of Surgery (*La Tribune Médicale*, October 30, 1895) three cases in which a portion of the vasa deferentia had been resected for hypertrophy of the prostate gland. Two of these were operated upon by Guyon and one by Leugeu. In one of the cases the enlargement was considerably diminished. In all, catheterism was more easily performed, and was required less frequently. In Legueu's case, a voluminous epididymitis was relieved.

In the light of these facts I believe excision of the vas to be a justifiable experiment, especially in cases which, while otherwise fitted for castration, are either so ill that even that operation becomes dangerous, or so well that they are prevented by sentimental reasons from attempting to arrest in that way an overgrowth of the prostate that unrelieved would surely end their lives after a more or less prolonged period of great suffering.

CLINICAL LECTURE.

SOME PHASES OF SYPHILIS OF THE BRAIN.

A Clinical Lecture delivered at the Philadelphia Hospital.

By CHARLES K. MILLS, M.D.,
NEUROLOGIST TO THE HOSPITAL; PROFESSOR OF MENTAL DISEASES AND OF MEDICAL JURISPRUDENCE IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

(Concluded from page 610).

Case VI. *Paralysis of the left abducens, with dilatation and immobility of the right pupil; slight neuroretinitis.*—The patient, J. D., aged 36 years, has a history of gonorrhea, syphilis, and alcoholism. He has improved so much since admission that I cannot show you the most striking feature of his case. As will be observed, a left internal strabismus is now scarcely detectable. On admission he had marked internal squint of this eye. The right pupil is seen to be larger than the left and does not respond to light. From the statements of the patient and the records furnished by Dr. Oliver I learn the following facts: Shortly before his admission to the hospital he had occasional spells of dizziness and some frontal headache. Dr. Oliver found that he had almost complete paralysis of the left external rectus muscle, and associated with this was slight dilatation of the right pupil with almost total immobility of the iris to light. No disturbance of accommodation was present. The left iris was mobile to light and accommodation. Slight neuroretinitis was also present and vision was reduced to 1/7 and 1/9. Under 50 grains of potassium iodid three times daily, the patient's vision became practically normal, the left internal squint nearly disappeared, and the general condition of the patient greatly improved. The dilatation of the pupil remains.

This is clearly a case in which the foci of syphilitic disease attacked the root-fibers or trunk of the sixth nerve and the nucleus or root-fibers for movements of the iris. A nodose periarteritis or a gummatous meningitis, or both conjointly, might account for the phenomena.

Case VII. *Implication of the cranial nerves (except the sixth) from the fifth to the ninth, inclusive.*—L. D., aged 26 years, a mulatto, had rheumatism about nine months ago. Seven years ago he was struck with a bar of iron on the top of his head. No other history of importance was obtained. Four months before admission he began to have constantly frontal and occipital headache, which gradually grew worse. One morning he found the right side of his face entirely paralyzed, and he had a ringing sensation as if his right ear was "plugged up."

On admission this patient was found to have complete paralysis of all the muscles of the right side of the face, including the muscles supplied by both the seventh

nerve and the motor distribution of the fifth (Fig. 6). No deviation of the tongue was present. Anesthesia was present on the right side of the face, extending from the median line to the angle of the jaw, and from 2 in. above the hair-line to the point of the chin. The conjunctiva of this side was also totally anesthetic, as was the right half of the tongue. No part of the body other than the face was anesthetic. Taste was entirely lost on the right side of the tongue, both at the tip and posteriorly, showing implication of both the chorda tympani and the glossopharyngeal. The electric reactions were those of degeneration in the affected muscles. A watch was heard by the right ear at about 2½ in., and by the left at 18 in. A fine haze spread over the right cornea, which on close examination proved to be due to numerous small points. A beginning neurokeratitis

FIG. 6.

Paralysis of the muscles supplied by the seventh and motor fifth nerve on the right side. In this case anesthesia of the right side of the face was also present, total in the ophthalmic division and partial in other divisions of the fifth. The eighth and ninth nerves were also implicated, as shown by loss of hearing and complete loss of taste on one side.

was evidently present. Under large doses of potassium iodid the patient made considerable improvement; in particular the area of anesthesia decreased, the neurokeratitis passed away, and there was considerable improvement of the paralyzed muscles.

In this case a large gumma probably occupied the lateral aspect of the pons and of the upper portion of the postoblongata. The abducens nerve escaped because of its more median position.

CASE VIII. *Complete facial and auditory paralysis.*—E. McC., aged 39, on awakening found her face drawn to the left, with mobility to shut her right eye. She is deaf and has marked tinnitus on the right side. The facial lines are obliterated on the same side. It is not necessary to go into a detailed study of this case which is one of comparatively common type. The majority of cases of peripheral facial paralysis, the so-called Bell's palsy, are of rheumatic rather than of syphilitic origin; but when a complete or nearly complete paralysis of the eighth (auditory) nerve is associated with paralysis of the seventh, as in this patient, the lesion is nearly always a gumma or gummatous meningitis localized near the superficial origin of these two nerves. Doubtless this patient, who has only been recently admitted, will improve rapidly under specific treatment.

It was my intention to take up the subject of syphilitic pseudoparesis in the present lecture, but this and some other phases of encephalic syphilis will have to be postponed to another occasion. We see in this hospital three types of syphilitic disease in which the diagnosis of general paralysis of the insane is the problem. In the first place the case may be one of syphilitic pseudoparesis, the lesion being of Fournier's true specific class, and more or less amenable to treatment; in the second place, the case may be one of general paralysis of the insane in its most usual type—a parasyphilitic disease, one that will not respond to therapeutics; and in the third place, the case may be of transitional type, one in which the pseudoparesis is seen passing into parasyphilitic disease.

It is probable that a true inflammation of the brain-substance sometimes takes place as the result of syphilitic infection, but this is rare, and occurs especially in the vicinity of gummata, and in association with meningitis. A softening which is in reality necrotic and due to obliterative inflammation of the vessels, or to the occlusion of the vessels by a growth or an exudate, is sometimes supposed to be an encephalitis of "inflammatory softening." A form of localized disseminated encephalitis has been described by Charcot and others. The symptoms of local or disseminated encephalitis may be as multiform and irregular as the lesions producing them, and they will often be associated with the symptoms of the associated tumor, meningitis, or arterial disease—indeed, the more pronounced symptomatology of the latter affections will largely mask or overshadow those of encephalitis. Paresis, anesthesias, amnesias, cranial-nerve disorders of slight or marked character, visual, auditory, and other phenomena of the special senses of cerebral origin, may be among the symptoms.

Some forms of focal sclerosis of the nerve-centers are due to syphilis. According to Lancereaux, the syphilitic forms of sclerosis can be diagnosticated from the non-syphilitic by the greater tendency of the neuroglia to fatty degenerations and by the occurrence of foci of softening in their neighborhood. Whether or not true insular sclerosis of the brain is of syphilitic origin may be regarded as doubtful, although analogy would favor this etiology. Cases of miliary sclerosis and of lobular sclerosis have been recorded with details of autopsies and microscopic examinations of patients with clear histories of syphilis.

In conclusion let me say a few words about the treatment of such cases as have been presented in the course of this lecture. Cases of these clinical types, if recognized early and treated actively, will often respond favorably to treatment; cures, or at least approximate cures, can in some instances be obtained. Often the disease has produced some effects that are permanent, and even when it is arrested it is necessary to keep a watchful eye for years on the patient, reinstituting the treatment at regular periods even if no renewed evidences of syphilis are present.

Many practitioners seem to hail the diagnosis of nervous syphilis with a sense of satisfaction which has underlying it a feeling that in all such cases the prognosis is

good. It is possible to remedy some of the effects of nervous syphilis or to remove some of its symptoms; it is even possible that a cure may be attained, but this, as Gowers asserts, has never been proved.

The great remedies for nervous syphilis are the iodids and mercury. Authors differ as regards their relative efficiency, most authorities believing that either or both may be efficient. Some would disregard mercury altogether in many cases. Gowers holds that on the whole the iodid is the most useful and the most certain of the two drugs; still that either may be used with success in most cases. When the iodids fail, which is very rarely if success can be obtained at all, mercury may be used successfully even for the late manifestations.

The administration of large doses of the iodids, as much as from 400 to 800 grains in a day, has been called the American method. The iodids should always be given in an efficient manner. My usual plan is to begin with doses of from 15 to 20 grains three times a day, and increase by 5 or 10 grains daily until as much as a dram or even more is taken three times daily. I have seldom found it necessary to administer more than half an ounce in a day. On the whole, the amount which has proved most successful is from 2 to 3 drams daily. If iodism is produced, it may be necessary to discontinue the use of the drug for a time or to diminish the dose, although strange to say, occasionally when iodism results from the use of small doses, it may be made to disappear by rapidly increasing the amount ingested. Undoubtedly in some cases from 300 to 400 grains of potassium iodid or of sodium iodid daily will be well borne and will produce rapidly beneficial results.

Of the preparations of mercury used by the mouth, calomel and the biniodid are to be preferred, the former in doses of from $\frac{1}{8}$ to $\frac{1}{4}$ of a grain every two or three hours, giving at the same time, if necessary, preparations of opium, such as paregoric or even morphin, in order to prevent looseness of the bowels. The biniodid may be used in doses of from $\frac{1}{12}$ to $\frac{1}{8}$ of a grain every two hours, administering after each dose, if the bowels are affected, small doses of paregoric.

The use of mercury by inunction, if this treatment can be systematically and thoroughly pursued, is one of the best mercurial methods in nervous syphilis. The official ointment of mercury and mercury oleate are the preferable preparations. From $\frac{1}{2}$ to 1 dram can be used daily. In order to be exact as to the amount used, a good plan is to divide an ounce of the ointment into $\frac{1}{2}$-dram portions, wrapping each of these in paraffin-paper. Mercurial inunctions and the use of potassium and sodium iodids may often be advantageously combined.

In Germany in particular and to some extent in this country, under the influence of the teachings of Wolff and others, mercury has been employed hypodermically and in some instances with striking success. The insoluble compounds of mercury and especially calomel are to be preferred.

Gowers wisely suggests that every syphilitic subject should for five years after the date of his last symptoms have a three-weeks' course of treatment twice a year, during which he should take from 20 to 30 grains of iodid daily. It is better that this rule should be adopted three times during the year instead of twice.

CLINICAL MEMORANDUM.

REPORT OF A CASE OF FECAL FISTULA—OPERATION WITH THE MURPHY BUTTON.[1]

BY A. E. SPALDING, M.D.,
OF LUVERNE, MINN.

A SIMPLE and effective means of uniting the intestine, which is often needed in case of wounds or gangrene caused by the various forms of strangulated hernia, has long been desired. To Dr. J. B. Murphy, of Chicago, belongs the credit of making an advance in intestinal approximation which, to my mind, is one of the greatest discoveries of this century. That his button fulfils all the requirements in such cases is shown by his reports in THE MEDICAL NEWS of Feb. 9, Nov. 16, and Nov. 23, 1895.

I wish to report the following case:

On May 13, 1895, I visited Mrs. S. W. Clement, aged 67, residing at Jasper, Minn., with a view of operating on a fecal fistula that had resulted from an old femoral hernia of several years' standing. The fistula had occurred four weeks previous to my visit, and the entire contents of the intestines escaped at the opening or openings near the right femoral ring. The integument at the upper and anterior portion of the right thigh covering Scarpa's triangle was perforated with numerous openings, and the tissues were excoriated and tender from the constant irritation caused by the intestinal discharges. The patient was weak and much emaciated; the feet and ankles were edematous and the urine showed considerable albumin. With this unfavorable outlook, taking her age into consideration, I refused to operate and returned home. About a month later I received a letter from her attending physician saying that she was anxious to have something done for her relief. On June 27th last, with the assistance of Dr. Jenckes, of Jasper, and Dr. McGillivray, of Pipestone, the patient being placed under the influence of chloroform, I made an incision 1¼ in. to the right of the median line and 3 in. in length, terminating at a point 1 in. above Poupart's ligament. The fistulous openings and the intestine had previously been irrigated with warm water. After the peritoneum was incised a catheter was passed into the fistula, and with two fingers in the abdominal cavity the adherent intestine was easily found. Great difficulty was experienced in detaching the bowel from the femoral ring, the adhesions being very firm. The clamp-forceps was used to prevent the escape of fecal matter into the abdominal cavity, this precaution being taken before an attempt to free the gut was made. After its separation the bowel was brought out of the abdominal wound and a section made on either side of the opening. This opening included the whole circumference of the bowel, excepting a small portion at its mesenteric attachment. That part of the intestine below the fistula had become contracted, owing to the continued non-performance of its proper function. The medium-sized Murphy button was used, and an end-to-end approximation made. Great care was taken in the adjustment of the peritoneal layers of the mesentery with the running thread previous to pressing the button together. The mesentery was

[1] Read before the Minnesota Valley Medical Society, Mankato, Minn., December 3, 1895.

then stitched with catgut and the abdominal wound closed. The patient recovered without a bad symptom. The bowels moved naturally on the sixth, and the button passed on the sixteenth day.

I believe this patient to be the oldest on record in which an end-to-end approximation was successful.

TOXICOLOGIC NOTE.

A CASE OF ATROPIN-POISONING IN WHICH ONE GRAIN WAS TAKEN; RECOVERY.

BY LAMBERT OTT, M.D.,
OF PHILADELPHIA.

THE patient, a woman, 59 years of age, had taken 20 drops of a 4 per cent. solution of atropin sulphate by mistake. One-and-a-half hours afterward she said to her daughter that she must lie down as she felt so very heavy and tired, scarcely able to stand up, and her daughter seeing that her face and hands were a bright scarlet began an investigation and discovered that she had taken the eye-drops internally. I saw the woman at 12.30 o'clock, about 4 hours after the ingestion of the poison, and found her with glossy eyes, dilated pupils, scarlet-red in the face and all over the body, the maximum redness being in the face, then on extremities, and minimum redness on the trunk except over presternum, where the blush equalled that of the face. She lay in bed complaining of great thirst, dry throat and tongue; she responded to my questions with difficulty, like one in the relaxation of alcoholic intoxication. She was scarcely able to move from one position in bed, and when I asked her to lift her arm she raised it slowly and with great effort only partly from the side, but not above the shoulder-level. Her tongue was protruded with difficulty, requiring several efforts to force it from the mouth. She spoke of a tingling numbness in the feet and hands, like one having cold, chilled hands when the numbness is so great that touch and prehension are nearly nullified. She swallowed water with difficulty, making several efforts before a dram was gotten down. She was constantly passing water, apparently an ounce every 20 minutes. About 1 o'clock, or 4½ hours after taking the drug, delirium of an ecstatic nature set in. She now was intensely red and puffed about the face like one bloated and reddened by excessive drink; she grew very restless, was tossing from pillow to pillow, with unquenchable thirst and lips so limp as to permit the water to run outside of the mouth. She passed water frequently. Her talk was rambling, of the scenes of her childhood, her native country, Sweden, and she said persons looked so far away, and when she reached her hands out and found them near she seemed amazed. The glass of water, bottles, and dishes on the table by the bedside seemed small and distant, and not to be standing upright or were inclining to fall. When given a glass of water to drink in the delirious excitement, having more strength than in the early stage, she insisted on turning the glass on an incline to drink therefrom. Then began an incessant picking at the bed-clothes; pinching the arms of her daughter, who by sheer force had to restrain her in bed; reaching out to grasp imaginary objects and not finding them; a moving forward until restrained. Her respirations were rapid and short, the pulse feeble and 100 per minute, the temperature 101°. There was great wakefulness, the most incessant restlessness I ever saw in an ill person. In the early part of the trouble she seemed unable to move, like one paralyzed, but when the delirium set in she moved with more celerity. Later she described, as part of the delirium, seeing those about her as if their faces were unusually small and covered with black spots. She could not taste or feel; apparently she could hear; her sense of smell was not tested.

At 6.30 in the evening, 10 hours after taking poison, and about 5½ hours since delirium set in, she began to improve, having lucid intervals in which she anxiously inquired as to whether she was in danger, but before she understood or received a reply relapsed into her mental wandering. The next day she had lost her florid complexion and seemed greatly prostrated. On the 3d day after taking the atropin her mind was clear, her face decidedly pale, the extremities weak and tremulous in motion, and she had a constant desire to pass water. After that her recovery was uninterrupted. A peculiarity was noticed in the pupil not being as fully dilated as by the direct instillation of a strong solution of atropin, and holding a lighted match directly in front of the eye caused pupillary contraction. On the fourth day I put 2 drops of the 4 per cent. atropin solution in one eye, and soon after a larger dilatation of pupil followed than when under the systemic influence of a lethal dose. I gave her ℥ss of brandy every hour, a cup of strong tea every half-hour, then cinchona and tincture nux vomica in strong and rapidly repeated doses. I did not give her the physiologic antidote, morphin, fearing to bring on a stupor and increase a dangerous relaxation; but active stimulation and large drafts of water as often as she could take them was my treatment.

MEDICAL PROGRESS.

Congenital Atresia of the Hepatic Duct, with Cirrhosis of the Liver.—M'CALLUM (*Archives of Pediatrics*, vol. xii, No. 11, p. 842) has reported the case of a male infant, four months old, born at term, with a history of jaundice dating from a fortnight after birth. The discoloration had progressively increased despite medication. At the age of eleven weeks the left eye became severely inflamed, leaving a scar upon the cornea. For a week there had been cough. The child had always taken the breast greedily, but for two days it had vomited curdled milk. The bowels were constipated and the evacuations were pale, as a rule yellow, but sometimes greenish. The urine stained the napkins of a coffee-color. There was no history of hemorrhages and no cause could be assigned for the condition; a history of syphilis could not be elicited. The liver was enlarged and an umbilical hernia existed. Later the child was seized with convulsive movements and vomited coffee-grounds material. Death took place two days after the little one came under observation. Upon postmortem examination, in addition to the general icteric discoloration, the lungs presented numerous deep-blue patches, some of considerable size, extending into the pulmonary structure, in the case of the larger ones to an appreciable depth. Similar isolated patches were also present in the midst of the pulmonary tissue. These were found to be hemorrhagic areas. The liver was of a deep-brown

color generally, but its upper surface was paler. The organ presented a finely granular aspect. The gall-bladder could not be seen projecting from the anterior edge, and careful examination revealed, in a recess on the under surface, only a greatly shrunken and flaccid structure. A bristle introduced into the papilla in the duodenum passed freely upward toward the transverse fissure of the liver. The duct was found to be continuous with the cystic duct, passing onward with a sigmoid curve to the empty gall-bladder, which was found collapsed and misplaced. No trace of hepatic duct could be found except a thin, white cord. The liver, which was tough on section, presented no appearance of dilatation of the ducts. In the neighborhood of the duct and of the transverse fissure of the liver were a number of enlarged glands presenting a deep-brown color resembling that of the spleen, and there were also glands in the abdomen not so much enlarged but similarly colored. Microscopic examination showed an extraordinary degree of cirrhosis of the liver.

A New Division of the Movements of the Heart.—As the result of a physiologic study Scheiber (*Zeitschr. für klin. Medicin*, B. xxviii, H. 5, 6, p. 402) has arrived at the conclusion that every revolution of the heart in circulatory activity presents three phases: (*a*) systole, (*b*) relaxation, and (*c*) distention with blood, dilatation, true diastole. In the action of the heart separated from the circulation and removed from the body, but two phases are discernible, *i. e.*, systole and relaxation. The rigid heart that has ceased acting represents a condition comparable to the relaxation of the living heart. The designation of a cardiac "pause" is not only superfluous, but embarrasses an intelligent conception of the individual phases of the heart's cycle. The successive or synchronous occurrence of the heart's movements in the several parts of the heart (auricles and ventricles) during a cardiac revolution are as follows: At first occurs the auricular systole and, at the same time, the ventricular diastole; then ventricular systole and, at the same time, after a scarcely appreciable auricular relaxation, a protracted auricular diastole continuing throughout the period of ventricular relaxation that follows the ventricular systole and up to the beginning of the auricular systole indicative of the beginning of the succeeding cardiac revolution. A change in the form of the heart and in the position of the apex appears not first during the systole but during the third phase, that of true diastole, inasmuch as the flattened-cone shape of the relaxed heart is transformed during this phase of distention with blood into that of a cone with a round base, and the apex of the heart is raised during this phase from its basis of support so as to assume a vertical position with relation to the plane of the base of the heart.

Tuberculosis of the Spinal Cord.—Haskovec (*Archives de Neurologie*, September, 1895) has reported the case of a woman, 22 years old, who presented slight symptoms of pulmonary disease, together with tingling and pricking sensations in the lower extremities and slight weakness. The weakness, after the lapse of some three months, rapidly increased in the course of a few hours to almost complete paralysis, with enfeeblement and soon abolition of the reflexes and retention of urine and feces. Tactile sensibility was preserved in the lower extremities and upon the lower part of the abdomen, but there was complete analgesia, with thermo-anesthesia. In the course of a few weeks tactile sensibility also was lost and muscular atrophy was apparent; and similar changes showed themselves in the upper extremities. Death took place a few weeks later. Post-mortem examination disclosed the evidence of advanced pulmonary tuberculosis, with extensive disease of the spinal membranes and cord, the lesions being most marked in the upper dorsal region, especially about the posterior roots; the infiltration was partly diffuse, partly nodular.—*British Medical Journal*, No. 1816; Epitome, p. 61.

Diphtheria of the Cutaneous Surface.—Flesch (*Berliner klinische Wochenschrift*, 1895, No. 43, p. 935) has reported the case of a girl, 2½ years old, who was accidentally burned with hot water upon the face and trunk. The lesion varied in severity in different places, being most profound upon the trunk. Under treatment with 2 per cent. salicylated vaselin marked improvement resulted in the course of a week. At the end of this time the mother kissed the child upon the neck and on the following day presented symptoms of diphtheria, passing through a well-pronounced attack. A sister and the husband also suffered attacks of diphtheria. In the course of three days the child presented in the situation touched by the mother's lips a circumscribed, whitish, swollen area surrounded by edema, from which on cultivation diphtheria-bacilli were isolated. The throat showed no evidence of involvement. Two injections of antitoxic serum of 100 immunity-units each were made, but without appreciable effect. Slight paralysis of the palate appeared as a sequel.

Two Consecutive Attacks of Scarlatina.—Sequeira (*British Medical Journal*, No. 1820, p. 1232) has reported the case of a boy, five years old, who suffered from two attacks of scarlatina in rapid succession. In the first the rash was well marked, the temperature high, and the tonsils swollen and injected. The disease pursued a moderately severe course, and desquamation began about the ninth or tenth day, and continued until the eighth week. Two weeks later, recovery having apparently taken place, the patient while out of doors was overtaken in a shower of rain, and during the night complained of sore throat and vomited twice. On the next morning the tonsils were congested and much enlarged; the temperature was 104°, and a punctate scarlet rash appeared on the chest and back, and soon spread over the whole body. The second attack was rather more severe than the first. Desquamation commenced about the end of the first week and lasted until about the end of the eighth.

THERAPEUTIC NOTES.

A Case of Bromid-intoxication.—Bruck (*Deutsche med. Wochenschrift*, 1895, No. 45, p. 753) has reported the case of a woman who took 300 grains of potassium bromid in five equal parts in the course of thirty-six hours. After the ingestion of the third dose the patient felt languid and apathetic, and these feelings became more pronounced with the succeeding doses. The mind became

obscure and confused, and the eyelids could be held open only with difficulty. A sense of dull pressure was referred to the temple and forehead. The ears felt as if displaced, and sounds appeared to be distant, although all that was said was comprehended. Tactile sensibility was benumbed. A bitter, burning taste was felt in the mouth and pharynx, but there was neither nausea nor vomiting. The appetite was unimpaired, although the patient had no inclination to partake of food. All movement required a distinct effort. There was an absence of drowsiness. The pupils were contracted and reacted sluggishly to light. The pulse was 62 per minute, the respiration 16, the temperature 98.2°. In the course of a few days uniform elevations and hyperemic efflorescences appeared upon the skin in various situations, notably on the face, the forehead, and the chest and back.

In the Treatment of Uremic Convulsions the following plan is recommended by MALBEC (*Rev. Internat. de Méd. et de Chir. Prat.*):

1. Removal of ten or fifteen ounces of blood, to be repeated if necessary.

2. Inhalations of chloroform until the convulsions are controlled.

3. Administration by enema of a mixture of

Musk	gr. vijss.
Chloral hydrate	gr. xlv.
Yolk of egg	No. j.
Distilled water	f℥v.

4. Administration hourly of a tablespoonful of a mixture of

Strontium bromid. . . .	℥j.
Sirup of orange-flower . .	f℥jss.
Distilled water	f℥iij.

5. Restraint of thighs and legs wrapped in cotton. Absolute milk-diet.—*Frauenarzt*, 1895, No. 11.

The Treatment of Akromegaly with Pituitary Extract.—At a recent meeting of the Société Médicale des Hôpitaux, MARINESCO (*Mercredi Médical*, 1895, No. 46, p. 550) reported three cases of akromegaly treated with pituitary extract. The first case was in a woman, fifty-three years old, in whom the first symptoms of the disease had been observed nine years previously; the second in a man, fifty-four years old, in whom the disease had existed for eight years; the third in a woman, thirty years old, who had been epileptic, and whose symptoms had begun nearly five years before. All three presented paroxysmal headache, visual derangement (concentric narrowing of the field in one, slight hemianopsia in the second, and well-defined hemianopsia in the third, in which there existed also diabetes mellitus). In the course of treatment headache and other pains disappeared, and the general state was much improved. There was increased freedom of movement of the extremities and perhaps some diminution in volume of the soft parts. In addition there occurred noteworthy diuresis.

Cold-water Enemata in the Uremic State.—FOXWELL (*Birmingham Medical Review*, vol. xxxviii, No. 207, p. 257) attributes the uremic state to the abnormal retention of waste products in the blood and to excessive peripheral contraction producing stasis of blood in the brain. Holding this view he was led to try the effect of simple dilution of the blood with a bland fluid, in order to lessen the concentration of the poison, with a consequent lessening of the peripheral contraction. He reasoned that by this means the brain would be more fully supplied with blood, and this would be of a better quality; and that the dilatation of the renal arterioles would allow a greater flow of blood through them, with a consequent increased excretion of morbific matter. To effect this purpose a half-pint of iced water is injected into the rectum every hour, in conjunction with such other treatment as may seem indicated.

Cobalt as an Antidote to Cyanid-poisoning.—ANTAL (*Physiol. Stud. aus der Univ. Budapest*, 1895) has shown experimentally that the salts of cobalt are the best antidotes to poisoning with the cyanids. Cobalt nitrate forms with potassium cyanid a non-toxic salt, potassium and cobalt cyanid, small doses of the nitrate sufficing to neutralize large amounts of the cyanid. The physiologic activity of the salts of cobalt depends upon the concentration of the solutions employed. Solutions of from ½ per cent. to 1 per cent., which are capable of counteracting the effects of lethal doses, exercise little influence upon the heart and upon the red blood-corpuscles. In cases, therefore, of poisoning with potassium cyanid it is recommended that from 10 to 30 c.cm. of a ½ per cent. or 1 per cent. solution of cobalt nitrate (gr. ¾—gr. ivss?) be administered both by the mouth and subcutaneously. —*Therap. Wochenschr.; Nouveaux Rem.*, No. 21, 1895.

Amygdophenin is the name given to a substitution-derivative of paramidophenol that appears as a grayish-white, crystalline, light powder, soluble in water with difficulty. STÜVE (*Centralblatt für innere Medicin*, 1895, No. 46, p. 1113) reports the results of clinical observations that show the new product to be exceedingly useful in the treatment of acute rheumatism; of some value in the relief of neuralgic pain; and of little or no use as an antipyretic. The dose employed was gr. xv once or several times daily, up to ℥jss, given in powder or compressed tablet. Bad effects were not observed. Exceptionally vertigo, ringing in the ears, and sweating occurred.

Pilocarpin for Aural Vertigo.— LEMAIREY (*Ann. des Malad. de l'Oreille, du Larynx*, etc., T. xxi, No. 11, p. 420) has reported the case of a man, twenty-nine years old, presenting symptoms of Ménière's disease, or aural vertigo, in which relief was afforded by the subcutaneous injection of pilocarpin nitrate. A 1 per cent. solution of the drug was employed, and gr. $\frac{1}{16}$ was injected daily in the morning before breakfast, the patient remaining in bed throughout the period of sweating.

For Hyperidrosis:—

R.—Balsam. Peruvian. . . .		gr. xxiv.
Acid. formic.	} . .	āā ℥ij.
Chloral hydrat.		
Alcohol.		f℥v.—M.

S.—Apply topically in spray or by means of cotton tampons. —HEUSNER, *Semaine Médicale*.

HEROISM AFTER THE BATTLE.

THOSE who were at a safe distance from the battle always seem to know much more about how it was fought than those who were actually engaged. If any body of men can claim to have borne the brunt of the battle in the long and painful war against smallpox—and its sturdy ally, prejudice—it is our own profession, and yet while for three generations we have been unanimous in our belief that the weapon most relied upon in every onslaught was the point of the vaccine-lance, now that the danger is over, and the enemy not only routed from every quarter but almost annihilated, in our rear goes up a piping cry, "It wasn't vaccination that won the battle."

What it was that *did* scatter the foe the criers have never deigned to explain until just recently, when the memory of the struggle has faded and smallpox and its ravages have become merely an historic fact with most communities. But some people confuse *historia* with *hysteria*, and in the fulness of time comes one of them, a Mr. Alfred Milnes, M.A., otherwise unknown to fame, and in a most imposing essay in the last *Arena* tells us "all about the war."

It is even worse than we had hitherto been led to believe; not only had our lance-points nothing to do with the victory, but the same is true of any other weapon or weapons carried by us, and also even of ourselves. We didn't win, or even take any prominent part in the struggle. It was the "sanitary march of civilization." In other words, the moral influence of the stay-at-homes had more to do with the victory than the onslaughts of the troops in the field.

The method of supporting this colossal claim is the well-worn and familiar one of juggling with a few selected statistics just so far as they will possibly stretch, and then filling in the gap with barefaced assertions. In the first place, vaccination, it is said, has had nothing to do with the decline of smallpox, for it has "been proved a failure," because it does not absolutely protect against an attack—as if any rational physician ever claimed that it did. This claim is supported by proudly pointing to the damning record of the three epidemics in England since 1850, which carried off altogether 78,000 people—that is to say, roughly (including the outbreak of 1881–1882), 85,000 people in half a century. These figures, in the mass, are certainly appalling to the nonexpert eye, but when we remember that they represent a death-rate of only about 60 per 1,000,000 living per annum, while by the figures of Dr. Farr (which Mr. Milnes himself later unguardedly quotes), the rate for the last half of the previous century was no less than 5000 per million living per annum, that a century earlier competent observers record that one person out of every three was pitted by the disease; and that only 50 years ago more than one-half of all the inmates of our blind-asylums were blind as a result of its ravages—they sink into comparative insignificance. The fact that the disease still destroys about one-eightieth ($\frac{1}{80}$) as many lives per annum as it did before vaccination is *hardly* conclusive proof of the "failure" of the latter to protect. In view of the fact that the immunity is only for a limited period, that revaccination is difficult to secure in many cases, and that the prejudice and fanaticism of thousands of such as our present essayist have had to be encountered, a "failure" of 1.2 per cent. is extraordinarily near success to the unaided eye, even granting a large credit to "general sanitary progress."

Besides, when we speak of progress in sanitation, we must remember that smallpox is not a filth-disease, although its mortality would unquestionably

be lessened by cleanliness, drainage, etc., and that the chief and almost only "sanitary measures" applied to it have been vaccination and quarantine.

Mr. Milnes also entirely neglected to mention that these epidemics, whose large lists of deaths he so triumphantly adduces in support of his belief, in most cases either started or made their chief headway and fatality in ignorant and prejudiced artisan communities, where a sufficient proportion of his unprotected sympathizers lived to furnish fuel for their flames. It, however, leaks out unintentionally in his last cited outbreak (Sunderland), where in his desperate endeavor to include some "protected" cases in the attack, he declared that the epidemic comprised 100 cases, "9 of whom were vaccinated;" the percentage of vaccinated persons in the country being about 80 per cent. !! Comment is unnecessary.

His next assertion is that not only does vaccination not prevent, but that it does not mitigate the virulence of smallpox. This he supports by a choice selection of statistics, and then proceeds to assume an air of pathologic authority, and boldly asserts that vaccination not only does not mitigate a later attack of smallpox, but *cannot*—"such a claim is without precedent in science."

In his beautiful metaphor one attack of a disease may *prevent* another, "but whenever such protection is overcome, and the enemy breaks through the defences, it is apt to cast off all discipline and sack the place." It is, of course, too much to expect of a pathologist of Mr. Milnes' magnitude, that he should burden his memory with such trifling "precedents" as the curative use of inoculation in tetanus, in diphtheria, and in anthrax, but he might at least have heard of Pasteur's antirabic inoculations.

His grand final *tour de force* is the marshalling of a massive array of statistics to prove that smallpox has simply shared in the declining prevalence and fatality of contagious diseases and fevers in general. By a skilful and arbitrary selection, for purposes of comparison, of a few decades during the past century, he makes it appear that between the dates chosen smallpox had actually diminished less rapidly than the "continued" fevers. In his last comparison he deliberately selects a five-year period *in which an epidemic of smallpox occurred* (1881–1885), for his second period, to show how small was the rate of its decline.

But even taking his own figures, and simply comparing the death-rate at the extremes of the entire series, the deception is revealed at once. Thus in the decade, 1771–1780, the death-rate from smallpox was 5020 per annum per million, the death-rate from "fever" 6210 per million, while from 1866 to 1870 the rate from smallpox had fallen to 105 per annum per million, while that from fever had only reached 1970 per annum—a decline on the part of smallpox to 20 per cent. of its former virulence, and of "fevers" to only 30 per cent of their fatality—a difference in favor of smallpox of fifteen to one; but then a little discrepancy like this has no discouraging effect upon an antivaccinationist.

The magnificent general progress of sanitary science and intelligence has, indeed, done much to lessen the horrors of smallpox, as of all other diseases, and would have done more if it had penetrated further into the consciousness of such as Mr. Milnes and his ignorant followers. But that this alone is to be credited with the entire achievement can be overwhelmingly disproved by the very figures adduced in its support.

EDITORIAL COMMENTS.

"*Only Nervousness.*"—In these days of sharp competition in almost every direction it is no wonder that there is a large field for the neurologists. In the commercial world we find that, as a class, the brokers are exposed to excessive nervous strain—one day they are rich, another day poor. They live on excitement, which is but another way of saying that they live on their "nerves." Among the professions, the country doctor is often pictured as living in a ceaseless round of toil, and while undoubtedly he is called upon for much exertion, both physical and mental, we cannot but feel that the young physician of our day who essays to build up a practice and a competency in a large city is subjected to a much greater strain in his struggle for existence. If he would succeed, not only must he effectually cope with the rivalry of his fellow-physicians, and live down the dispensary-abuse, but he must give clinical instruction, participate in the proceedings of the various local medical societies, write numerous medical papers, and attend to a host of other things.

This incessant strife for a livelihood involves an amount of nervous strain which should bring home to us with a sense of personal concern the importance of a condition which physicians are continually besought to relieve, and which they are prone to carelessly diagnosticate as "only nervousness," and straightway to dismiss from their minds. Such a diagnosis is on a par with the common use of the terms "malaria" and "nervous prostration;" and while it serves as a cloak for the ignorance or indifference of the physician, it also obscures the true seriousness of the condition, and deprives the

sufferer of the relief which medical science and the healing art can and should afford.

It is to this phase of the subject that we desire to direct attention, and we cannot do better than refer to some of the suggestions thrown out by Dr. Herman Canfield in a paper recently read before the Society of Alumni of Bellevue Hospital. After calling attention to the "length, depth and breadth of that glib phrase—'only nervousnes,'" this writer makes an eloquent plea to physicians not to turn a deaf ear to the "only nervous"—or, as they are too often dubbed, "cranks"—but to sharpen their wits and bring their best energy to bear upon the difficult problem before them. "Do not tell the patient," he says, "that it is all foolishness, and that nothing terrible is going to happen, for she knows that already; but endeavor by systematic and painstaking inquiry and observation to unravel the tangle of cause and effect, and from the many disturbing elements try to discover the true cause of the nervousness." In doing this, one should, of course, draw out the essential points in the family-history and in the previous history of the patient, but it should be remembered that a quiet half-hour of observation of the patient, when the latter does not suspect it is going on, is worth more than any amount of direct questioning. These individuals, as a rule, become nervous not from any one distinct cause, but from a gradual dropping one after another of the links in their automatic life, thus throwing into prominence symptoms which are really exaggerated traits of the true character. It is not right, therefore, on discovering the existence of a slight inequality in the muscles of the eye, or of some abnormality in the nasal passages, or of phimosis, or an enlarged or adherent clitoris, or of pelvic disease, to jump to the conclusion that this condition is the prime cause of the nervousness. It is quite possible that the nose may be a little out of line or the uterus tipped slightly out of the usual position without giving rise to any symptoms; and when it is remembered how seldom are the nervous symptoms relieved by operation for pelvic disease until the symptoms themselves have also been treated, it is evident that we should search long and deeply for the cause rather than to seize rashly upon some slight abnormality for an explanation of the diseased condition of the nervous system. It is fashionable to ascribe all sorts of affections to overwork, but it has always seemed to us that worry rather than work is responsible for most of the mischief done.

In the paper referred to, the author gives a most graphic description of the steps by which a young girl commonly reaches that pitiable condition so lightly spoken of as "only nervousness." It is well known that young girls or young women are most likely to be so affected, and this may be readily explained by their greater impressionability, their education and training, and their mode of life. How often do we see delicate, anemic, high-strung nervous girls spending many hours each day in school, often without any lunch, or with a lunch of chocolate-cake or pastry, and then going home to spend more weary hours in preparing the school-lessons for the next day! They have had no recreation and no exercise in the fresh air, and are so tired that they can hardly eat, to say nothing of digesting, their evening meal; but that does not hinder them from going out in the evening to exciting entertainments or plays at the theaters. Amid such toil and dissipation, with no opportunity for proper rest and recuperation of nerve-force, with imperfect digestion, and, therefore, failing nutrition, how can nature be expected to produce a healthy, well-developed and properly balanced individual? She cannot, and does not. Of course, such improper training and environment tell most upon the young girl just budding into womanhood who, as Dr. Canfield aptly says, is usually "full of purity and innocence, and replete with ignorance as to her physical make-up." It is just at this time that the family-physician is called upon to treat the anemia, the amenorrhea, the dysmenorrhea, or the menorrhagia, which is nature's protest against this monstrous foolishness or gross negligence on the part of parents and guardians.

But to return to the management of these cases of nervousness. Having gained the confidence of the patient, and studied every minute detail, the cause or causes will be usually detected, and then the treatment may be begun. One of the first propositions laid down by Dr. Canfield in considering the treatment is the importance of demonstrating to the patient the futility of drugs or external means, and the fact that a successful issue depends chiefly upon herself. The whole life should be carefully regulated, and a change of environment and associations at once instituted. This is in itself a great help, for sympathetic friends rather serve to deepen false impressions, and among strangers the patient will feel a healthful moral restraint. The patient should be well fed—indeed, overfed—on a most nourishing and digestible diet, and should be especially cautioned not to pay any attention to symptoms that may arise, or may be supposed to arise from taking certain articles of food; for in a nervous person the feelings "should seldom be consulted, and never relied upon." A neglect to insist upon this has often made all the difference between success and failure. When the patient is very weak, rest in bed should be prescribed, and the needed exercise furnished by massage; but after the strength has returned sufficiently to admit of more exertion, the patient should be compelled day by day to do a little more, until finally vigorous outdoor exercise, such as riding horseback or on a bicycle, may be indulged in. The main points in the treatment are: (1) The physical restoration of the weakened nerve-centers; and (2) the education and discipline of the nerve associations.

The Tubercle-bacillus as a Human Benefactor.—In the November number of the *Dietetic and Hygienic Gazette*, Mr. Lawrence Irwell endeavors to show that the tubercle-bacillus is a benefactor of the human race, and that its extermination would have a detrimental effect upon the world at large. He contends that the larger portion of the community is made up of the "unfit," from an evolutionary standpoint, who marry and procreate from sexual rather than natural selection, and that this class includes those of a tuberculous diathesis. Such individuals are exceedingly prolific; but to counteract the baneful result of this state of affairs the tubercle-bacillus rapidly destroys the mother and her offspring. The remedy proposed is the education of the people in order to prevent marriage among those "unfit" from any cause.

While there is a modicum of truth in these several propositions, there is enough of fallacy to lead to incorrect

conclusions. In the first place, we cannot admit that infection with or escape from tuberculosis (or other infectious disease, for all infections are alike in requiring a certain susceptibility upon the part of the individual) may be made the criterion of "fitness" or "unfitness." Tuberculosis is a disease from which recovery is not only possible but even common; while exemption may be overcome by exposure to given conditions. The tubercle-bacillus only develops where the soil has been brought to a certain grade of cultivation and fails to secure lodgment under opposite circumstances. Further, the offspring of tuberculous parents are not necessarily "unfit." Suitably surrounded they may reach a state of vigorous growth and robust health.

We fear that a logical application of the principles advocated by Mr. Irwell would lead to a test-exposure of all individuals to infection with the tubercle-bacillus (and other pathogenic microorganisms), and any that escaped would fall into the class of the "fit." We can agree to a voluntary restriction of marriage among those that manifest morbid physical or mental tendencies, and cordially indorse the proposal to disseminate this view as an educational measure.

While directing efforts to increasing the resistance of the individual to the invasion of disease, we must not neglect as far as lies in our power to limit the dissemination and diminish the virulence of its active causes.

The Billings Testimonial and Presentation, an account of which is given in another column, was a unique and epoch-making event. To have conceived and to have carried it out will always be held by the profession as of the greatest credit on the part of Dr. S. Weir Mitchell. The heartiness of response in England and America testifies to a distinct advance in clearness of the professional consciousness, and to a feeling most worthy of congratulation. By it all there comes to light the fact that the heroism thus celebrated and rewarded is, as we have intimated, of a unique variety, and that this is its first clear recognition. The medical literary hero has never before been known, or at least not pointed out. But in very truth is there in all the world more genuine heroism than that in which one thus toils for many years with daily persistence and against ever-recurring difficulties to lessen the labors of thousands born and unborn, and to place medical literature and medical science on a vantage-ground whence we may all better carry on the long warfare against ignorance and disease? There is just as much genius, there is often more, required and expended in collating, classifying, and fittingly presenting the work of others, than in original research or in other work called, or miscalled, "original." Assuredly our gratitude to such lonely and tireless workers should be unstinted, and on this occasion it was so. One enjoyed the delightful generosity with which Dr. Billings honored his assistants as equally worthy with himself, and that with which the principal of these assistants, Dr. Fletcher, gave back all the honor to the friend and chief. Above all was the glad and affectionate pride the goodly company had in the new hero, and the common enjoyment of the noble emotion of unselfishness and delight in professional progress. Dr. Fletcher's explicit concession to Dr. Billings of the entire honor of the conception of the *Index-Catalog* effectually disposes of any claim of the kind by another.

In view of the large number of contributors to the testimonial, rendering it difficult to make proper acknowledgment to each without much delay, Dr. Billings has asked us to assure each and all of his friends of his profound appreciation of the fact that this is the highest honor that could be given him, and to return his heartfelt thanks.

Syphilis through Flea-bite.—Jonathan Hutchinson, in the last (October) number of his unique and valuable *Archives of Surgery*, reports a primary lesion of most unusual origin.

An elderly member of the profession presented himself covered with an evidently syphilitic eruption, which rapidly disappeared under the use of mercury.

The only interest about the case was the question as to how the disease had been acquired. The doctor was evidently anxious to give all the information in his power, but was positive that he had never been exposed to any sexual risk, and, as he had retired from practice, no possibility of infection in that manner existed. He willingly stripped, and a careful examination of his entire surface revealed no trace of lesion whatever on the genitals, or at any point, except a dusky spot on one leg, which looked like the remains of a boil. This the doctor stated had been due to a small sore, the dates of the appearance and duration of which were found to fit exactly with those of a primary lesion. There had also been some enlargement of the femoral glands. He had never thought of the sore in this connection, but remembered most distinctly that it followed a *flea-bite* in an omnibus, and had been caused, as he supposed, by his scratching the place, though he could not understand why it lasted so long.

Mr. Hutchinson concludes that all the evidence tends to show that the disease had probably been communicated from the blood of an infected person through the bite of the insect. It thus appears that even the proverbially trivial flea-bite may prove a serious injury at times.

SPECIAL ARTICLE.

BANQUET AND PRESENTATION IN HONOR OF JOHN S. BILLINGS, M.D., LL.D.

The American subscribers to the Billings Testimonial met at the Hotel Bellevue, Philadelphia, November 30, 1895, at 7.30 P.M.

Following the discussion of the menu, DR. S. WEIR MITCHELL, Chairman, after a few pleasant introductory words, called upon PROFESSOR J. M. DACOSTA, of Philadelphia, who said that he felt keenly the responsibility of speaking on behalf of the Committee, and of representing so many distinguished men, both in America and in England. He was, he further said, gratified that henceforth Dr. Billings was to be connected with one of our greatest institutions, and that hereafter he could be greeted, not only as a most distinguished member of our profession, but as a most distinguished Philadelphian. Dr. Billings, he continued, has many claims to distinction: he is well known in hygiene, he is a hospital-constructor, he has written a dictionary; but above all he is the author of the greatest index-catalog of our day,

which has now reached sixteen volumes, with over 300,000 books and articles catalogued, and cross-references to over 800,000.

Commenting upon the enormous labor of such a task, the speaker referred to what Scaliger said of the bibliographer, the dictionary-maker, and the index-maker: that it was worse than toiling in the mines or at the anvil; and that a French author, in this connection, had said: "If there be an odious crime on earth; if any one has blasphemed the gods or killed his father, let him make a dictionary as punishment!"

Dr. Billings has made a dictionary, and has made an index, and yet he does not regard either of these tasks as a punishment, but speaks of one in his preface as "a labor of love." This seems the most extraordinary pathologic development of the amorous instinct on record! For a man to love so constantly for sixteen years, embracing in that love eight-hundred-thousand persons at least, is certainly something almost beyond belief!

Dr. Billings has done the whole of literature, the whole of science, a great good by this unselfish work, which has been of the kind that builds up literature and science indirectly by removing obstructions and saving time. Let us give thanks also to his able coadjutors, to Fletcher, his learned colleague, to another friend who is with us to-night and who helped to read proof, to the indefatigable Chadwick, who, whenever any work is to be done of a public kind, is sure to be in the midst of it. This work will continue for generations and generations to be a benefit. It is a great national credit; an illustration of what a powerful and rich government can do; an illustration of the tact and sagacity of the men successively in charge of the Surgeon-General's office. It is a credit alike to the nation, to the corps to which Dr. Billings belongs, and to the medical profession.

Dr. Billings has been justly honored all over the world, having been made an Honorary Member of the University of Munich; a Doctor of Laws of Dublin and of the University of Edinburgh; a Doctor of our own Harvard, and a Doctor of Civil Laws of Oxford. It cannot be said that he has not received just recognition; indeed, with reference to Oxford, it is reported that he was recognized there in more than one way; that when he went up to Oxford to receive his degree, clad in red robe and purple gloves, the students, recognizing that there were some other qualities in him lurking under the solemnities, broke out in loud cries of "Josh Billings!"

The great lexicographer, Dr. Samuel Johnson, said that the life of the bibliographer was one of constant work without the least thought of possible reward; to escape censure was all that could possibly be hoped for. But if Dr. Samuel Johnson were here in this goodly company to-night—in his brown coat and brass buttons, after having swallowed enormous quantities of fluid, and eaten, as was his wont, like a tiger—he would think that, at the end of the Nineteenth Century, things were very much better, and that, in a new country, talent and ability and industry were duly honored. And if Dr. Billings were to choose one occasion of all his life that he would like best and most constantly remembered, I believe fully it would be this—to-night here among his friends, among men who have come from long distances, among his associates, who are all only too glad to do him honor. The memory of this meeting must, indeed, remain with him to the end of his days, and his children's children will tell each other of to-night.

DR. S. WEIR MITCHELL then said that after hearing how good a speech a man could make who was altogether unprepared, they would hear how bad a speech a man can make who is entirely prepared. He alluded to Dr. Da Costa's reference to the great power of a government to assist a noble project, such as Dr. Billings has brought to a satisfactory conclusion, and remarked that it was a pity that our republican form of institution lacked all methods of systematic remuneration for any man except the soldier and the lawyer, to both of whom it can give promotion, high place and reward, though they may have done little in comparison to that which has been done for mankind by two score men at this table to-night.

He spoke of a dinner attended in London as far back as 1853, when he dined with "several reasonably obscure people"—a Mr. Jenner, a Mr. Paget, a Dr. Quain, also a Mr. Carpenter, who was then rising into note and was older than the others. The speaker commented upon the fact that all of the men named are to-day, or have been, baronets; that all of them have been attendants upon members of the Royal family—all on the Queen, he thought; that all were decorated in some way, Knights of the Bath, etc. This he contrasted with the practice in our own country, where there are no fitting marks of distinction to point out to the mass of mankind who are the best, and to indicate this in some formal way. In this connection he said: "When I think of the work that has been done by men like Flint, Da Costa, Osler, or of lives like those of Atlee or Sims, or of what my friend Welch has done in pathology, or the brilliant achievements in surgery of a man like Henry Bigelow, or of the recent distinguished addition to the despairing surgery of the prostate—I mention no name—and know how small are any but the commercial rewards, which are surely the smallest for this sort of thing, it makes one feel that there is nothing for us to do except occasionally to meet together as we are now doing, to say what we think about men like the honored friend of many years, whom we have here to-night as guest."

He referred to a recent meeting of the National Academy of Sciences, at which, for the first time in the history of that association, it took courage to say to two of its members: "You have done noble and great things, and we wish to congratulate you upon them." It turned on this occasion to Professor Lesley, of this city, and congratulated him warmly upon having finished the 12th volume of the Geology of the State of Pennsylvania; it turned to Dr. Billings, getting a little ahead of us, and congratulated him on the noble library which he created, and the catalog which he has just brought to satisfactory completeness. Neither has the profession of medicine shown any tendency in its societies or in its central association to point to its greatest men and thank them in any manner or in any way. This should have been done long ago for more than one who has gone unthanked to the world where all accounts are settled.

Dr. Mitchell read extracts from a number of letters received from Great Britain and the United States, speaking in the highest terms of praise of Dr. Billings' work.

"There was but one hitch in all this," he said. "My friend, Dr. Lauder Brunton, having collected a very con-

siderable sum in and about London, sent me a draft which was drawn to the order of Samuel Weir Mitchell. Now the bank refused to pay the draft, because that is not my name, and when I came to inquire as to how it was that my old friend had made this mistake it turned out that in this great catalog of Billings, where there are no mistakes, my name is written Samuel Weir Mitchell!

"I am not going to say anything about the character of the work done which brings us here thankfully to-night to represent about 250 of the members of the profession in America and Great Britain. You have been told in language better than I can use what is the reason of our meeting. It becomes now my pleasant duty to place in Dr. Billings' hands the gift of a silver box which contains a check for $10,000, and which has engraved upon it, 'To John S. Billings, from 259 physicians of the United States and Great Britain in grateful recognition of his services to medical scholars.' On the side of the box there is, in Latin, a statement to the effect that he who has made a catalog of a great library has created a memory of the wisdom and learning of the past.

"In offering this box to my old friend, and the gentleman you desire to honor to-night, I would say that while the silver box contains this practical recognition of his services it also contains something more, as my imagination figures it. You all remember that phrase of Dr. Johnson's, 'Wealth beyond the dreams of avarice.' There is, as I think of it, within this box, for an imaginative man, that wealth which represents the good feeling, the friendly opinions, the thankfulness, of the scholarship of two continents. Also I may say that this wealth represents a noble avarice, of that kind which my friend has shown all his life—a desire to be loved and respected by those in our profession whom men most rightly honor."

DR. JOHN S. BILLINGS said: "I think that not the most eloquent speaker among you would feel himself at all able to make a fitting reply to the addresses to which you have just listened. It is impossible for me to do so, and I can only say that I thank you all from the bottom of my heart. To judge from my own sensations, that is not going very deep, because to me my heart seems at present to be in the neighborhood of my larynx.

"Of course, in this honor I am, in a way, but a representative, a large part of it being due to individual personal friendship and good will. The work has been rendered possible by the cooperation of many men working for many years, and a very large number of those men I see around this table. Besides, a very large part of this has not been due to individual merit, but, as you know, to opportunity."

Dr. Billings referred particularly to the cooperation of Dr. Chadwick and Dr. Fletcher. He explained that early in his medical experience he had occasion to look up the literature on the subject of the surgical treatment of epilepsy, and he was unable to obtain French journals to verify references. A canvass of New York, Philadelphia, and Boston, only resulted in obtaining one-half the journals, and Dr. Billings conceived the desirability of a library where all information of this character could be obtained. After the war, being placed on temporary duty in the Surgeon-General's Office, it seemed to him a very judicious time to get together some books for the library. At that time there were only two bookcases in the office which constituted the library. The long and arduous difficulties and labors attendant upon the enterprise before it reached assured success, as also in establishing the catalog, were briefly recapitulated by the speaker.

"As to this gift, I accept it in the spirit in which it is given; I cannot yet say how it shall be used. It represents power; it represents the power of getting knowledge; the power, perhaps, of developing knowledge and increasing it. I will endeavor to use it in a way that will perhaps be satisfactory to those who have contributed it.

"In conclusion, gentlemen, I beg of you to accept my warmest and heartfelt thanks, and the assurance of my appreciation of your kindness."

The Chair then called upon DR. J. R. CHADWICK, of Boston, who said:

"Before fulfilling the role which you have assigned to me of alluding to the merits of Dr. Billings' able collaborators in carrying out the stupendous work of which we meet to celebrate the completing, I want to testify to the gratification that we New Englanders always have in gathering to do honor to your distinguished men. I am here reminded of the words of a famous orator, Rufus Choate, of Boston, in addressing a similar audience in this city many years ago. 'It gives me great satisfaction,' he said, 'to honor, by my presence here to-night, the two most distinguished sons of Pennsylvania—Benjamin Franklin, of Massachusetts, and Robert Morris, of New York.' May I not add another to the galaxy in naming Dr. Billings, of Washington? This phrase may be interpreted in more than one way, but I prefer to assume that the orator meant to imply that you had the discernment to recognize the merits of genius wherever found, and the ability to offer them such inducements as would lead them to become citizens of this metropolis.

"As Librarian of the Medical Library of Boston, and a warm personal friend of Dr. Billings, I have had many opportunities of appreciating the rare combination of qualities in Dr. Billings which has fitted him to conceive the task of creating from a very small nucleus the immense library over which he till recently presided, and then making an index-catalog of it more comprehensive in scope and more perfect in detail than any catalog hitherto made in any special branch of science. In proof that this praise is none too great, I would call your attention to the reasons emblazoned in letters of gold upon the honorary degree conferred upon him by the University of Munich (the translation from the Latin is mine):

"'A man who deserves of his country and of literature the highest praise, not only for his numerous important writings on the relations of physicians, on the proper construction and administration of hospitals, on the public health in the United States according to the precepts of the science and art of hygiene, on the preservation and improvement in the health of the army, but also for the great collections thereto relating, which he has established and extended; a man, who in the *Index Medicus*, of which he is editor, includes, by indefatigable industry, all the branches of medicine that are being advanced throughout the whole world, who, also, as author of the book that is entitled the *Index-Catalog* of the Library of the Surgeon-General's Office, United States Army, which, by the remarkable munificence of those who control the Government of the United States, has

been laid before an immense number of learned men, has entitled himself to the gratitude of physicians and students of history throughout the whole world, and has built for himself a monument more lasting than brass.'

"All who consult this catalog can perceive its merits; but few can appreciate the incessant labor bestowed upon it by Dr. Billings; no one, in fact, who has not, as I have, had the privilege of being his frequent guest during the past sixteen years and seen him sit down night after night at eleven o'clock with a pencil in his hand and a huge basket of current journals in all languages by his side, and, taking up one after another, run his eye over every outside and check those that were worth cataloging—about four out of every five. This is but one of the many stages in the work to which he gave his personal attention.

"It is not for me to be his panegyrist on this occasion; but there is one direction in which his influence has been felt throughout the length and breadth of the land which others might fail to note. I allude to the extent to which the formation of the Library of the Surgeon-General's Office and the publication of its catalog have stimulated the formation of medical libraries in every large center of population. This in itself entitles him to the gratitude of this and future generations of medical men.

"One of the most valuable of his many qualities has been his common-sense. 'He is like a pin,' to use a Frenchman's simile, 'in that his head prevents his going too far.' His knowledge of men and his ability to secure their enthusiastic cooperation form the secret of much of his power. For instance, he not only despoiled my private library of many of its treasures in the early days of our acquaintance, but persuaded me to listen with equanimity, when, as at the dedication of the medical library in Boston, he boasted of the fact publicly, and intimated that the experience had doubtless proved a valuable object-lesson for me as a librarian. Mr. Thomas Windsor, formerly Librarian of the Manchester Medical Library, in England, is another who has succumbed to his wiles, and from the beginning has sent box after box of medical rarities culled from his extensive private library, and this, despite the fact that he is the most inveterate collector and reader of books, and has a more intimate knowledge of their value than any living man. We are but types of his many victims.

"The effect upon the *Catalog* of this quality in Dr. Billings is made manifest by the ability and indefatigable labors of his subordinates. No one familiar with the workings of the library can help being impressed with the exactitude and unfailing courtesy of Mr. F. W. Stone, who keeps the books and carries on the multifarious correspondence; with the energy and executive ability of Mr. C. P. Clarke, who has general supervision of the clerical work; of the genial, cultivated persistence of Mr. Edward Shaw, who, despite his many years and independent fortune, labors early and late to complete the files of periodicals. I cannot repent my weakness in sending him from my private collection last year, after many years of solicitation, the number of the *Gazette de Jardine* lacking to complete the file of that journal, when I realize that it is to him chiefly, owing to such persistence, that the periodicals in the library now number 29,000 volumes, and is the largest collection of medical periodicals in the world. I have no personal acquaintance with the other employés, such as Mr. W. T. W. Moritz, who, as chief cataloguer, writes and revises the cards and compares them with the titles of the books; the late Mr. F. L. Apel, who was in charge of the library in 1865, then numbering 800 volumes, and who kept the library in order in the two little bookcases, and sent patients to the Providence Hospital; he subsequently became clerk and was specially useful in revising proof, owing to his knowledge of eight of ten languages; Mr. Hardy who, as successor to the late Dr. Wise, is curator of the books; and Mr. Watson, keeper of the unbound books.

"I have reserved to the last, in order to give it deserved prominence, mention of the name of Dr. Robert Fletcher as the most distinguished collaborator with Dr. Billings on the *Index-Catalog*, and the actual editor of the *Index Medicus*. As his qualification for this work is only exceeded by his modesty, I may be pardoned for giving a few brief biographic data.

"Dr. Fletcher is of English birth, received his medical education in Bristol and London, was married at the age of twenty-one years, and brought his bride at once to America, establishing himself in practice in Cincinnati, Ohio. In 1861 he was appointed Surgeon of Volunteers, served throughout the War of the Rebellion in the Armies of the West as Medical Purveyor. At the end of the war he became an acting Assistant Surgeon, and was assigned to assist Dr. J. H. Baxter in compiling the Statistics of the Provost-Marshal General's Office relating to drafted men, a work of great value for reference for anthropometric data, much of which value is due to the accuracy and general attainments of Dr. Fletcher. In 1877, after the publication of this work, he was assigned for duty in the medical library, where he at once became the chief assistant and received the title of Principal Assistant Librarian by Act of Congress in 1891. His mental equipment to fill the important functions of this position has been continuously augmented by the fact of his private studies, which have covered a wide field, ranging from the old English poets and dramatists to modern anthropology. As proof of his attainments he has given us desirable papers "On the Vigor and Expressiveness of Older English;" "The Poet, is he Born, Not Made?" "Medical Lore in the Older English Dramatists of the Elizabethan Era, excluding Shakespeare;" and in another field, "The New School of Criminal Anthropology." He has been President, successively, of the Anthropological Society of Washington, the Philosophical Society of Washington, and the Literary Society of Washington.

"In preparing the *Index-Catalog* his assistance has been of the utmost importance, the accuracy and typographic excellence of the volumes being entirely due to his careful and skilful supervision.

"It is fortunate for the medical profession that Dr. Fletcher will remain, in the future as in the past, the editor of the *Index Medicus*. When this important publication was started he took entire charge of the editorial work, and the excellence of this record of current medical literature is wholly due to his skill and ability. We know that its revival is assured. I trust that he will tell us fully of its present status.

"One word and I am done. When Dr. Fletcher was five years old, his father, who was a lawyer, had as a

client a man possessed of a large landed estate, whose exigencies required that an insurance should be effected upon a young life. Dr. Fletcher then had the only necessary qualification, and his life was insured for a large sum. The premiums have been paid regularly ever since. During the time of Dr. Fletcher's active service in the field the premiums were doubled. When it became known in England that Dr. Fletcher was assigned to duty in Nashville, the premium was reduced to the former rate, on the ground that he was stationed 'in a walled and garrisoned town.' It seemed to me that this insurance must not be allowed to lapse, and I think that part of the funds in your hands, Mr. Chairman, should be employed to prevent the loss of this mascot. I propose a toast to Dr. Robert Fletcher of Washington."

DR. FLETCHER then said:

"I am somewhat in the position of a friend of mine, who, being in Alaska in the early days of that territory, was supposed to have been killed there. He returned, fortunately, to San Francisco, and, being a member of the San Francisco Academy of Sciences, he went to a meeting of that society, and listened with great interest to a most pathetic account of his career and untimely death. I feel somewhat in his position after having heard this very untimely obituary.

"I need not say with what pleasure I have listened to the various tributes paid to Dr. Billings. It is needless for me to add anything as to the merits of the particular work which he has been engaged in; but I can speak of it from a different standpoint from any of you—that of twenty years' daily intercourse with Dr. Billings, an intercourse characterized always by the gracious readiness he has ever shown to contribute to my insufficient knowledge.

"While the thought of a great index-catalog might have occurred to thousands of persons, there have been more than once attempts made to deprive Dr. Billings of the credit of the first conception, and, indeed, of some of the carrying out of the work connected with that index-catalog. I take the opportunity to say—and there is no man living who can speak more positively on that subject than I can—that I know positively that the first conception of this stupendous work, the planning of it, the arrangement, the classification—in short, the whole merit of it, are all due to Dr. Billings exclusively.

"My friend, Dr. Chadwick, has kindly associated my name with the *Index Medicus*, that fascinating romance of which you have all heard. It is right that I should say something on this subject. Some sixteen years ago this was commenced at the suggestion of a New York publisher. Later Mr. Davis, of Detroit, asked permission to carry it on, and it certainly has been a great credit to him and his generosity, for it was every year with a certain definite loss of money that he continued the publication; at length he tired even of that, and the journal ceased to be published last April. I think, on the whole, I was rather pleased, for I could go to the seashore without thinking whether appendicitis should be classed under diseases of the digestive system or under the surgical treatment of the abdomen. We all know that when a man dies it is astonishing how many men find out how much they thought of him, and how much they really valued him in his lifetime, although they may have done nothing to help him. So it was with the *Index Medicus*. In the pathetic language of Erin they said: 'Arrah, then, why did you die?' The result was that those who really wanted the journal continued were asked to subscribe for it on terms heretofore unheard of in the history of medical publishing. Instead of the minimum number of subscribers we have received so many that we have begun to decline additional subscriptions, so that I have the pleasure of stating that in January next the first current monthly number will be published, and another number, as soon as the material will allow of its being printed, will cover the entire space since the cessation of the publication last spring."

DR. A. JACOBI, of New York, being introduced, rather took issue with Dr. Mitchell's views as to the better position of the profession on the other side, and thought there was not much to complain of; that everyone in actual practice in this country attends sovereigns every day. Continuing he said:

"When you, Mr. Chairman, in your irresistible and pleasant dictatorial way, told me a few days ago that I should be one of those who would speak here, I meekly submitted to what I prefer to call *your* fate. Originally I had expected to be on what you have seen mentioned in the books as a Weir Mitchell treatment, with ample rest, good feeding, and the most pleasing silence. But you willed differently, and I, 'cedo majori,' speaking for New York last, least, and briefest.

"I look upon to-night's gathering as a manifestation of great moment. As a rule, a professional man's reward for long-continued work and meritorious services consists in the universal but silent recognition of his labors. We do not, as they do in monarchical states, attach long-winded titles to his honored name; nor do we ornament his coat with insignia and decorations; nor are there many instances in which his distinction and the veneration felt for him are substantiated by a calligraphically written and embossed address or other documentary evidence. To-night, however, many of us have assembled for the purpose of proving both to the profession and the public some proof that his colleagues love to publicly honor a great and good man, whose efficient work medical men all over the world have long learned to appreciate. I trust the notoriety of this occasion (I wish there were many of the kind) will prove to the community at large the existence of the public spirit which prevails in the bulk of the medical profession and of good will toward a deserving colleague. The jealous and mercenary spirit of a commercial era must not and does not enter into the ranks of a scientific and ethical brotherhood. That spirit may be natural and congenial to the stock-exchange, the labor-market, and industrial enterprises; but—'quod licet bovi non licet Jovi'—it does not govern the motives of the most humane of all the professions. Nor is this exhibition of the spirit of the profession without its reward, for the esteem the medical fraternity is commanding among the lay world stands in due proportion to the regard we evince for ourselves, for each other, and for our achievements, rights, and duties.

"The last take the first rank in the minds of whomever looks on himself as one of the cells constituting the living organism of science and of society. Therefore, appreciating my own duties, I try to read in the soul of our guest; unless modest to a fault, that he has the right to claim that there is no man who has been more active in

the service of the profession, and through the profession to all countries. Not a year of his life but has been filled with the results of the labors of an always seething brain. Fortunately it was warmed by a generous heart and sustained by great physical powers. Thus only was it possible to know and amass books, old and new, to gather and systematize specimens, to write history, prepare censuses, exhibit statistics of the greatest value, organize the *Index-Catalog* and the *Index Medicus*, and the Medical Museum, and always to combine the powers of a savant and of an administrator. . . .

"All of the latter are wanted in his present position. Hygienic institutes will henceforth require the best talent of the land. Modern and future medicine must rest on biology and hygiene, including as these do bacteriology. Thus far practical surgery has reaped the most beneficent harvest from their labors. Internal medicine has just begun to participate in their blessings. Antitoxins are to take equal rank with antisepsis and asepsis. Thus laboratories are the most efficient agents, both curative and immunizing, that is preventive. And the best minds should be placed at the head of the institutions destined to render experimental research subservient to suffering mankind. From that point of view I was not sorry to learn that Billings gave up his unique position in Washington to charge himself with the direction of his laboratory of hygiene. He is more than eminently qualified; for not only the best minds are required for such places, but the stoutest hearts also. A position like his is no longer a mere office; it becomes a mission. Modern medicine shares both in its objects and in its methods the dangers of a gospel. It is our present exact experimental methods that are constantly assailed by the obscurists of all countries and all stations in life. They have succeeded in almost crippling English physiology and pathology by depriving the most objective and brightest observers of any nation of the means of systematic experimentation. In our country we have had to to exercise constant watchfulness over legislatures and wary lobbyists to ward off contemplated blows against the liberty of scientific research; and the last reports carry the news of a new onslaught along the whole line. Strong conviction, eternal watchfulness, and stout resistance of closed ranks will be required to fight and defeat the sickly sentimentalists who shed tears over a rabbit while staring in stupefaction at the epidemics of preventable diseases, which slay humankind by the hundreds of thousands, and call it a dispensation of Providence. In the imminent combat against misled ignorance and semi-instructed and opinionated fanaticism, we shall require not only universal cooperation, but also the strongest voices fit to be heard in the uproar of the battle. Such a Diomede you have secured for Philadelphia. Show us many more, so as to at least convince the millions that the world of the future should belong to man and not to rabbits, guinea-pigs, and horses.

"We should not imagine that victory will be easy; even an attack once repulsed affords no security. It is a pity that this should be so, but this uncertainty must be borne along with the blessings of our political and social habits, of which it is the direct result. Individual, political, and social life cannot be at rest and settled forever in a progressive community. We are used to unceasing agitation. Constant motion clears the atmosphere; perpetual turmoil the stagnating waters of the ocean; and it takes a restless and never-pausing circulation in protoplasm and cells to preserve the health of organic life. Thus, if we must fight, let us do so with the conviction that through fighting only in accord with what we forever see in living matter can we work out our salvation and that of mankind. It is certainly true, as the great German proclaimed, that he only earns both liberty and life who conquers them on every one of his living days.

"I came near forgetting, however, that I am speaking before my betters, recognized masters in modern medicine, and, I trust, just as conscientious citizens of the political republic as they are leaders in that of science. There is no use carrying owls to Athens, or to speak of the duties of the medical profession to the successors of Rush and Physick. The mention of these illustrious names carries me back to where I started, to Philadelphia.

"What shall I say of and to Philadelphia and of this grand demonstration of hers, for hers it is? From what I know we should not be here without her having taken the initiative. It is but just that she should have done so, for indeed she is equally interested with all of us, and the gainer by far for gobbling up the guest of the evening as her own immediate property. She reminds me in part of what William Sterling in his life of Charles V says of Austria: "Bella gerant alii tu felix Austria nube—let others fight, Austria makes her fortune by marrying." So Philadelphia enriched herself by having Billings wedded to her. Still let us be just and admit that she never was a mere receiver and that he made no contract with a mean spouse. From the time of Benjamin Rush to the present, American medicine found a home and fertile cultivation in Philadelphia, and not a few of her medical citizens have been Rush's successful rivals in all his exertions and achievements. That is no mean praise if you refer to what is said of him in *A Century of American Medicine*, by Edward N. Clarke, Henry I. Bigelow, Samuel D. Gross, T. Gaillard Thomas, and J. S. Billings. In the article on 'Practical Medicine,' written by Clarke and R. H. Fitz, Benjamin Rush is called 'a devoted enthusiast in his profession, an ardent patriot, a lover of liberty, eminent as a physician, distinguished as a philosopher and a scholar, who, holding a high social position in the community, contributed largely to raise the profession of medicine in the estimation of the community in which he lived, and of the whole country.' I am anxious to add that this very day the ranks of Philadelphia's great physicians contain more than one man to whom that eulogy bestowed on Rush would be but a just tribute. Thus, while she may be envied because of her securing Billings, she offers no mean gift to the newcomer.

"And now a word about this newcomer and old friend. At the close of my remarks I mean to become quite personal and tell a story. Those who know me well are aware of my not commiting many sins of that kind. I am even suspected of knowing no stories at all. But there are a few in my repertory, and their beauty consists in their being true—some of them. Now, there was a letter written fifty years ago, somewhere in South America. It bore the address, 'Alexander Humboldt, Europe.' That letter was not slow in finding the little great man in his side street in Berlin. In the same way the honored guest of the evening is called by me and all of us 'Billings,' not even Dr. Billings. Not in my

most melancholic dreams did it ever occur to me that he would condescend to descend to our level. I say our level, for I am afraid there are but few here so distinguished as not to be professors. Most of us, I fear, *are* professors, more or less. And Billings is one of us now, I am told. But I need not be told that he will remain big enough to require no title additional to that which he carried in Washington. That title was 'Billings.' And I also know that when in Europe—which, after all, is also a part of the world—and the rest of the continents, men whom we all know and revere count the very best names of all countries, one of the few will be 'Billings, of America.'"

DR. WILLIAM OSLER, of Baltimore, being called upon, said:

"I have to make the very pleasant announcement that though Dr. Billings has left Washington, and the Army Medical Museum and that the Army Library will know him no more as we have known him there, yet his counterfeit presentiment is to appear on the walls of the library. A sufficient fund has been raised to have Dr. Billings' portrait painted, and it will be presented to the Army Medical Museum."

Dr. Osler read a letter from U. S. Surgeon-General George M. Sternberg, expressing pleasure at the fact that such a handsome sum had been raised for Dr. Billings, and that his portrait was to be painted by an artist of ability, adding that the portrait, when completed, would be gladly received.

SOCIETY PROCEEDINGS.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in Washington, D. C., November 12, 13, and 14, 1895.

FIRST DAY—NOVEMBER 12TH.

Morning Session.

The Association met in the banquet-hall of the Hotel Shoreham at 10 A.M., and was called to order by the President, DR. L. MCLANE TIFFANY, of Baltimore, Md.

DR. H. C. BUSEY, of Washington, delivered an

ADDRESS OF WELCOME,

on behalf of the medical profession of the District of Columbia. In his closing remarks Dr. Busey said:

"I solicit your aid and cooperation in our effort to secure the protection of our people from the horde of impostors and charlatans which you have driven from your borders by the enactment and enforcement of medical-practice laws, and which has made the District of Columbia a common rendezvous where the most atrocious methods of the charlatan and mercenary impositions are openly and flagrantly committed, to the wrong, injury, and robbery of its citizens. You represent the most influential and intelligent class of suffragists for whose aid on the hustings and at the polls we plead.

"To state the deplorable condition of this District fully and broadly, there are five medical schools and several medical societies chartered by acts of Congress, or under the general incorporation-law authorized and empowered to license persons to practise the art and science of medicine, without any uniform, and by some without any standard of qualification beyond the ability and willingness of the applicant to pay the required fees, or give promissory notes for such payment; and under the provisions of the general incorporation-law any dozen of persons can obtain a charter upon payment of the fee for recording of the same, authorizing them as a body corporate to confer the degree of M. D. at their pleasure and will. Such is the status of this Federal territory, which is under the exclusive jurisdiction of the highest tribunal of legislation in the land, made up of the Representatives and Senators from forty-nine States and Territories, which have enacted medical-practice laws for the protection and welfare of their citizens. Take these facts home with you, and reecho them throughout the length and breadth of the land, that such criminal neglect, not less disgraceful and scandalous than the slums of vice, may not continue to afflict the citizens of the Federal territory."

PRESIDENT TIFFANY then responded to the Address of Welcome for the Association.

After some announcements had been made by DR. JOSEPH TABER JOHNSON, of Washington, Chairman of the Committee of Arrangements, the reading of papers was taken up.

DR. BEDFORD BROWN, of Alexandria, Va., read a paper entitled

PERSONAL EXPERIENCE IN THE TREATMENT OF STAB-WOUNDS OF THE INTESTINES AND PERITONEUM.

He stated that about 130 cases of stab-wounds of the peritoneum and intestines had come under his care dur-

ing his entire professional experience in both private and military practice. In less than one-third of the cases the intestines were wounded. It was considered a little remarkable that there should be such a disproportion in the number of intestinal wounds in these cases; in other words, it is a singular fact that in a large majority of abdominal wounds the intestines escape injury even when such wounds are extensive. Transverse and longitudinal stab-wounds of the intestines were then considered at length. Dr. Brown regards the saber-wound as one of the most dangerous in its immediate and remote results. If the edge and point of the saber are sharp the wound inflicted is large and deep. The weapon cutting through the intestines and mesentery, usually passing through the abdomen, severs large bloodvessels, and causes frightful hemorrhage, which is speedily fatal. He had only seen three saber-wounds of the abdomen, and they ended fatally in a short time. The stiletto is a dangerous instrument, as it almost invariably enters the intestine or other organ. It does not kill by hemorrhage usually, but makes an opening in the intestine sufficiently large to permit the escape of a small quantity of fecal matter, causing septic inflammation. It is one of the most difficult of all intestinal wounds to detect.

The diagnosis of intestinal wounds was then dwelt upon, reference being made to Senn's hydrogen-gas test to detect wounds of the intestine. While Dr. Brown considered it a useful test, in remote sections of the country far from large cities and towns it is not practicable because of the impossibility of procuring the apparatus and generating the gas. In all abdominal stab-wounds his rule has been, after cleansing the hands and thoroughly disinfecting them, to insert the index-finger and explore the intestine to ascertain if there is an opening. In certain cases a wound may exist in the intestine, but it may be so small as to escape detection. But if the intestine is wounded, whether we can insert the finger or not, there is always more or less extravasation of fecal matter and gases, and if the finger comes in contact with this matter it is certain to retain for some length of time the peculiar odor of human feces. This will always afford positive evidence of an intestinal wound.

In treating simple wounds of the peritoneum it has been Dr. Brown's rule to close them with silver-wire sutures, after thorough disinfection. Formerly these wounds were closed regardless of antiseptic measures, except that the wound was washed with hot water and soap. On the battlefield and in field-hospitals wounds were washed with any water that was convenient, and were not washed at all when water could not be obtained. Previous to the introduction of antiseptic treatment in dressing wounds but little attention was paid to the condition of the instruments, sutures, sponges, and dressings, except the practice of ordinary cleanliness, and the percentage of cases of healing by first intention of simple wounds of the peritoneum was large. In dressing simple wounds of the peritoneum scrupulous attention should be paid to the laws of cleanliness. In treating wounds of the intestines two vital procedures are necessary: 1. Complete and thorough closure of the intestinal wound; and 2. Cleansing the peritoneal cavity of all fecal matter, blood, and gases escaping from the intestine.

Dr. Brown then described a simple method of reducing a protruded intestine in stab-wounds. He takes two long, slender, curved needles, threaded each with a silken cord 10 or 12 inches long. One of these needles is passed midway through the margin of the wound, the other through the opposite margin; and then each is tied in a separate loop. These cords are drawn in opposite directions by two assistants, upward and outward, firmly and tightly. By this means the wound is made to expand or gape widely, and at the same time the walls of the abdomen, for a large area around the wound, are considerably elevated above the intestines, while the patient reclines in the dorsal position, and a considerable vacuum is in this way created, and the intestines will glide back without force or manipulation to fill this newly created vacuum.

DR. RICHARD DOUGLAS, of Nashville, said that in peritoneal wounds we always have a mixed infection, which is more serious than infection with the colon-bacillus alone. Peritonitis, whether local, adhesive, general, or septic, should be considered of germ-origin. In closing the abdominal wound the peritoneum should always be approximated, as by so doing we lessen the danger of hernia.

DR. C. A. L. REED, of Cincinnati, expressed himself as being apprehensive about mere exploration with the finger to detect stab-wounds of the intestines. However erudite the tactile sense of the surgeon may be, at times it proves misleading, and, therefore, in certain cases it is exceedingly important to enlarge the original wound, so that part of the viscera lying immediately beneath it should be brought out and carefully inspected. He believes with Dr. Douglas that the peritoneal margins should be carefully approximated.

DR. JAMES EVANS, of Florence, S. C., related an instance in which nine men had received chest-wounds by bayonets during the war, the bayonets having been previously stuck in the ground, and yet all of the men recovered. He attributes their recovery to the form of wound made by the bayonet. In another case, a man had been shot within half an inch of the navel. He had no rise of temperature; yet when the doctor saw the patient the omentum had extruded to the size of both his hands. A double ligature was applied, a piece of adhesive plaster applied over the surface, and the man recovered. Dr. Evans had frequently seen gunshot-wounds of the abdomen during the war, in which there was extravasation of fecal matter through the wound, but unaccompanied by shock.

DR. A. VANDER VEER, of Albany, has always made it a practice to first inquire carefully as to the kind of weapon with which the wound had been made. He had seen several wounds inflicted by bayonets during the war, but did not remember having seen the intestines or stomach penetrated. There should be no delay in treating stab-wounds. The surgeon should act promptly and not wait for symptoms to develop. Just as a case of perforative appendicitis will terminate fatally in a short time, so will stab-wounds of the intestinal tract, unless timely interference is resorted to.

DR. HUGH T. NELSON, of Charlottesville, Va., said that the necessity of enlarging the abdominal wound, under all circumstances, was an imperative one. Four years ago he saw a case in which the small bowel was wounded by a knife and the patient refused operation

for twenty-four hours, believing that this viscus was not cut. The symptoms became alarming and the patient finally consented to have an operation performed. Dr. Nelson opened the abdomen by a long incision, finding it impossible to remove from the peritoneal cavity the extruded contents of the bowel, owing to the fact that an adhesive inflammation had taken place and had agglutinated them to the bowel so firmly that he could not wash them away. He attempted to resect the peritoneum into the pelvic cavity where the fecal matter had burrowed, but could not do so. Peritonitis became general and the patient died. The sooner the abdominal incision is enlarged in stab-wounds the better.

DR. GEORGE ROSS, of Richmond, Va., asked whether there was any way to distinguish between the symptoms of nervous shock and shock due to hemorrhage.

DR. BROWN replied that one of the most unerring symptoms was rapid reduction of temperature, although there is no symptom that will enable the practitioner to distinguish accurately between the different forms of shock except the gravity of the condition.

DR. W. E. B. DAVIS, of Birmingham, desired to speak upon the point in reference to injuries of the gall-bladder. The essayist referred to the fact that injury to this viscus would produce a septic peritonitis. He thought that an injury that would produce peritonitis would speedily result in death if there was a large escape of bile into the peritoneal cavity, but he does not believe it is a septic peritonitis. In the majority of cases the shock following abdominal injuries is due to hemorrhage, and that hemorrhage plays a more important rôle in the production of symptoms in intestinal injuries than has been believed. In fact, it was the hemorrhage from these wounds that frequently caused death.

DR. JOHN D. S. DAVIS, of Birmingham, expressed himself, in regard to the diagnosis of intestinal wounds, as having very little confidence either in Senn's hydrogen-gas test or the flushing method spoken of. He had seen perforative wounds of the abdominal viscera where it was impossible, from their character and location, to flush the abdominal cavity through the opening sufficiently to thoroughly clean it. In addition to the three forms of shock mentioned there should be added the shocks of sepsis.

DR. BROWN, in closing, agreed with Dr. W. E. B. Davis that all cases of violent or dangerous shock were due to hemorrhage. In regard to approximating the peritoneum, he had always left it untouched in closing simple wounds in the abdominal wall, and had found the practice a good one.

(To be continued.)

CORRESPONDENCE.

WHAT IS THE VALUE OF OUR MEAT-INSPECTION?

To the Editor of THE MEDICAL NEWS,

SIR: The butcher of the University Hospital at Ann Arbor, Mich., recently called my attention to a beef-liver just received with a lot of other meat from a large meat-firm. The surface of the liver showed numerous irregular or stellate scars, up to two inches in diameter. Beneath these the tissue was dense. On section we found calcified cysts scattered through the liver. These varied from 0.5 cm. to 2 cm. in diameter, had firm walls, and were filled with dark, gritty material. All the cysts were old; no evidence could be found as to the origin of the cysts. The cysts were so numerous that a section could hardly be made through the liver without revealing one. The liver could not be looked on as dangerous to the consumer. It was not, however, inviting. It raises, I think, the question at the head of this note. Every quarter of meat received from the firm concerned bears a seal, attached to a card. The latter has on it the legend, "United States Department of Agriculture, Bureau of Animal Industry. Inspected Meat. J. Sterling Morton, Secretary." There is also a number and a letter stamped in red ink. If lesions such as were found in this liver are overlooked, how can we suppose that trichinæ, measles, or tuberculosis can be discovered by the so-called inspectors? Does not the use of the card under the circumstances tend to create a false sense of security, or is the matter one in which the public takes no interest?

Respectfully, GEORGE DOCK.

ANN ARBOR, MICHIGAN, Nov. 11, 1895.

THE EVERLASTING "GOLD-CURE."

To the Editor of THE MEDICAL NEWS,

SIR: I enclose a document which may have already reached you. You will notice the improvement in moral methods indicated by the circular. This gentleman proposes to have the physician who purchases the right to use the "cure" do his own lying. Hitherto this has been done wholesale, so to speak, and by institutions benevolently chartered for that purpose.

Yours very respectfully,

JOHN K. MITCHELL.

PHILADELPHIA, November 15, 1895.

[COPY.]

DEAR DOCTOR: We ask you to give the following careful consideration, knowing that the greater portion of advertising literature is thrown into the waste-basket. We have a proposition to make you, which we think should not even be "pigeon-holed," but rather considered as a good thing for your adoption:

All medical journals for years past have teemed with discussions, *pro* and *con*, on the subject of gold-cure for alcoholism. Physicians have as a rule antagonized this method of treatment, mainly from the fact that the drugs employed and the conditions imposed in these cases have been withheld from them as a body. The number of patients treated successfully by the various methods under the name gold-cure have forced the medical world to the conclusion that conditions, not theories, confront them. A leading manufacturing chemist prepares an article after a certain secret formula; he advertises through the medium of medical journals that his preparation will cure certain maladies; the physician is given knowledge of the remedy, uses it, finds it efficacious, and adopts it in his practice.

The gold-cure formula is a closed door to the medical fraternity. Pronounce the "open sesame," place it in their hands with full instructions for use, and they are compelled as conscientious healers to use it in all cases of alcholism that may come to them.

Our proposition is as follows: Until January 1, 1896, we will furnish you with sufficient medicine (with directions for use) for the treatment of any number of cases of alcoholism at the nominal price of $10 each, on condition that you will charge each individual case not less than $75 for full twenty-one days' treatment.

We shall be pleased to have you become interested with us; call at our offices at any time and you will be made welcome. Very sincerely,

———— ———— ————.

PREVENTIVE INOCULATION FOR DIPHTHERIA.

To the Editor of THE MEDICAL NEWS,

SIR: In view of the fact that the diphtheria-antitoxin is a well-recognized agent, not only in the cure but even to a greater extent in the prevention of diphtheria, it seems to me that it would be very advisable to inoculate all children visiting public schools.

It is well known that as soon as the schools open in the autumn the number of cases of diphtheria immediately rises, and if the children were all protected this autumnal increase in the cases would hardly occur.

I see no reason why preventive inoculation for diphtheria should not be practised just as for smallpox, in cases in which large numbers of children are thrown in contact with each other. Yours truly,

B. M. BOLTON.

PHILADELPHIA, PA., Nov. 21, 1895.

NEWS ITEMS.

Football-incidents.—The members of the University of Pennsylvania Football Team, together with a host of substitutes and Woodruff, the coach; Leaman, the manager; ex-Captain Knipe; Bryan, the trainer; a cook and two "rubbers," departed this afternoon for the Berkshire Hills, where they will stay until they meet Harvard, at Cambridge, on Saturday.

Yale composers are busily engaged in the preparation of football-songs, to be sung at the Princeton game at Manhattan Field, New York, next Saturday. Three songs have been selected, and they will be sung by the mass of Yale students and sympathizers, led by the crack glee club.

One of the songs is sung to the air of "I Can Knock, Oh, No." It is as follows:

The Princeton tiger's stripes, they say,
Are orange and coal-black;
They run in fancy diagrams
All up and down his back.
But when he strikes old Eli's team
He'll find it sad but true,
That the only stripes upon his back
Are black and blue.
I can knock, oh, no,
I can knock, oh, noke,
I can knock, oh, no.
Yale.

[*New York Herald* of November 20th.]

During the third scrimmage, as the Wichta team were shoving their captain through their opponent's rush line, Jenne fell, and in an instant both teams were on top of him. His head was bent under his breast, and in this position he remained for over a minute. He was picked up unconscious and carried off the field. When he regained consciousness, after half an hour, he was unable to talk, and the discovery was made that he was paralyzed from the head down. He can hardly live through the night.

After the accident another man was substituted, and the game progressed until the end of the first half, when Captain Mason, of the Eureka eleven, was tackled while making an end run and fell on his face and was knocked into insensibility. He became delirious and had to be carried home.

As a result of the football-game at Decatur, Ill., Thanksgiving Day, between the Young Men's Christian Association, of Springfield, and the local team, William McGerron, one of the visitors, is likely to die. He went down in the scrimmage and the two elevens fell upon him. When they arose McGerron was unconscious. The attending physician fears he is suffering from concussion of the brain. McGerron's home is in Chicago, and he is private secretary of the State Treasurer.—*New York Herald*, November 30, 1895.

Meetings of Philadelphia Medical Societies:

	Meets.	Next meeting.

Congress of American Physicians and Surgeons.—At a meeting of the Executive Committee of the Congress of American Physicians and Surgeons, held in New York City, November 23d, the following officers were elected:

President of the Congress, Dr. Wm. H. Welch, Baltimore, Md.; Secretary of the Congress, Dr. Wm. H. Carmalt, New Haven, Conn.; Treasurer of the Congress, Dr. Newton M. Shaffer, New York City; Chairman of the Executive Committee, Dr. Landon Carter Gray, New York City; Secretary of the Executive Committee, Dr. Wm. K. Simpson, New York City.

The next Congress will be held at Washington, D. C., in May, 1897.

The Revival of the Index Medicus.—It is announced that the *Index Medicus* will be revived. The editors say further that "the replies to the inquiry made as to the preferred date of commencement of the journal have been overwhelmingly in favor of its continuance from May 1, 1895, thus making the work continuous. The first current number will appear in January, 1896, and it will be continued monthly thereafter. The preceding bibliography, from May to December, will be printed in one number (perhaps divided into two parts) as quickly as the large quantity of material will permit."

ORIGINAL ARTICLES.

DIETETICS IN GASTRIC DISEASES.

BY PHILIP ELKIN, M.D.,

OF PITTSBURG, PA.

THE means employed to combat diseases of the gastric apparatus may be summarized under three headings, dietetic, mechanic, and medicinal. Of these the dietetic are of primary importance. Nearly all pathologic states of the stomach imply a disturbance in either its motor, resorptive, or secretory function, or a combination of these. In the first and second it is usually in the direction of retardation; in the third we find diminished and heightened activity of the glandular apparatus of the stomach to be of equal frequency of occurrence. All abnormalities in the chemification of the food can be traced to either one of the preceding factors or a combination of them.

Wherever there is an inhibition of the motor power of the stomach, whether due to mere functional adynamia, as in atony, or to structural changes, as in dilatation or carcinoma ventriculi, the same principles of alimentation obtain, modified, of course, by the various chemic conditions present, as well as certain etiologic considerations. In this condition a restriction of the quantity of liquids and adherence to a solid diet mainly are indicated. Liquids in any considerable quantity further the relaxation of the stomach: 1. By their dead weight alone. 2. They do not furnish anything tangible on which the walls of the stomach can contract, as in the case of solids. 3. By their very fluidity they fail to make that impact upon the nerve-filaments of the mucous membrane which is so necessary for the production of peristalsis.

It is especially in dilatation, in which the resorptive function of the stomach suffers such marked impairment, that a strict adherence to the preceding principle becomes imperative. As corollaries of this principle must be added the consistence and preparation of the food, which must be such as not to be incompatible with tolerably easy digestion. As retardation in the motor function of the stomach is usually associated with alterations in the gastric secretion, the selection of a suitable regimen in any given case will have to be modified to meet the chemic conditions.

As a rule, whenever there is an appreciable retardation of the peristaltic function of the stomach we shall find also a concomitant diminution in the production of both free and combined hydrochloric acid. There is, however, one marked exception to this rule, namely, dilatation either idiopathic or due to stenosis of nonmalignant origin, as, for instance, in constricting cicatrices of healed ulcers. In these cases we will generally find a marked increase in the production of the normal acid elements of the gastric juice. In several cases of benign dilatation that have come under my observation, I found a percentage of 120 with $\frac{1}{10}$ normal alkaline solution, or somewhat more than twice as much as usually obtains in normal gastric secretion.

Again, we may have very marked hypersecretion in gastric disturbance of nervous origin, when there is present very little or no retardation of the motor function.

As the motor and resorptive phenomena of gastric digestion furnish us with the first principle laid down, which, for convenience' sake, may be called the physical principle of dietetics, in the same way the chemic phenomena of digestion furnish us with a second fundamental principle in dietetics, which may be called the chemic principle. This second principle may be roughly stated as follows: The administration of the albuminous, starchy, and saccharine articles of diet is to be regulated by the quantity of hydrochloric acid and ferments which the examination of the gastric contents reveals.

In the application of these two fundamental principles of dietetics, let us first consider those conditions characterized by a diminution in the production of hydrochloric acid and ferments and retardation of the motor function. To this group belong acute gastritis (frequently), chronic gastritis, certain forms of nervous dyspepsia, carcinoma ventriculi, and atony.

By selecting one of these conditions as a type for all, we may construct a paradigm of treatment which, with some slight inflections to meet certain conditions obtaining in each, we can apply with tolerable accuracy to all. Of the whole group, chronic gastritis offers by far the largest field for instruction in respect to dietetics.

The dietetics of chronic gastritis.—Whenever there is manifested a disposition to repeated attacks of acute gastritis, the condition known as chronic gastritis ultimately sets in. As chronic gastritis is associated with a progressive change in the interstitial elements

of the stomach and a diminution in the acid and peptonizing elements of the gastric juice, which progress *pari passu* with the interstitial changes, our dietetics should conform to the degree of chronicity attained by the disease.

In the very first onset of chronic gastritis, when the disturbances in the functions of the stomach are slight, any considerable departure from the normal rule of diet is unnecessary. When, however, flatulence, eructations, a sense of weight and pressure, diminution of appetite, a disinclination for meat and other albuminous articles of diet denote a lessened activity in the secretory and motor functions of the stomach, the moment has supervened when it becomes necessary to contract the promiscuity of the ordinary bill of fare into narrower limits. The symptoms, both subjective and objective, and especially the examination of the gastric contents, must guide us in our choice of a suitable regimen.

When there is any appreciable diminution in the quantity of free and combined hydrochloric acid, together with diminished activity of the rennet-principle, as evinced in the slower and inefficient coagulation of milk to which a few drops of the gastric juice have been added, the careful selection and preparation of the albuminous articles of food are indicated.

In testing for rennet, we best proceed by adding a few drops of the filtered gastric contents to about 5 c.cm. of milk and setting aside the same in a thermostat at a temperature of about 100° F. If rennet be present, the characteristic coagulation will supervene in ten or fifteen minutes.

In the choice of animal food it is best to avoid those tough and fibrous varieties of beef that require a longer period for their disintegration. For this reason also "smoked" articles of food should be eschewed. Our choice should be restricted to calves' brains, sweetbread, the more tender parts of the beef, boiled ham, boiled tongue, hare, chicken, fish, and oysters, as requiring less time for their digestion. Eggs in any form are also suitable.

The preparation of the food is a nice point in dietetics. As a rule, boiled, baked, and stewed meats require less time for their digestion than when fried. As to the hydrocarbons (vegetables and farinaceous articles of food), those containing the least proportion of cellulose, and consequently leaving little or no residuum after digestion, are to be preferred. Potatoes, cauliflower, peas, turnips, wheat-bread, rice, and spinach should receive preference. Cabbage and celery should be eschewed; likewise raw fruits, apples, pears, etc.

In the advanced stages of chronic gastritis, when there is marked change in the interstitial elements of the stomach, causing a partial obliteration of the glandular elements, with a concomitant diminution in the production of hydrochloric acid and ferments, the most careful preparation of the food is imperative. In this stage the inclination of the patient will lean toward the farinaceous articles of food. Vegetables, such as potatoes, carrots, spinach, etc., should be eaten in the form of *purée*.

As in this stage the stomach responds but feebly in the digestion of animal food, the most careful selection and preparation in this respect are indicated. Beef especially, if partaken of, should be chopped or hashed.

Patients with chronic gastritis manifest a desire for hot and piquant condiments, such as pepper, mustard, pickles, etc. As these articles only serve to irritate the mucous membrane, but no more than a very moderate indulgence in them is permissible. On the other hand, a liberal quantity of salt is indicated, as it furnishes the material out of which the gastric juice is elaborated, and thus contributes to the formation of hydrochloric acid, of which there is such a lack in chronic gastritis.

In order to guard against the possible denutrition that may occur, owing to the marked disinclination of the patient for albuminous articles of diet, we would do well to include in our regimen such vegetables as peas, beans, and lentils, which contain a large percentage of leguminose (vegetable albumin).[1]

This scheme of diet for chronic gastritis will amply satisfy all the demands to be filled in cases of atony. As in atony there is very little curtailment in the production of the gastric juice, we may abate somewhat the severe restrictions which in advanced stages of chronic gastritis we place upon the albuminous elements of diet.

In cases of acute gastritis the let-alone principle is the best; a two or three days' rest for the overtaxed organ is all that is required to meet the conditions.

A word may be said here respecting the inhibition of the gastric functions of nervous origin. As a rule, any attempt on the part of the physician to erase the discomforts of the patient suffering from nervous dyspepsia, by the regulation of the diet, will prove unavailing. It is surprising in these cases how the heaviest articles of diet are borne without the slightest discomfort, when the lighter articles of food, even milk, will be intolerable. The best rule of dietetics to be followed in these cases is to submit to the idiosyncrasies and inclinations of the patient.

It remains for us to consider in how far we can utilize the scheme of diet laid down for chronic gastritis in cases of carcinoma ventriculi.

[1] "That legumin constitutes not only a nutritious article of diet, but also suffices for all the demands of nutrition as respects the nitrogenous metamorphosis, is evinced by the experiments of Rubner on an adult in whom, by the administration of 520 grams of peas, all the demands necessary to preserve the equilibrium of the nitrogenous metamorphosis in the body were satisfied." Quoted from Munk, Uffelmann, Ernährung.

So long as the glandular apparatus exhibits a tolerably fair activity and the motor insufficiency is not so marked, we may with advantage employ a diet such as is indicated in advanced states of chronic gastritis. Milk, containing, as it does, a considerable percentage of albumin in a digestible form, will aid much to support the nutrition of the patient.

As the diminution in the production of hydrochloric acid progresses, the farinaceous articles of food will be found to agree best with the patient. As the early supervention of motor insufficiency is one of the characteristic features of carcinoma, the most scrupulous care in the preparation of the food is necessary. Alcohol in the form of cognac or port-wine is of service in supporting the nutrition of the patient. Fat, in the form of good butter, is not contraindicated. Cacao and chocolate because of their high nutritive value do good service.

When the ferments show a very slight or negative reaction we may render the food somewhat more digestible by the process of peptonization. Peptonized milk and gruel may in this way be administered to advantage.

With the Germans the preparations known as "Leguminosen" are held in high repute on account of their large nutritive value. I have myself, in my clinical experience abroad, seen very good results from the use of these preparations in diseases of the alimentary canal attended with impairment of nutrition.

When the motor power of the stomach exhibits a marked degree of impairment, the nutritive demands of the body must be satisfied by rectal alimentation. As the prognosis in carcinoma ventriculi leads to but one inevitable result, all that can be accomplished by alimentation is to support the nutrition, and in this way postpone the final catastrophe.

PHIMOSIS IN CHILDREN.

By WILLIAM MARTIN, M.D.,
of Bristol, Pa.

The only apology I shall offer for bringing this subject before the profession is that its frequency as a factor in children's diseases warrants it. Although no doubt thoroughly understood from all its various standpoints, I feel justified in emphasizing the necessity of more care in examination of children, when such conditions are the possible cause of many of the reflex symptoms from which these children suffer, and which seem so difficult for us to locate when called upon to prescribe.

Phimosis is looked upon as a natural condition in children, and to a certain extent it is so; but in the average practice there are, no doubt, many such apparently normal conditions that act as the sole cause of ills that are difficult to trace. It is generally said that if the glans can be partially uncovered during early infancy, the normal condition is assured later. In many cases this may be true. The time for operation is said to be when the preputial meatus is barely sufficiently large for purposes of urination; yet even in this condition it is not infrequently left to nature to perform what the knife should do, and I do not hesitate to say that many physicians do not think to examine for phimosis in infants, and only operate when compelled to do so by urgent symptoms or by the persuasions of the parents. That this is not the general practice of the profession, I feel assured; yet, to my knowledge, it is true with some. When we find the still more aggravated condition of "ballooning," or when the prepuce is practically a sac allowing only a dribbling of urine, operation is imperative. The intensity of symptoms depends upon the amount of phimosis. These may be divided into direct and reflex. The former are due to the local irritation, and are purely those confined to the part; the latter, or reflex, may be said to be almost innumerable and not confined to any particular part of the organism. Of the direct symptoms, the most important are those of an inflammatory nature, which in time may develop into a suppurative form. Accompanying this inflammation, and often the result of it, we have adhesions and vegetations. Of these two, the adhesions are the more constant features and on which the reflex symptoms depend to a great extent.

The more common reflex disturbances are those of the digestive apparatus. We have all the features of indigestion, both of the stomach and intestine, aggravated and rebellious to treatment when the true cause is not determined. Irritability is another feature, accompanied by sleeplessness. Sedatives and hypnotics seem to have no permanent effect, and are almost useless. The effect of urination is sometimes startling to the mother, and the crying and discomfort are so pronounced that it directs the attention to the real cause when otherwise not known. The more aggravated the phimosis, the more decided are the reflex disturbances. Convulsions, while not so common, are frequently the result of this condition. These, if not serious, are at least alarming. Dr. Sayre, of New York, published some time ago several cases of relaxation of the muscles of the back with curvature of the spine in children, caused by phimosis with adhesions, the local irritation being so great as to keep the child in a condition of almost constant priapism.

Some physicians have claimed that a condition similar to Pott's disease has been the result of these adhesions and has been mistaken for it, and which

has been cured by operation for this preputial condition.

Prolapsus ani frequently accompanies phimosis in children when there is preputial inflammation. Symptoms similating stone in the bladder have been traced to this condition. I feel confident that phimosis will aggravate the symptoms of any coexisting disease and be responsible for slow recovery in many cases. Without considering other possible reflex symptoms, I feel sure that those already enumerated will be sufficient to attract attention to the real necessity of examining each male child for this condition.

Passing from symptoms, the one evil most frequently the result of phimosis in its less decided type is masturbation, often the result of the local irritation in the small child, which he seeks to relieve by manipulation of the parts.

The statement that most cases will in time correct themselves is not altogether true, if by this the power of total retraction of the foreskin is meant; for if it were true, why would there be so many adults, with various venereal diseases, that come to the average physician's office who cannot retract the foreskin to any great extent? What does this condition mean when treatment is taken into consideration? I do not doubt that many will agree when I say that they have felt that had the family-physician done his duty to this man when a child, that he now would not be the disagreeable and difficult case to manage that he is. The proper treatment for a positive cure means the long-neglected operation in addition to the treatment for venereal disease.

Take another set of cases—those who consult the physician for real or fancied symptoms the result of masturbation. It is my experience that few, if any, can uncover the glans. There is nearly always local irritation, and often inflammation later as a result. Here, again, the early operation would have saved all this, and must be done now in order to cure. The sooner we come to pretty general circumcision, the better, physically and morally, will it be for coming adults.

As the operation is not an uncommon or difficult one, it is not necessary to enter into details. I wish to place myself on record as against the operation of simply slitting the prepuce in infants. This is of no practical value for permanent results. It will often suffice in adults, but in children, after union of the several parts, the condition is not much improved, and certainly the redundant prepuce is still there.

I will cite one case that I feel is quite typical of those of a more decided character:

The child was about two years of age, and the mother brought him to be treated for convulsions. These had become more frequent and of a more severe type a few weeks preceding this time, happening as often as every day or so. The physician in attendance had done everything in his power to remove this condition, but in vain, sedatives and every remedy tried only having temporary effect. The condition of phimosis could not have been suspected, as the mother had no suspicion of trouble there. The child was anemic, had lost in flesh, had no appetite, seemed very irritable, and was sleepless. The mother seemed to feel that the child was not destined to improve, and was willing to have anything done to benefit him. Hearing the history made me suspicious of the real cause, and an examination quickly confirmed my opinion. The prepuce was elongated and inflamed, and exuded a purulent discharge which was typical. Of course the parts were very sensitive, and the child objected with energy to any manipulation. Operation was suggested and acted upon immediately, after which, under proper care, the inflammation subsided and improvement began. The child entered upon a new state of being, as it were, losing all the old symptoms, and gaining in every way.

This case is not an unusual one, although many are of a less severe type. I feel sure, however, that they occur sufficiently often to warrant the one thing I plead for—careful examination of every male infant, and when necessary the proper remedy for each case of phimosis.

CREOSOTE CARBONATE IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

BY WILLIAM H. DUKEMAN, M.D.,
OF LOS ANGELES, CAL.

IN recommending any remedial agent in the treatment of tuberculosis of the lungs nowadays, one must do so with great reserve, and he should be fortified with such facts as will bear out his assertions. So many medicines have been recommended of late for this disease that even the nonskeptical are becoming shy, and are again falling back on the old empiric treatment. One by one each new remedy has fallen by the wayside for other newer ones to be tried that have come into the market. Of the latter creosote carbonate takes its place at the head of the list, and from reports so far I think we are justified in giving it a prominent place in the treatment of the disease. In many cases, however, the physician, the pharmacist, or the patient is more to blame that a remedy fails rather than that the remedy itself is of no value. First, we must have a pure drug, then a system in its administration, and finally a dutiful patient to carry out in detail, systematically and thoroughly, everything advised. Without these precautions well followed up, no one should expect to be able to combat so destructive a disease.

In creosote carbonate the manufacturing pharmacist has succeeded in giving us a preparation of

creosote that is nonpoisonous and nonirritant, and capable of being given in doses sufficiently large to produce a general systemic effect without any evil drawbacks. Creosote carbonate contains 92 per cent. of the purest beechwood-creosote chemically combined with 8 per cent. of carbon dioxid. The preparation is a limpid, oily-looking solution, and remains in perfect solution for some time. As age or conditions of weather grow on it, it partially separates, forming a thickened, cloudy mixture, which, however, is readily overcome by placing the bottle in a water-bath, keeping the water boiling until the temperature of the creosote carbonate reaches 210° F., which will sometimes take from twenty to thirty minutes or longer, when it will again resume its perfect normal solution, and remain so for a long time.

The remedy is expensive, retailing at $1 an ounce, by weight. In each of the several cases in which I have given the remedy a careful, systematic trial, every other detail in the treatment as to *diet* and *hygiene* being also thoroughly considered, I have had very marked improvement. These cases, however, were selected, none being in the far-advanced stage of the disease. The objective and subjective symptoms were well marked in all, and all had undergone other treatment by different physicians before coming under my care, as these patients were sent to this climate for their health. Two of these patients were under my care previously, at which time I then pursued an entirely different course of treatment. Both had previously taken creosote, from which they in both instances received very little benefit. While under treatment with creosote carbonate they have rapidly improved, and now continue to gain in weight. The advantage of creosote carbonate over the plain creosote is that it is completely assimilated, and can be given in much larges doses, and does not produce, in my experience, any ill effects. To prove that the drug is thoroughly assimilated, the skin and the breath eliminate the characteristic odor, and after long-continued use of the drug the urine presents the usual dark color and odor due to its presence in the urine.

The best mode of administering the drug is to drop it in the yolk of an egg, well-beaten up, and taken after each meal and before retiring at night. I also make use of the white of the egg by having it beaten up in a glass of milk, and taken between meals, with or without wine, as desired. I usually commence with 5 drop doses, and increase 1 drop a dose each day until the patient takes the amount necessary to produce the desired effect. When I arrive at the dose from which the patient himself notices marked improvement, I advise the continuous use of that dose for a week or two without increasing it, but then to again increase 1 drop a day for a week, or until marked signs of improvement again show themselves. The dose then remains uniform for some time. In this way I have had no reason as yet to give beyond 40 drops, although much larger doses have been given. I should not hesitate to increase the dose up to 60 drops should indications demand such a quantity.

As an illustration of the efficacy of this treatment I report the following case:

Mr. G., 33 years old, now a real-estate agent in his city, came under my care two years ago. There was a history of tuberculosis in the family. Two years before coming to Southern California he was afflicted with malarial fever, and about one year later with right-sided pneumonia. A gradual decline in health followed, and he states that after six months his physician advised a change of climate to Arizona, explaining to him that his left lung was also slightly involved. For four months previous to coming here, while in Arizona, he took 10-drop doses of creosote in capsules t. i. d. Under this treatment he did not improve. After coming here he continued the creosote for a short time, and the change of climate resulted in a slight improvement in his condition, but for a short time only. He then discontinued all treatment. It was not long, however, before he again commenced to fail in strength, and his health again broke down. It was at this time that he consulted me. I made a thorough examination, and found the upper portion of the right lung and the apex of the left lung involved, well advanced in what I would term the second stage of the disease. Night-sweats were causing a great drain; there were harassing cough and free expectoration, in which many bacilli were present. I at once advised a complete change in his habits, his diet, hygiene, etc., and put him on 10-drop doses of creosote three times daily, and good tonics. He improved a little for a time. He was then manager of a clothing-house, and in this occupation he was advised to make a change. He went into the real-estate business to do outdoor work. With all changes made for his benefit he did not improve, and about ten months ago he had another attack of pneumonia involving the middle lobe of the right lung. This came near taking him "from this earth of misery," as he expressed it, and it was a great struggle for him to gain strength enough to get about. He lost 20 odd pounds in weight. Under the best of care with the former treatment he made very little improvement in general health or in the condition of his lungs. I then put him on creosote carbonate, commencing with 5 drop doses in the yolk of an egg, 4 times daily, and increased the dose until he was taking 15 drops at a dose. In less than two weeks there was marked improvement, and from this time on he has gained now over 20 pounds, or his former weight. Later he took 20, then 30 drops at a dose, and at present is taking 40 drops, four times daily, and beyond this dose there has been no indication for an increase. In less than two months of the creosote-carbonate treatment he was able to resume work, and has been at active work every day since. He is gaining in strength and

weight daily, and is again encouraged and confident that he may live a long and useful life for the benefit of his wife and four children.

The other cases have done equally as well if not better, but were not in so precarious a condition.

The minor details of treatment I pursue in these cases would require too much space to relate, but I would state that the personal habits of every patient are thoroughly investigated in every detail and all faults corrected, so that the patient actually lives a new life.[1] The creosote carbonate I hold, as it were, in reserve, and do not give it promiscuously.

In conclusion it may be said that although this climate is no doubt a helpful agent in the treatment of patients with pulmonary tuberculosis in its earlier stages, yet under other treatment they do not always show very marked gain, or what gain there is in many instances not continued; but under the creosote-carbonate treatment the gain is of a more strengthening character and apparently will prove permanent.

CLINICAL MEMORANDUM.

A CASE OF MILIARY TUBERCULOSIS WITH UNUSUAL SYMPTOMS.

By CASPAR W. SHARPLES, M.D.,
OF SEATTLE, WASH.

A. B., a male, aged 24, some time in his early life had a mitral murmur which was not present at any time after he came under my observation. In 1891 he went to college in New Haven, taking while there a good deal of exercise. One day after some exertion he had hemoptysis, raising quite a large amount of blood. This was followed by three other copious attacks. Accompanying, or soon following, these hemorrhages, he had pneumonia involving the lower lobe of the right lung. In all he was confined to bed for three weeks. There was also diagnosticated at that time tuberculous involvement of the left apex, on account of which he was advised to go to some southern climate, which he did, and by travel and care his condition improved so much that he returned to Seattle to all intents and purposes well.

For the last year or so he worked very steadily on a newspaper as manager, putting in long hours, often late at night, and subjecting himself to more or less exposure. In the meantime he had attacks of iritis and ulcerative keratitis with quite persistent frontal and basilar headache accompanying and following, and it was on account of these that I first saw him in consultation with Dr. Dawson. The next time was for life-insurance purposes, on November 21, 1894, when I found evidences of very moderate consolidation of the apex of the left lung, on account of which I advised his rejection. Some time later he consulted his regular physician, who found some rise in temperature but with no regularity, and advised a change of climate and occupation.

On Friday, March 15, 1895, coming down town he faced a cold piercing wind. It was about 9 A.M. He then had hemoptysis to the extent of about a pint, so far as could be told from his description. On Saturday night following, his temperature was 104°, and Sunday morning it was about 103° all the forenoon. At 11 A.M. of that day he had a second hemorrhage of less than a teacupful. The temperature remained high through and after this. At this time my connection with the case began, on account of the illness of Dr. Dawson.

There are four points in the subsequent history of the case which are of more than ordinary interest, and it is on account of these that I venture to report a case of tuberculosis: 1, the physical signs and the expectorate; 2, the course of the temperature; 3, the action of the heart; 4, the nervous symptoms.

When I first saw the man the respiratory rate was 40, but this soon dropped to 32, remaining at about that rate till midnight of the following day, when it began to fall, coming down as low as 22 on the evening of the next day—the 19th—ranging from that to 26, from that time till the morning of the 22d, when it began to increase again; 28 was the lowest and 58 the highest reached after that period, averaging about 44 for the remainder of his illness. For two days just preceding his death he had a respiratory rhythm that very much resembled the Cheyne-Stokes respiration, which, however, was not constant, for at times he would breathe regularly. Dyspnea never was extreme.

Soon after the last hemorrhage, when I examined his chest there was no expansion at all on the left side, the right consequently expanding the more. Vocal resonance and fremitus were absent over most of the left lung. Percussion gave a very dull note over the left apex, and a flat one over the rest of the left chest, with some impairment over the lower part of the right lung (which, as I understand, had been the seat of the old pneumonia). Auscultation showed that no air was entering the lung excepting a small amount in the apex, where there was bronchial breathing, and at the border of the scapula midway up could be heard very high-pitched but not intense bronchial breathing. But this was all changed as suddenly as it no doubt came, for on Tuesday the 19th, about 11 A.M., he spat up the cast of the bronchial tubes depicted in the accompanying illustration. It appears to have been lodged in the primary bronchus, branching out immediately into the tubes next in size, the smallest pieces being formed in tubes a sixth in size. Assuming that it was formed as a result of the second hemorrhage, it lay where it was formed for 48 hours. The day when this was brought up marks the day of the slowest respiration. The percussion-note also changed. At the apex it remained the same, but over the rest of the lung the resonance was still impaired, but by no means to the extent that it had been. It continued to clear up for the next 24 hours, when it would have been classed as impaired resonance. In three days it again became duller, but never to that degree that characterizes a pneumonia. It so remained until his death. That of the right lung on March 24th became more extended. The respiratory sounds consisted of very intense bronchial breathing over the left apex with mucous râles, while they were not materially altered over other parts of the chest, except for the presence of subcrepitant and mucous râles, chiefly the latter

[1] See Article on "The Hygienic and Dietetic Treatment of Consumption, with Reference to Southern California Climate," by Wm. H. Dukeman, in New England Medical Monthly, Nov, 1895.

for the last few days. He coughed very little then, and rarely raised anything; consequently no stains were made.

The temperature on the 16th at night was 104°, and in the morning of the 17th 103°, being up to 104° by midnight, and this with a cold pack constantly around his chest and ice-bags on the outside of the packs. At 8 the next morning it was 104.4°, being in the evening only two-tenths of a degree higher, and so it ran for five days in spite of the constant application of packs and sponging; only once after sponging was his temperature reduced to 102.8°. On the 21st I applied ℥xij of guaiacol to the abdomen, at 9 o'clock in the forenoon, when the temperature was 104.4°, with very little effect. At 1 P.M., with a temperature 104 4°, I applied pulse was taken as 116, and a few minutes later 68. At noon it was 104, and fell to 60. Once while I was listening to his heart this change occurred. It came with a throb as though the heart had turned over on itself. Once or twice the heart maintained this slow rate for a day. It would change back as suddenly to the rapid rate as it had previously changed to the slow one, sometimes in five minutes, and sometimes not for hours. The rhythm during the times of slow and rapid action was good. The volume was very changeable, sometimes being fairly strong and at others very weak, almost imperceptible. The most marked drop was when the nervous symptoms were severely coming down from 140 to 70, or from 130 to 60, a clear change of rate in a second of 70 beats.

Bronchial cast. Natural size.

to his chest ℥xx, with the result of causing the temperature to drop to 99° in four hours, and it also caused a chill that lasted 30 minutes. In two hours more his temperature had again risen to 106°, when I used ℥x of the guaiacol. His temperature at midnight was 100.6°, with another chill less severe than the last. This was the last of the excessively high temperature that was continuous. It was often between 99° and 100° for a long time.

At some previous period he had a mitral systolic murmur, but nothing was present at this time but a pulmonary murmur. At my first visit the pulse was about 100 and regular, of very good volume, everything being considered. On the second day it was so in the morning, ranging from that down to 88, but gradually decreasing in strength till the 22d, or fifth day, when I ordered the infusion of digitalis in half-ounce doses every six hours, without making any marked impression. But on the morning of the 26th, the ninth day, the

The nervous symptoms were not constant. At first there were none, though he slept poorly from the first. On the sixth day he was in a semicomatose condition, or, as the nurse described it, a stupor-like sleep, all day long, followed by periods in which he talked in his sleep or moaned constantly. On the night of the tenth day he was awake all night, while on the next night he slept all night. On the thirteenth day the nurse reported a general convulsion lasting an hour, occurring at four A.M., and between eight and nine o'clock he had a severe tremor of the right side. There were four more convulsive seizures all of which were general for a few minutes, but for most of the time affected only the right side. One of these right-sided affairs I saw, which was like the others. The entire right side was in a state of clonic spasm, with more or less rigidity of the muscles. There was ptosis of the right side and partial paralysis of the face. This condition of the face passed away with the cessation of the other condition. Each of these

convulsive periods lasted three or four hours, and during them the heart was more irregular than at any other time, as was the delirium more marked. But after the three days in which the convulsions occurred his mind again became so clear that he seemed to realize all that was said and done. While jerking so much he perspired as though he had taken a large dose of pilocarpin.

On the seventeenth day he began to vomit, raising large quantities of a dark-colored liquid, far in excess of the amount he drank. It was to all appearances like beef-tea, and for thirty-six hours very offensive, being nearly fecal in odor. At the same time he retained nothing by the rectum. This continued until his death, except that the odor of the vomited matter was less offensive and the color changed to green.

There may be a question in regard to the diagnosis, the only possible diagnosis other than tuberculosis being catarrhal or croupous pneumonia. At first the temperature was higher than one would expect with tuberculosis, though it later ran the course of ordinary cases. When the lung was found so solid soon after the hemorrhage and associated with the high temperature, it seemed very probable that we had a pneumonia to deal with, and the more so on account of the high-pitched bronchial breathing posteriorly, but there were no râles over all this dull area; and practically, with the exception of that immediately after the hemorrhage, there was no cough. In fact, the only expectoration from the lung was that dependent on the hemorrhage. Again, had there been a croupous pneumonia involving these areas the lung would not have cleared up to so remarkable a degree just after the expectoration of this bronchial cast. Cough, too, is a prominent symptom of catarrhal pneumonia, and as a rule is present in cases of miliary tuberculosis of the lungs; but all of us have seen cases of miliary tuberculosis that resembled typhoid fever and were so diagnosticated before the autopsy showed the difference. I have seen one case of miliary tuberculosis that was practically without any cough.

To recount this history has been an easy task. To accurately explain the symptoms recounted is not so easy, and at any rate must be pure theory. However he may have acquired it, the man had four years ago a pulmonary tuberculosis, whose activity was checked by proper hygienic and climatic influences till this winter, when it again started up, and on top of it all came this sudden outbreak of miliary tubercles, ushered in by the hemorrhages. The apical bronchial breathing was due to the tuberculous inflammation at the apex. The high-pitched bronchial breathing posteriorly was due to the small amount of air passing by the plug formed in the bronchial tubes from the clotted blood. The absence of the breath-sounds and the flat percussion-note of the other areas of the lung were due to the air-supply having been cut off by this bronchial plug. The expectoration of this plug explains the reappearance of resonance and breath-sounds. In the râles there was no peculiarity.

The temperature was remarkably high, and no doubt depended simply on the tuberculous trouble.

The action of the heart was peculiar. The irregularities did not appear until three or four days after the man had had a couple of ounces of the infusion of digitalis a day. However, I do not think that the digitalis could be held accountable for this action, since its effect is to steady a heart, decrease its rate, and increase its force. This heart was not steadied, its rate was not permanently decreased, nor was the pulse fuller and stronger when this decrease in rate occurred; on the contrary, it was often weakened.

It seems possible or probable that there was a tuberculous inflammation around the base of the brain, and that the vagus nerve was either in its origin or course involved or irritated by this tuberculous deposit, and so the heart was made irregular. Yet there are shortcomings in such an idea as this that I cannot bridge over. The convulsive actions, general and unilateral, seem to have depended on tuberculous deposit at the base of the brain, as would also the ptosis and the inequality of the pupils. That these should have passed off is rather remarkable, though in nearly all text books we find a statement that cases that seem to be undoubted ones of tuberculous meningitis recover. So in this case there may have been only a limited deposit, and this the more so since so much more of the convulsive action was unilateral in place of general.

It is unfortunate not to have determined the cause of such a queer symptomatology.

MEDICAL PROGRESS.

A Case of Quintuplets.—STOKER (*Lancet*, No. 3767, p. 1164) has reported the case of a healthy woman, thirty-five years old, five feet one inch high, and of slight build, whom he delivered of five fetuses in the seventh month of pregnancy, none of the children surviving. The patient's mother had on two occasions given birth to twins. The woman herself had been married for six years and had borne four children at full term, having no difficulty in labor. When she came under observation she computed that she had been pregnant for six months, and had had her attention attracted to the unusually large size of her abdomen. She complained of fixed pain in the left side of the abdomen, on which side she thought she was larger. Pains set in with regularity and the labor lasted eight-and-three-quarters hours. After the rupture of the membranes the first child presented by the shoulder. Version was readily performed; the child was dead (recently). Examination after the birth of the first child disclosed the existence of more than one remaining fetus. The membranes protruded and became tense with each contraction. The presentation was a transverse one. In this case also there was little difficulty in effecting internal version. The child lived a couple of hours. The third fetus was also enclosed in a separate sac which had to be ruptured. The child presented by the breech and was delivered naturally, and lived for an hour. In the fourth case, too, the membranes had to be ruptured, and alarming hemorrhage ensued. Version was at once practised, but the chin became locked with that of the remaining fetus. There was some difficulty and considerable delay in freeing the children, though the extent of locking was not at any time formidable. The child was dead (recently). The fifth fetus presented by the head and was delivered naturally. It lived for half an hour. The placenta was delivered about five minutes after the birth of the last child, and consisted of two portions united by

a narrow isthmus. One, the smaller, had two cords attached centrally and close together; the other, and larger, had two cords attached in a similar way and one where it was joined to the isthmus. The organ appeared to be perfectly healthy. The cord of the fourth child was so short that it had to be ligated in the vagina. The children were all females, and much about the same size, making a total weight of eight pounds. The mother rallied quickly and got on well.

A Case of Spontaneous Gluteal Aneursym.—Delaup (*New Orleans Medical and Surgical Journal*, vol. xxiii, No. 5, p. 257) has reported the case of a strong, well-developed, seemingly healthy negro, 21 years old, who complained of a pulsating tumor of the right buttock, which disabled him from hard work. On examination an irregularly defined, fluctuating, elastic, pulsating tumor, unattended with inflammatory symptoms, was found situated about an inch above the right gluteal fold and nearer the median line. The patient's attention had first been attracted to his trouble about three years before, when he felt a vague, throbbing sensation and a feeling of heat about the affected region after severe muscular exertion. Some time later he noticed a swelling, which grew constantly and steadily. The expansion of the tumor was especially marked at its lower part, where the bulging was most prominent. The right thigh was larger than the left, and the upper and inner branches of the saphenous vein were much dilated and varicose. There was no diminution in the volume and force of the pulse of the right leg as compared with the corresponding vessels of the opposite side. On palpation, a distinct vibrating thrill could be felt over the lower part of the tumor, which imparted also a sense of heat and had the consistence of a cyst. Forcible digital pressure at the upper third of Nélaton's line restrained both pulsation and thrill, as did also pressure with the closed fist over the abdominal aorta. The patient stated that there had been a birthmark in the region of the tumor, and the skin in this situation was darker than elsewhere. A diagnosis of arterio-venous aneurysm was made and an external operation undertaken, which was, however, not successful, from failure to secure the gluteal artery. Extraperitoneal ligature of the internal iliac artery was proposed for a subsequent occasion, but the patient failed to put in an appearance at the proper time.

The Treatment of Invagination of the Bowel.—As the result of a careful study, Rydygier (*Deutsche Zeitschr. für Chirurgie*, B. xlii, H. 1, 2, p. 101) arrives at the conclusion that in cases of acute invagination of the bowel operation should at once be resorted to as soon as bloodless therapeutic measures, thoroughly employed, have proved fruitless. After celiotomy has been effected, disinvagination should be undertaken unless contraindicated by unusual difficulties. If the condition of the walls of the bowel, especially at the point of inversion, is suspicious, a strip of iodoform-gauze is to be passed to this situation or the affected part is to be placed external to the abdomen. When disinvagination is not feasible, resection of the invaginated portion is the least serious operative measure. Resection of the entire invagination is to be undertaken when the invaginating sheath presents decided changes in the walls and perforation is threatened. The establishment of an artificial anus and enteroanastomosis are usually not applicable in the treatment of acute invagination of the bowel; the former would only be allowable in case of profound collapse. In the treatment of chronic invagination bloodless measures should at first be employed repeatedly, but not over too long a period. The interval after an attack is the best time for the performance of a surgical operation for the relief of the invagination. After celiotomy has been done, disinvagination is to be attempted. In the event of its failure, resection of the invaginated portion is to be preferred over other operations.

Acute Yellow Atrophy of the Liver Following Torsion of the Pedicle of an Ovarian Cyst.—Stocker (*Centralbl. für Gynäkologie*, 1895, No. 45, p. 1181) has reported the case of a woman, 25 years old, in whom, six weeks after the birth of her first child, the existence of an ovarian cyst was detected, which gradually increased in size. Operation was agreed upon, but before the time set the patient was seized with symptoms of twisting of the pedicle, and the temperature rose slightly. Upon opening the abdomen at this time there presented a bluish-black cystic tumor as large as an adult head and attached to the ovary. Douglas' pouch contained a small quantity of hemorrhagic serum. The pedicle of the cyst was twisted four times upon itself and was also bluish-black in color. The tumor was readily removed, but death ensued three days after the operation, being preceded by restlessness, sleeplessness, and coma. The secretion of urine was scanty and examination disclosed the presence of albumin. Finally, toward the close, jaundice appeared. Upon postmortem examination no abnormality was found in the field of operation. The liver, however, was small, flabby, and of striking yellow color, punctated with numerous red spots. The kidneys were swollen. In the urine were found crystals of leucin and tyrosin.

Acute Glossitis due to Urticaria.—Hamilton (*Medical Press and Circular*, No. 2949, p. 494) has reported the case of a man, 42 years old, who, during a period of eight years, was from time to time seized with attacks in which the tongue became swollen and thickened and protruded an inch beyond the edge of the teeth, together with thickening and swelling of the submental region. There were also scattered spots of urticaria in various situations. The swelling usually subsided in a short time. On one occasion it was necessary to incise the tongue on the sides to prevent suffocation. The attacks could be controlled by the sucking of ice. The patient always felt a bald-like spot on his tongue in anticipation of the swelling. To induce sweating, sodium salicylate and an infusion of pilocarpus were administered, and the attacks were for a time controlled. The seizures sometimes, though not always, followed the eating of fish or oysters and even the smoking of a cigaret. They yielded most readily to subcutaneous injections of pilocarpin.

Blastomycetes in Sarcomata.—Roncali (*Centralbl. für Bakteriol. und Parasitenk.*, B. xviii, No. 14, 15, p. 432) relates that in five sarcomata, arising in three different situations and from different tissues, he found in vary-

ing numbers, but constantly, parasitic bodies, which he designates blastomycetes. These resemble the bodies already described as present in adeno-carcinomata of the ovary, and stain in a specific manner, resisting the action of alkalies and acids. The parasites may be located within and without the cells, and exceptionally within the nuclei. They multiply by budding, and may be encountered at an early stage—that is, free from membrane and containing an abundance of chromatic protoplasm; or even at an advanced stage—that is, with a thick membrane and containing slightly chromatic, variably granular protoplasm; or finally with or without such protoplasm as has lost the property of staining with anilin colors.

The Relation between Phagocytosis and Immunity.—As a result of an experimental investigation into the phenomena induced by corneal inoculation with anthrax-bacilli in susceptible and refractory animals, LIAKHOVETSKY (*Archives des Sciences Biologiques*, T. IV, No. 1, p. 42), while admitting the existence of phagocytosis in animals susceptible to anthrax and attributing to this condition an essential rôle in the process of establishing resistance in individuals inoculated with the virus of anthrax, contends that it must be recognized at the same time that immunity is far from being determined by phagocytosis solely. Phagocytosis represents only one of the general functions of the animal organism, quite independently of its susceptibility or resistance to anthrax, and the intensity of which is at times in inverse proportion to the degree of immunity.

Persistent Secretion of Gastric Juice.—BOAS (*Berliner klinische Wochenschrift*, 1895, No. 46, p. 1001) expresses the opinion that persistent secretion of gastric juice is in most cases not a definite disease, but an accompaniment or sequel of other well-recognized disorders. It many cases it is a result of motor insufficiency. Practically a distinction is to be made between a natural and an artificial excessive secretion of gastric juice. When motor insufficiency is recognized it should be treated, and with its disappearance the excessive secretion ceases. When pyloric stenosis acts as a cause, the two conditions can be relieved by operation.

A Young Mother.—GLEAVES (*Medical Record*, No. 1306, p. 715) has reported the case of a girl who gave birth to a well-formed child at the age of ten years and two months. The girl lacked the development of a woman, although she had menstruated regularly from the age of five years. The labor was short and uneventful, and two hours afterward the girl wanted to get up and dress. The mammary glands were undeveloped, and there was no secretion of milk. The infant lived a week, being nourished by its grandmother, who was nursing a child a few months old.

THERAPEUTIC NOTES.

Fatal Poisoning with Phenacetin.—KRÖNIG (*Berliner klinische Wochenschrift*, 1895, No. 46, p. 998) has reported the case of a boy, seventeen years old, who looked ill and depressed, and complained of pain referred to the occiput and also to the right hypochondrium. The face and body presented a dirty-yellow or ashy-gray color; the conjunctivæ were also yellowish, and the lips were cyanotic. The temperature was slightly elevated and pulse and respiration accelerated. The liver was a little enlarged and of increased consistency; the spleen considerably enlarged and of normal consistency. There was a purulent discharge from the right ear, with perforation of the tympanic membrane. A diagnosis of septicemia of undetermined origin had been made, but the peculiar aspect of the patient suggested some form of intoxication attended with blood-destruction. Examination of the blood disclosed, in addition to an increased number of white corpuscles (mononuclear equally with polynuclear), destructive changes in the red cells—a true erythrolysis. Upon further inquiry it was now learned that the patient had received for the relief of occipital pain five powders of phenacetin of 15 grains each, of which he was to take one during the attack, but not more than two in twenty-four hours. After taking the fifth powder, at the end of three weeks, the patient was seized with vomiting, and a bluish-gray color of the face and lips was observed. The bowels became loose and the urine assumed the color of chocolate. Finally the skin generally presented a yellowish hue, while the lips, ears, hands, and feet became cyanotic in color. Death took place, and the post-mortem examination confirmed the diagnosis of septicemia, together with universal methemoglobinuria. Spleen and liver presented pronounced brownish discoloration. The kidneys were enlarged and discolored and the seat of hemorrhage. The lower lobe of each lung was pneumonic. The gastric mucous membrane close to the pylorus was the seat of an irregular ulcer.

For Chronic Pyelitis.—

Take of

Benzoic acid	3 grains.
Theriaca	1½ " —M.

Two pills from two to four times a day.

Or, take of

Sodium benzoate . . .	℥j.
Sirup of raspberry . . .	f℥j.
Distilled water	f℥iij.—M.

A dessertspoonful three hours after each meal.

Or, take of

Venetian turpentine } Powdered camphor } .	āā ℥iss.
Extract of opium . . .	5 grains.
Extract of aconite-root . .	5 " —M.

Divide into twenty pills. One every eight hours with a small cup of decoction of uva ursa.

—ROBIN, *Sem. Méd.; Progrès Méd.*, No. 46.

For Whooping cough.

Take of

Infusion of belladonna-leaves (7½ grains) in distilled water	f℥vj.
Antipyrin	gr. xv.
Simple sirup	f℥j.—M.

A teaspoonful every two hours.

—ESCHLE, *Médicine Moderne*, No. 92.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 14, 1895.

RUPTURES OF THE PANCREAS AND THEIR RELATION TO PANCREATIC CYSTS.

DURING the past few years much information that is interesting and important has been added to our knowledge of the morbid changes occurring in the pancreas. Since the appearance of Fitz's Middleton-Goldsmith lectures acute inflammatory affections of this organ have received a good deal of attention. Little, however, has been written on rupture of the pancreas, and there is scarcely a surgical text-book that even alludes to the subject. Leith, of Edinburgh, in an excellent article which appeared recently in the *Lancet*, has thoroughly reviewed the subject and has contributed much valuable information to our knowledge of the relationship of pancreatic cysts to ruptures of the pancreas.

When one considers how thoroughly the pancreas is protected from traumatism, it is not surprising that rupture is so rare. The gland lies transversely across the posterior abdominal wall about on a level with the first lumbar vertebra, this corresponding very closely to a line drawn across the anterior abdominal wall about three inches above the umbilicus. Posteriorly, and from the sides, the pancreas is completely protected from injury by the bony framework of the chest, so that, for any violence to do injury to it, the point of impact must be over a very limited area in the epigastrium, and the force must be expended directly backward in the median line in order that the pancreas may be crushed between the object producing the violence and the unyielding vertebral column. Rupture of the pancreas seldom occurs unassociated with injury of some of the other abdominal viscera, owing to its being more or less protected by them. Leith has collected from the literature seven cases of rupture which terminated fatally a few hours after the injury. Two cases that he himself reports make a total of nine, and in only two of these was rupture of the gland found unassociated with injury of any other organ.

The symptoms following rupture are not at all well defined, and this is rather remarkable when one considers how definite and characteristic are the local signs in acute pancreatitis. The chief symptoms are collapse and shock, which come on almost immediately and are mainly due to bleeding. The hemorrhage takes place chiefly from the organs that are ruptured in addition to the pancreas, hemorrhage from the pancreas alone being very slight, unless the splenic artery and vein are torn. From a medicolegal standpoint it is interesting to know that in none of the fatal cases have there been any evidences of external injury.

Owing to the absence of any localized symptoms it is practically impossible to make a diagnosis with any degree of certainty. Leith claims that the pancreas can be thoroughly explored by the finger introduced through an incision three inches long to the left of the median line in the epigastric region, and that it is only by this means that we are able to make a positive diagnosis.

A fatal result need not necessarily follow rupture of the pancreas. At varying intervals after the occurrence of an injury received in the epigastrium, cystic tumors have been found to be present in this region, and the chief interest in Leith's article centers on the relation of these cysts to ruptures of the gland. Leith has collected from the literature seventeen cases of pancreatic cysts in which there was a history of traumatism. That all these cases were true pancreatic cysts it is impossible to say with certainty. A considerable number of them were undoubtedly such, as the fluid obtained by aspiration gave the reactions characteristic of the pancreatic juice when submitted to chemic analysis. The interval that elapsed after the

injury, before evidence of a cyst appeared in the epigastrium, varied a great deal. The shortest time was ten days and the longest eight years. The greater portion of them, however, appeared between two weeks and four months after the injury.

There have been many conjectures as to the mode of origin of these cysts. Kuhlenkampff held that the injury caused an inflammation of the gland-substance which led to a closure of the duct, with the consequent formation of a retention-cyst. Senn, although he at first held this view, found from experimental work on animals that obliteration of the main duct was not followed by much distention, and that really the part of the gland thus physiologically cut off from the main duct underwent simple atrophy. He then formulated three main hypotheses, as he considered that the cyst might be formed in various ways: (1) by hemorrhage into a preexisting pancreatic cyst; (2) by parenchymatous hemorrhage producing a cyst, followed by hemorrhage into the cyst-wall; and (3) by a dilatation of one of the bloodvessels of the pancreas. The second view seems to be the most probable one, and is supported by Cathcart, Lloyd, and Leith himself. Cathcart explains the process more fully, and holds that the laceration of the gland is followed by an extravasation of blood, which becomes mixed with secretions from the torn pancreatic ducts. The cystic tumor gradually increases in size owing to the secretion poured from the pancreatic ducts, and owing to the irritating character of the mixed fluid a capsule forms about it, so that a definite cystic tumor is formed.

There are several conditions that may simulate a traumatic pancreatic cyst very closely, as, for example, a pancreatic cyst of spontaneous origin. Spontaneous hemorrhage may take place into the substance of the gland, finally leading to rupture of some of the pancreatic ducts, with a consequent admixture of pancreatic juice with the extravasated blood, and leading to a cyst which it would be practically impossible to diagnosticate from one of traumatic origin. Again, as Fischer suggests, a spontaneous hemorrhage may occur in the neighborhood of the pancreas, and the effused blood, by pressure on the pancreas, lead to atrophy of this gland, with an escape of pancreatic juice from some of the opened ducts. Here it is obvious that the resemblance to a traumatic pancreatic cyst will be striking.

It is well recognized that the peritoneum in its various reflections, particularly the lesser omentum, is a fruitful source of cystic formation. Quite a number of other instances might be enumerated in which pathologic changes distinct from the pancreas simulate closely traumatic cysts of that organ, but sufficient has been said to show that it is extremely difficult to say positively whether we are dealing with a traumatic pancreatic cyst or with one of some other origin.

Chemic analysis of the contents of the cyst will aid materially in the diagnosis. Reactions characteristic of the pancreatic juice afford strong evidence in favor of the cyst being pancreatic in origin and of the traumatic variety, if there has been an injury. The failure to obtain the reaction for the pancreatic juice does not definitely exclude the condition, as it has been found that the contents of the cyst become materially altered after a time. Leith therefore suggests that the term "epigastric" rather than the term "pancreatic" be used for any cyst of doubtful origin which occupies the epigastric region.

In a case in which severe shock and collapse follow an injury in the epigastric region, the expectant plan of treatment, as absolute rest, and the application of ice to the abdomen, must be adopted unless a celiotomy be performed. If an exploratory incision be made and a rupture of the pancreas be found, Leith recommends the application of pressure to stop the hemorrhage, and then that the ruptured ends of the glands be coapted by means of sutures passed superficially through the capsule which is closely adherent to the gland-substance. This may result, however, in the collection of blood and pancreatic juice between the ruptured ends of the gland, leading finally to the production of a cyst. Senn has proposed to obviate this danger by first ligating both ends of the ruptured gland and then bringing them together by means of sutures as already indicated. He found that glands treated in this way healed rapidly without the formation of any cysts in the distal portion, as all portions of a gland thus physiogically separated from the rest of the gland undergo simple atrophy.

With regard to the treatment of pancreatic cysts, aspiration has not proved a success, as it has been found that the cyst almost invariably refills. Consequently at the present day celiotomy is the favorite treatment, the cyst being brought forward to the abdominal wall, incised, emptied, and drained. This was the method used in all the seventeen cases

Leith collected from the literature, in all of which except one it was successful. Drainage through an anterior incision is not thorough, and occasionally an obstinate fistula follows. Cathcart and Littlewood suggested that the cyst might be opened from behind. Leith, acting on this suggestion, experimented on the cadaver and found that it was not at all difficult to reach the tail of the pancreas and enter the lesser peritoneal cavity through a posterior incision three inches long on the outer side of the "left rectus," beginning above at the twelfth rib. As evidence in favor of the efficacy of this method, Gould had a case in which an obstinate fistula followed the opening of the cyst through the anterior incision, which, however, rapidly healed after making a counter-opening behind.

POPULAR SUPERSTITION AS TO PREMATURE BURIAL.

There are probably few more generally felt dreads than that of being buried before life is extinct; and this fear is fostered by a huge assortment of gruesome tales of alleged instances of this mishap. The well-known story, for instance, of the skeleton that was found on exhumation years after burial, with its bony hands full of its own hair, or the still more celebrated one that appears in some form in every language and literature, of the lady buried with a valuable ring who was brought to life by the rascally servant cutting her finger in order to remove the ring. The medical profession has never placed much confidence in these weird tales, although they are implicitly believed by the laity. An English newspaper has recently been trying to create sensation for the dull season by denouncing the profession for its skepticism and its failure to invent or agree upon some absolutely unmistakable sign, test, or proof of death. More than this, the accusation is made of intentional disbelief and of an endeavor to suppress and discourage belief in such stories, because they impeach the infallibility of medical diagnosis and death-certificates, and destroy public confidence in medical wisdom. According to this judgment the professional position may be thus expressed: "If we say a man is dead, he must be dead, and anyone who contradicts the statement tells an untruth."

The medical profession is denounced for never having taken the trouble to discover some absolute and reliable sign of death, which, it is argued, the profession does not care for, because people are always buried out of sight as soon as life is pronounced extinct, and they can never come back to expose the mistake. According to the same authority there is one absolute and infallible sign to which our noses would have led us long ago if we had but taken the trouble to follow them, and that is decomposition. Unfortunately for this assumption, however, this sign may appear in any part of the body to almost any extent, and involve a large part of either the external or the internal body-surface long before death, as the merest tyro knows who has seen a case of hospital-gangrene, of membranous dysentery, of phagedena, or pemphigus. It is, however, a striking commentary on the vagueness of the line that divides living from dead matter that, after all these centuries of investigation, no one, nay, no two, signs can be designated, the presence of which absolutely indicates death and the absence of which positively proves life.

Nevertheless we venture the statement that, except in war-time, cases of premature burial have been and are extremely rare, and will be practically impossible in the future. In the first place, nearly all the reports of such incidents are of a luridly sensational and dramatic character, and either highly improbable in themselves or utterly unsupported by adequate evidence.

In a recent conversation a prominent undertaker, a man of national reputation in his guild, stated that he had carefully studied this question for a number of years past, and through his editorial connection with two trade-journals he had either investigated personally or had caused to be investigated every report of premature burial in the United States for the past ten years. The reports were numerous and highly colored, but in every instance they were found upon examination on the spot to be absolutely devoid of adequate foundation—in short, to use his own expressive words, to be "pure fakes." From what he had been able to glean of the history of such occurrences in the past, he was inclined to regard the vast majority of such reports as mere folk-stories and legends.

So much for the external supporting evidence of the occurrence of premature burial. The statement is both an expert and a judicial one, for even the most vividly suspicious lay mind could hardly regard an undertaker as likely to be prejudiced or biased in his view of the question.

As to the internal evidence, in nearly all of these weird stories, the chief dramatic incident and the principal proof of their claim to consideration are found in active and often vigorous muscular movement on the part of the buried body, escape from the vault or tomb in some cases, and in others the discovery of the skeleton in an attitude indicative of struggling and efforts to escape. No touch is omitted that might heighten the imagined horrors of the situation and the agonies of the victim in his hopeless struggle. Now, a moment's consideration of the physiology of the situation will show that such occurrences are not only highly improbable, but practically impossible under the circumstances. All bodily activity depends upon combustion, and combustion requires abundance of oxygen. What are the mathematics of the situation? The amount of carbon dioxid given off by the average man in the process of quiet respiration is 0.6 cubic feet per hour, and whenever the proportion of this gas reaches 20 parts in 10,000, the air becomes highly injurious to life, and when a proportion of 40 parts per 10,000 is reached death rapidly ensues. Now, the internal dimensions of the average coffin or casket are about 6 feet long, by 2 feet wide, by 18 inches deep, rather under than over these measurements giving an air-space of 18 cubic feet, of which the body occupies at least one-third, leaving only 12 cubic feet of clear air-space. A proportion of only 40 parts per 10,000 equals $\frac{1}{250}$, which multiplied by 12 gives roughly $\frac{1}{20}$ cubic feet as the amount of carbon dioxid that would render the air in a coffin rapidly fatal to life. But at the rate of 0.6 cubic feet per hour it is evident that this density would be reached in one-twelfth of this time, viz., in five minutes.

The ordinary coffin, moreover, still retains the traces of an origin that has long been otherwise forgotten, in both its peculiar "coffin-shape" and its tightness, viz., the original Norse custom of burying the dead in boats or galleys sent out to sea at sunset; so that the amount of air that can penetrate its joints when the lid is screwed down is extremely small. The modern casket, it is true, has lost the peculiar shape, but has added to the tightness, and, indeed, ability to render it air-tight is an especial boast. Granting, however, the highly improbable condition that one-half the carbon dioxid diffuses through these chinks as fast as it is expired, we would still be confronted by the fact that the air in a coffin in which a breathing body is enclosed would be a rapidly fatal narcotic poison within ten minutes after the lid has been fastened down—in fact, before it can be lifted into the hearse. This has been actually proved in a most ghastly manner in several curious cases, most notably in Frederick the Great's attempt to kidnap a Scotch carpenter, of gigantic stature, for his celebrated Grenadier Guards. The man was entrapped by being given an order for a coffin for a fictitious individual, several inches shorter than himself. When completed it was declared too small, and the indignant carpenter was induced to lie down in it himself, to show that it even was larger than ordered. He was at once overpowered, the lid nailed down, and the coffin carried rapidly to a deserted house, where it was opened only to find that the poor fellow was asphyxiated, although he had been confined in the box for but a very short time.

It is popularly supposed that in cases of suspended animation or trance, when there is a danger of living burial, both breathing and the heart-action are entirely suspended, but the general opinion of physiologic authorities denies this entirely. Although breathing may be so light and shallow as to be really imperceptible by ordinary tests, yet some degree of respiration and oxidation must persist as long as life lasts. In the case of bears and other hibernating animals and their human descendants, trance-sleeping dervishes, while vital metabolism, with its oxidation, is reduced to a very low ebb for a considerable period, yet it does continue steadily, as the markedly reduced weight of both bears and men testifies. Whenever oxidation, vital or otherwise, occurs, carbon dioxid is formed; so that even admitting the additional possibility of the volume of respiration being diminished to one-fifth of the normal, we still find that within fifty minutes from the time of fastening down the coffin-lid the most vigorous subject would be asphyxiated, and within one-half the time comatose—in fact, long before the funeral-procession could reach the grave. Yet nearly every one of the legends dealing with premature burial depends for its possible veracity upon feats of muscular strength performed hours and days after burial. Even supposing, to take an extreme case, that a person in a state of temporary unconsciousness from a blow on the head were placed in an ordinary coffin and the lid screwed down, he would simply be narcotized by a rapid and painless process, and become unconscious from that cause within five minutes and die within fifteen or twenty minutes. There is, absolutely nothing about the

process to provoke a return to consciousness. On the contrary, many a man has been fatally poisoned by the gradual formation of this gas in his bedroom, not only during sleep, but while awake and engaged in reading or undressing. In the case we are considering we have to deal with not only carbon dioxid, but also several other more poisonous gases formed at the same time with it.

In fine, no one need have any fear of being buried alive as coffins are at present constructed, and even if placed in the casket before life is extinct no return to consciousness is possible, and, it may be added, it is not so much being buried alive that people dread as the waking up and finding themselves buried. That this fear is a genuine and widely spread one there can be no question. Indeed, one enterprising firm has actually devised an elaborate and expensive mechanism to prevent the possibility of such mishap. The casket is provided with air-holes and the lid is so fastened down that the lightest pressure from inside throws it off by means of springs. This, instead of being placed in contact with the earth, is enclosed in a vaulted steel chamber six feet high and nine feet long, so that the "resurrected" may not only stand up, but may also walk about in it. An abundant supply of air is provided by metallic ventilation-shafts that pass up at each end to some distance above the surface of the ground, while the same spring that throws off the coffin-lid presses an electric button connected by a wire with a large gong in the house of the sexton or care-taker; though whether it indicates the number of the grave and the nature of the occupant, and his wishes as to ice-water or towels, etc., we are not informed. The apparatus is most elaborate and costs some two-hundred or three-hundred dollars, and yet so vivid is the dread of being buried alive that a considerable sale is reported already by the inventors.

Should any of our patients still retain some nervous doubt on this head that cannot be dispelled by respiratory mathematics, there is yet another safeguard that we can assure them is absolute. This consists in the modern methods of preparing bodies for burial, commonly known as embalming. There are various processes, but all essentially consist in injecting into the veins a strong solution of some preservative, such as mercuric chlorid or sodium arsenite, with which the tissues are literally saturated, at least one-hundred times the fatal dose being used in every instance. Further than this, in a very ingenious method of preventing postmortem discoloration of the corpse, a long flexible canula is introduced, by one of the basilar veins, into the right auricle and the venous system is as completely emptied as possible by aspiration. In short, as a well-known embalmer has remarked, he would guarantee any of his subjects against coming to life again. "If by any chance they are not dead when they come into my hands, they are before I get through."

When to the sufficient safeguards of professional skill and watchful relatives can be added the proceedings of the embalmer and the air-tight coffin, the phantom of premature burial, which has walked so many centuries, ought to be laid at last in the limbo of exploded superstitions, where it really belongs.

EDITORIAL COMMENTS.

"Toxin," a Novel.—A remarkable novel has recently appeared written by the famous "Ouida." It is "an up-to-date" affair, and is called "Toxin," receiving its title from the fact that the toxin of diphtheria is employed by the villain to rid himself of his rival.

This in itself would hardly suffice to attract our attention, since novelists from time immemorial have made use of powerful and strange drugs to dispose of their victims, but the villain happens to be an experimental physiologist, who has been much engaged in scientific research, and so the authoress, who has evidently joined the antivivisectionists, makes a fierce attack not only on those who directly make use of the lower animals for experiment, but her words are levelled against scientists in general; her villain is taken as the type of the modern man of science. He is a man without humanity, cruel, unsympathetic, knowing no other law than his own necessity.

The man of science of to-day, according to "Ouida," uses his wisdom as tyrants in former ages used their brute force. Speaking of him she says:

"The infliction of death was nothing to him. He was used to kill as he was used to torture, with profound indifference, with no more hesitation than he ate or drank, or fulfilled any natural function of his body. To obtain knowledge, even the approach of knowledge, he would inflict the most agonizing and most endless suffering without a moment's doubt or regret."

From his boyhood upward he had always lived in the "hells" created by modern science, "wherein the bodies of animals suffer, the souls of men wither and perish."

And so the scientist does not hesitate to inject into the veins of his sleeping friend, who was recovering from diphtheria, the toxin of the disease instead of the antitoxin, for, as the writer states, "what was the man lying sleeping there to him? Only an organism like those which daily he broke up and destroyed and threw aside. His professional conscience, which would have shrunk from giving the disease, did not shrink from making death certain where it was merely possible. He did but add a stronger poison to that which nature had already poisoned."

According to "Ouida," for the scientist there is no such thing as crime or virtue, "only lesions of the brain and absence of temptation and opportunity." And so "there is no sanctity in life for the wise man; to kill a man who stood in his way was no more than to kill a mole." Of course, the modern man of science is a woman-hater; "he likes her best on the operating-table," and the villain in the story does not love the woman for whom he kills his rival, he merely wishes to have the satisfaction of dominating over her, and though she marries him it is a sort of hypnotic influence that forces her to it. All this brutality, according to the authoress, is engendered by the modern scientific laboratories, which "justify and make permissible any action, providing the catastrophe is deemed necessary to the operator." The doctor in the story is asked "if creatures to interest him must not suffer?" and he coolly replies "certainly;" and again he is asked if "there are not many men of science, many surgeons whose desire is to console, who care for the poor human material on which they work?" and the answer comes, "there are some, but they are not in the front ranks of their profession, nor will science ever owe them much."

What a libel on the noble men of science who have given their lives and their comfort, who have toiled day and night, that coming generations of men might have less sorrow among them. No mercy in science, no kindness, only egotistic brutality. Wrapping herself in the dignity of a prophetess, the antiscientist exclaims that "the time is nigh at hand when there will be no priests and kings but those of science, and beneath their feet the the nations will *grovel in terror* and *writhe in death*." We poor votaries of science had no idea that the reign of the kingdom of reason was so near at hand. We have been content to let others enjoy the good things of the earth while we starved and toiled; but if we are coming to our inheritance at last, and will have unlimited power, let us not worry any longer about the antivaccinists and the antivivisectionists. We will reserve them for the time when we can use them for experiment.

We would advise "Ouida" to organize an *antiscience* society, have the hands on the dial of progress turned back a few centuries, and any addition to our knowledge considered an offence punishable by death—the only form of cruelty permissible that of man to man. It is, indeed, a new teaching that would have us believe that all the strivings of a Claude Bernard, a Pasteur, a Virchow, and a Koch, served merely to gratify their own brutish, murderous tastes; that they were born murderers. No doubt Lombroso will be called in to show the stigmata of degeneracy in them, and the experimentalist will have his lineage traced back to the priests of the Inquisition, or perhaps to the cannibals, from whom it will be shown he inherited his terrible cruelty.

It is a very common idea among the laity that the surgeon loves to use his knife, and cares naught for the patient, and this popular idea has been taken hold of and fitted together with a few stock antivivisection-phrases, and applied by the writer to the whole of science. We hope that science will recover from this terrible attack.

Illegitimacy.—Thirty-five per cent. of the children born annually in the city of Vienna are illegimate. According to the official statement, out of 46,000 births 16,500 are born out of legal wedlock. How does this compare with other cities and countries? In *Virchow's Jahrsbericht* we find that in 1893 in the whole of Germany there were 1,928,270 births, of which 176,352 were illegitimate, or 9 15 per cent., and in ten years previously the annual average was 9.29 per cent.

Bertillon claims that in Paris 80,000 families are living in harmony, although in a legal sense the parents have not entered into marriage. In all France, in 1893, 8 per cent. of births were illegitimate. In separate provinces of Germany, Königsberg for instance, which is near the Russian frontier, 10 per cent. of the births are illegitimate, whereas the province Posen, with its population largely composed of Poles, returns 9 per cent. in the cities and 5 per cent. in the villages. Hamburg, a seaport, has a rate of 11 per cent., while Stuttgart, in the southern part of Germany, returns 20 per cent. of illegitimate births.

In European countries some attempt is made to procure accurate returns on this and other questions in vital statistics, and consequently the figures presented are in some accordance with the exact condition of affairs; but in the United States we have no way of knowing anything about the subject, although most large cities pretend to keep records relating to the matter. In Philadelphia the Registrar of Vital Statistics records every birth as illegitimate in which the name of the father is not given, but as some 10,000 births fail to be registered each year, and as undoubtedly many of these are illegitimate, the figures published have little or no value. Thus in the last ten years 2 per cent. of the births registered are set down as born out of wedlock, the rate varying but little each year. In New York City statistics on illegitimacy have only been collected since 1891, and are still very incomplete; the birth-returns are likewise lacking in completeness. In 1894, 1069 births were recorded as illegitimate, or 1.9 per cent. of the total number registered. Cincinnati records 1.4 per cent. In the States of Vermont, Massachusetts, Rhode Island, and Connecticut the rate is 1.3 per cent., but here also the returns are very defective.

While in the large cities of America the immorality of the inhabitants is not so great as in the capitals of Europe, yet if the facts could be ascertained; perhaps we would have little to boast of. The standing army is, of course, at the bottom of much of the licentiousness in continental Europe. Acccording to Töply, in the Austrian army 65 in every 1000 men are under treatment annually for venereal diseases, in the French army 43 in 1000, in the German army 37 in 1000. In Vienna out of every 1000 persons treated in civil hospitals and dispensaries, 132 are afflicted with venereal disease, at least 16 per cent. of this being syphilis. Computed on the whole population, we find that 65 persons in every 10,000, exclusive of the soldiery, are treated in the hospitals of Vienna for venereal trouble, and in Copenhagen, where physicians are obliged to report venereal disease as other contagious diseases are reported, Hjelt states that 25 of every 1000 inhabitants are affected. Illegitimacy is sometimes as common in distinctly agricultural districts as it is in military towns, as statistics gathered by Leffingwell show.

Although the question of illegitimacy is largely one of a social nature, yet medical men come in contact with it from the fact that children born out of wedlock are sup-

posed to have a higher death-rate than legitimately born children. The medical statistician, therefore, must recognize this condition as one of the possible causes of influencing health, but just why it should do so is another question. The desire for concealment on the part of the mother, the early abandonment of the infant, the poverty of the mother obliging her to work and leave her infant in the hands of strangers, or the farming out of the child, thus ridding herself of all responsibility—these and many other reasons are given for the increased rate of mortality. In France, where the unmarried mother is in a measure carefully looked after by the State, Blakie reports that illegitimate children thrive better than legitimate ones. Whether the State should take more pains to record illegal births or not is a matter for argument, many holding that the State has no right to subject the individual to such an inquiry. We have not been able to ascertain just why Vienna should lead the world in the greatest number of illegitimate births.

Advertising for Patients is considered highly unethical for individuals. Why is it not also the same for hospitals? Are right and wrong matters of the number of people committing the deed? If it is wrong for one physician to seek to get ahead of others by advertising, is it less wrong, nay, is it not much more wrong, for a club of physicians (for nowadays that is about all a "hospital" means) to seek by the same means to get ahead of all the rest of their fellows? Here is a copy of a widely scattered circular begging and singing for alms and patients—*arma virumque cano*, it might be punningly entitled:

The Board of Trustees of the —— —— of the city of —— strongly recommends the following advantages offered to the public:

Mill and factory owners, lodges, and beneficial associations can secure a bed at the —— —— for 365 days by paying $200, and upon averaging the days may have several patients in the hospital at the same time.

Subscription books can be obtained by working people of both sexes up to the age of fifty, subject to the regulations of the hospital, whereby, on paying an initiation fee of one dollar and monthly instalments of fifty cents, each subscriber may be treated in case of sickness entirely free of further charge. Heads of families and owners of factories should particularly recommend to their servants and employés to avail themselves of this excellent facility.

It will be noted that not a word is said as to discrimination. Like "saving grace," the institution is "free to all." Indeed, another part of the circular speaks warmly of the advantages "to the wealthier classes by the advantages of our home-like private rooms, whose number and comforts," etc., etc.

How very like a composite-store newspaper "ad." "A full line of all styles and qualities to suit every taste and pocketbook."

We also read: "While our annual expenses are increasing, our income remains far behind our requirements"—and this is just the condition of many of us—especially those of us who are not trustees, or who do not hold hospital positions. Ugh!

REVIEWS.

A TEXT BOOK ON NERVOUS DISEASES. By American Authors. Edited by FRANCIS X. DERCUM, A.M., M.D., PhD., Clinical Professor of Diseases of the Nervous System in the Jefferson Medical College of Philadelphia. With 341 engravings and 7 colored plates. 8vo, pp. 1056. Cloth, $6; leather, $7. Philadelphia: Lea Brothers & Co., 1895.

THERE are not wanting good books on nervous diseases, but in none has the subject received presentation similar to that given it in the volume under review. The text has been prepared by 22 collaborators, and is cast into 34 chapters. General Considerations are dealt with most admirably by Weir Mitchell and F. X. Dercum; and C. A. Oliver treats of the Examination of the Eye from the standpoint of the neurologist. General Morbid States of the Nervous System occupy 3 chapters, which include excellent articles on Neurasthenia by F. X. Dercum; Hysteria by J. H. Lloyd; Nervous Affections following Railway and Allied Injuries by P. C. Knapp. In successive chapters E. D. Fisher deals with Diathetic and Toxic Affections of the Nervous System; W. Osler with Diseases the Direct or Indirect Result of Infection; W. Sinkler with Choreiform Affections; C. W. Burr with Local Spasm and Occupation-spasm; L. C. Gray with Functional Tremors, Paralysis Agitans, and Epilepsy. General Diseases of the Brain are discussed in 2 chapters in an article on Arrested Development and Malformations by N. E. Brill, and in another on Diseases of the Membranes, Sinuses, and Brain-tissue by F. X. Dercum. C. K. Mills treats with clearness and fulness of the Anatomy of the Central Cortex and the Localization of its Functions. Focal Diseases of the Brain occupy 3 well-executed chapters: Hemorrhage, Embolism, and Thrombosis by C. L. Dana; Tumors by M. A. Starr; Cerebral Palsies of Childhood by F. X. Dercum. Diseases of the Spinal Cord are considered in 3 chapters: General Affections by J. H. Lloyd and by M. Prince; Systemic Affections by F. Peterson. Peterson also treats of Palsy and Multiple Cerebro-spinal Sclerosis. F. X. Dercum presents Paretic Dementia and Syphilis of the Nervous System; W. Sinkler Diseases of the Nerves. Diseases of the Cranial Nerves are considered in 2 chapters, one by G. E. de Schweinitz, the other by C. A. Herter. Herter also discusses Diseases of the Spinal Nerves and their Plexuses. G. W. Jacoby has written the chapter on the Diseases of the Muscles; J. Collins that on the Trophoneuroses; C. W. Burr that on Trophic Diseases Associated with Pathological Changes in the Thyroid Gland; J. C. Wilson that on Symptomatic Diseases; W. W. Keen that on the Surgery of the Brain, Spinal Cord, and Nerves; and G. W. Jacoby that on Neuro-electrotherapeutics.

It may thus be seen that the list of contributors is made up largely of those entitled to speak with authority by virtue of special study or investigation in diseases of the nervous system, and the work is to be viewed as a representative American production. Not only has the editor contributed a considerable number of articles—and they are among the best in the book—but the influence of his hand is appreciable on nearly every page. The book labors somewhat under the disadvantages

common to most composite works. The brilliancy of some of the articles exaggerates by contrast the weakness of others; while repetition of statement necessitates sacrifice of space, and diversity of opinion is calculated to confuse rather than to enlighten the ordinary reader. The illustrations are numerous and for the most part well executed; many are original.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF SKIN-DISEASES. By ARTHUR VAN HARLINGEN, Ph. B. (Yale), M.D., Emeritus Professor of Dermatology in the Philadelphia Polyclinic, Dermatologist to the Howard Hospital. Third edition, enlarged and revised, with sixty illustrations, several of which are in color. Philadelphia: P. Blakiston, Son & Co., 1895.

DR. VAN HARLINGEN'S *Textbook of Skin-Diseases* has been before the profession for several years, and that it has in a comparatively short time reached a third edition is good evidence of its popularity as a student's guide, and a work of ready reference for the physician.

As stated in the preface, the book has been considerably enlarged by the addition of new matter, both in the text and in many foot-notes, and an examination shows that a number of the original articles have been given a thorough revision. Several of the rarer skin-diseases are considered for the first time, and, although the accounts are very brief, sources of more extended information are pointed out to the interested reader. A variety of new illustrations has also been introduced.

In the present edition the author has retained the alphabetic arrangement of subjects, "with the object of ready reference in view," and no doubt also because there was no system of classification that fully met the requirements.

After some experience and a good deal of reflection on this method, the dictionary-method, of writing books, we are forced to believe that the plan is a bad one, and that an imperfect classification is better than none at all.

It seems that a classification, Hebra's for example, gives the student a more coherent idea of the nature of skin-diseases, whereas the alphabetic plan presents a large mass of unconnected facts that are difficult to remember and properly associate. Moreover, on the purely literary side, this kind of an arrangement lacks dignity and gives an impression of scrappiness that does not really exist. We sincerely believe that Dr. Van Harlingen would do himself only real justice if in another edition he would rearrange his book in accordance with some well-matured system of classification.

We have no fault to find with the manner in which Dr. Van Harlingen has dealt with the various subjects contained in the book. As would naturally be expected from the author, his views are sound, his information extensive, and in matters of practical detail the hand of the experienced physician is everywhere visible.

In reading this book it should be always borne in mind, as explicitly stated by the author, that it makes no pretensions to be considered a comprehensive treatise on dermatology, but rather that it is a handy volume for the physician and student; and consequently the pathology of cutaneous affections is but briefly considered, if at all, and unsettled questions in nosology and etiology, and other matters of interest to the specialist, receive but little notice. The illustrations in black and white are for the most part good, but the chromolithographs are not especially helpful. Although we must repeat that the alphabetic arrangement of the subjects is to be regretted, the work is a mine of carefully collected practical information, and will prove a valuable desk-companion to all who come in contact with skin-diseases.

1. BLOOD SERUM THERAPY AND ANTITOXINS. By GEORGE E. KRIEGER, M.D. With illustrations. Chicago: E. H. Colegrove & Co., 1895.

2. IMMUNITY, PROTECTIVE INOCULATIONS IN INFECTIOUS DISEASES, AND SERUM-THERAPY. By GEORGE M. STERNBERG, M.D., LL.D., Surgeon-General, U.S. Army. New York: William Wood & Co., 1895.

FEW things illustrate more forcibly the stupendous zeal and activity of the present age than an inspection of the bibliography of antitoxins and immunity. In the short space of six years a literature of vast proportions has accumulated, to master which few have the necessary opportunity or leisure. The majority of physicians are compelled to obtain their information at second hand, and it is for their benefit chiefly that the books before the reviewer are written.

The little book of DR. KRIEGER covers very well the salient points on the subject of blood-serum therapy, dealing, as it does, with the theoretic questions, as well as with the practical applications of the new therapy in the two best-studied diseases, diphtheria and tetanus. Although the diction is somewhat quaint and "foreign," the matter is clearly presented, and the book warrants a careful perusal.

The work of SURGEON-GENERAL STERNBERG is divided into two parts. The first treats of immunity, the second of protective inoculation and serum-therapy. In the first part natural and acquired immunity are separately considered. The former, the author believes, is due to "a germicidal substance present in the blood-serum which has its origin (chiefly at least) in the leukocytes and is soluble only in an alkaline medium. Local infection is usually resisted by an afflux of leukocytes to the point of invasion, but phagocytosis is a factor of secondary importance in resisting parasitic invasion." Regarding the action of antitoxins in acquired immunity, the author does not give his adherence to either of the opposing schools, that represented by Buchner, which teaches that antitoxins are modified toxins and act by rendering the body-cells immune to the toxin, or that of which Behring and Roux are the chief exponents, and according to which the antitoxins are produced by the body-cells and act, as Behring at least maintains, by neutralizing the toxins directly. The source and method of production of the antitoxins in the animal body and their mode of action are still undetermined.

In the second part the author deals with the infectious diseases in which experimental immunity has been produced in man and animals, or in which attempts at its production have been made. Of human diseases, cholera, diphtheria, hydrophobia, influenza, pneumonia, smallpox, streptococcus-infection, tetanus, tuberculosis, typhoid fever, and yellow fever are discussed.

The volume will prove very useful to everyone interested in the absorbing subjects of immunity and serumtherapy, and it is rendered doubly valuable by the extended bibliography appended to each chapter.

Medical Gynecology. A Treatise on the Diseases of Women from the Standpoint of the Physician. By Alexander J. C. Skene, M.D., Professor of Gynecology in the Long Island College Hospital, Brooklyn, New York, etc., etc., etc. With illustrations. Pp. 529. New York: D. Appleton & Co., 1895.

In these days, when the cry is almost entirely for surgical interference in the pathologic conditions of womankind, a book of the nature of the present volume carries with it an agreeable freshness that is more than attractive. It must be evident to all that but a very limited number of physicians are so qualified by training and convenient environment as to become practical abdominal and pelvic surgeons, while it is incumbent upon all who are actively engaged in the practice of medicine to be fully acquainted with the methods of diagnosis and the medical treatment of the minor gynecologic complaints, and to be so well prepared to recognize the initial stages of the graver conditions as to summon the skilled abdominal surgeon before the time for operative procedure has passed. To all such is Dr. Skene's admirable work most cordially recommended. The book is especially rich in the description of methods of treatment of neurasthenia and other nervous affections to which so large a proportion of women are heirs. Unfortunately, however, as we think, by far too much prominence is assigned the subject of electricity in gynecologic practice, in which, as is now largely admitted even by its former most earnest advocates, it has but a limited scope. Especially would we recommend, on the other hand, a careful study of the section on the application of massage to gynecologic conditions, a subject that is comparatively but little known, and the immense value of which is beginning to be recognized. Diet in gynecology and a suitable regimen for aged women are also ably disposed of. The illustrations, while few in number, as would be expected from the nature of the subject-matter, are good, and the general arrangement of the book is excellent.

CORRESPONDENCE.

THE VIVISECTION-CONTROVERSY.

To the Editor of The Medical News,

Sir: As a subscriber to The Medical News, I have always found its columns both entertaining and profitable; but I must confess to a little disappointment in your long editorial of Nov. 30th, and its references to myself. I venture, therefore, to ask the courtesy of your columns, less for reply to your criticisms than for explanation of apparent inconsistencies.

It does not seem to me, in the first place, that your summary of my paper concerning the manifesto of the Harvard professors is as fairly set forth as the facts would warrant. Permit me to state them.

On the 13th of last July there appeared in the Boston *Transcript* a long article "Concerning Vivisection," signed by the Assistant Professor of Physiology in Harvard Medical School, and drawn up at the suggestion of five other leading professors. It distinctly claimed to be "a plain statement of *the whole truth*" regarding experimentation on living animals; and, referring to the occasional necessity of painful investigations, it went out of the way to make the strange assertion that "none such have been made in the Harvard Medical School within our knowledge."

Now this statement was either true—or untrue. I doubted its accuracy, and in the columns of the *Transcript* of July 22, I called attention to this most peculiar assertion. Surely a mistake had been made? But no explanation came. The oracles had spoken; the public must implicitly believe. Confronted with a statement like this, made by men of the highest scientific reputation, what is one's duty simply as a lover of truth? To accept it? To be silent? I must not decide for others; but, to me, it seemed that refutation was demanded in the interests of Science herself. You say, sir, that I have "given the lie" to men whose "names and work are well known in all the scientific world." You are mistaken; I am not given to overstepping thus the amenities of discussion. But I brought out "in bold relief some of the more or less shocking features of the experiments" in Harvard Medical School, without at the same time touching either the object of the investigation or the results obtained. I admit it. Pray, what had these to do with the one question of the *painlessness* of the vivisections? How can there be any "shocking features" to *painless* research? The truth is, somebody blundered, and was too proud to confess it, even when confronted with the proof. That may be taken as fidelity to science; everyone must judge for himself. At all events it is not my ideal of what truth demands.

Your comments upon the preliminary report of the American Humane Association would be more satisfactory if they could have been based upon the complete report, now in the printer's hands. I do not think that any scientific man, physician or otherwise, need be ashamed to find his name—where I place my own—beneath that of Herbert Spencer, in favor of vivisection regulated by law.

And, finally, permit me gently to protest against being classified by you or anybody else as an "antivivisectionist." Is there no middle ground within the scope of imagination? Cannot a man be temperate without being a teetotaler? It is fifteen years since I first wrote on this subject, and never a line that denied the utility or the rightfulness of vivisection, *per se*. But what I do abhor and execrate is the licence, cruelty, and abuse that I have seen for myself. Does The Medical News deny that abuse exists? I wish denial were possible. Let me cite admission by a writer who has most accurately represented my views regarding this whole question. It is from a work that I have long admired for its bold and reverent treatment of one of the deepest problems with which the human intellect can engage; a work which I believe will be better known a century hence than it is to-day: "If," he says, with significant caution, "if a very limited use of vivisection-experiment is necessary for scientific and medical progress, *it must be regulated by law*, carried out with jealous guarding against excess and against suffering, and the maimed animals painlessly killed when the experiment is complete. The

practice carried on by conceited jackanapes to prove over again already ascertained results, *to minister to egotism*, for didactic purposes, *these are not necessary, and must be forbidden.*"

There, sir, is a fair expression of my sentiments regarding vivisection. I have never denounced abuse with greater vigor, nor asked for more stringent regulation than is here demanded.

I am, sir, etc.,

ALBERT LEFFINGWELL, M.D.

CAMBRIDGE, December 3, 1895.

—

We regret that we classed Dr. Leffingwell among the prohibitive antivivisectionists, as this was an error. But we do not think he allows sufficient credit for the scientific beneficence that has come through vivisection. He seems to be somewhat blinded to this aspect—to the uses—by the fervor of his indignation against the abuses.

In addition to the foregoing letter, we have received others—one protesting that for teaching physiology vivisection is highly necessary; another that the methods of obtaining information by the Humane Association were not thorough, etc. It seems to be a difficult matter for men to consider this question dispassionately, and the extremes of opinion of most worthy people tend to make one despair of the reasonableness of *homo*, and of his ability to ascertain truth. It is especially difficult to preserve one's aplomb under such criminal logic and falsetto screams as *Life* and "Ouida" treat us to. The judicial quality of mind is in danger of being lost, and one feels tempted to roar one's self hoarse with the anti-anti-vivisectionists. But neither would this do any good. If we are men we must seek the truth, and all of that partial truth to be found in partisans. Undoubtedly abuses, deplorable abuses, have been perpetrated by vivisectors—and just as undoubtedly the antivivisectors have been guilty of excess, *e. g.*, in trying to do away with the use instead of the abuse. We do not think that vivisection for didactic purposes or for acquiring operative skill would, uncontrolled by legislation, yield probable good results to outweigh the probable evil results. Assuredly the modern sentiment of kindness to animals is one of the best things gained by civilization. Just as certainly have there been splendid gains in the relief of human suffering and disease that were impossible to reach except through vivisection. The task of wise and good men is to preserve and carry on both gains. One need not scream with the anti's nor roar with the anti-anti's. Reasonable men know the excellence of moderation.

There is much woful confusion of ideas as to what is really meant by vivisection. It is very evident that the disputants often set up their own imaginative concepts, and viewing them as realities fight for or against them, *vi et armis*. The larger number of vivisection-experiments consist simply in the painless death of animals. They are not *vivi-sections* at all, but *mortui-sections*.

Professor Wilder has also devised two excellent words which should come into general use, because they make clear a necessary distinction. They are *callisection*, or *painless vivisection*, and *sentisection, i. e., painful vivisection, or that without the use of anesthetics*. No meat-eater, except the most egregious ranter, can object to postmortem dissection. No sensible person can object to callisection for proper purposes. The only question remaining pertains to sentisection, and if silly controversialists would stifle their stupid frenzies and look at facts, they would soon find that decent people differ but little about the matter, and that there has been a very childish quarrel, of which both sides should be ashamed.

Now antivivisectionists are not vegetarians, but generally meat-eaters. They do not, therefore, object to the death of animals, and if we may judge, we fear they are far more critical of the manner of death in laboratories than in slaughter-houses. They even wear—as we suppose—woolen clothing, although there is seldom greater suffering possible than often exists in the exposure of freshly-sheared sheep. There is more suffering in the transfer of a single shipment of cattle from their Western plains to England than has ever taken place in all the laboratories of all the world. All of which by no means justifies the—comparatively few—horrible abuses of scientific vivisection of which men have been guilty, who have clothed the wolf of their vanity and ambition with the sheepskin of pseudo-science. Nor can we forget that within a year a physician, a leader in science, if not in medicine, has in reference to vivisection publicly uttered these infamous words: "I certainly think that children and everyone ought to be familiarized with the sight of blood, the pangs of disease, and the solemn event of dying." It is such atrocities as this, few and non-representative as they are, that offset the silly and stupid ravings of shortsighted sentimentalism on the part of lay-enthusiasts. Let us have done with both sorts of egregious extremists.—[EDITOR, MEDICAL NEWS.

TOXIC EFFECTS FROM ACETANILID APPLIED TOPICALLY.

To the Editor of THE MEDICAL NEWS,

SIR: I have read with interest, in THE NEWS of November 16, 1895, the Progress-note upon "Toxic Effects from Acetanilid Applied Topically." A short time ago I was called to see a child, five months of age, that was extremely cyanosed, with a pulse of seventy-five beats to the minute. Nothing else abnormal could be discovered. The child did not seem to be in distress in any way, but quiet and comfortable. No medicine had been given internally. The heart was normal excepting for its slowness, and at birth no irregularity was noticed. Upon close inquiry it was found that the mother had obtained from a neighbor a white powder, which proved to be acetanilid, and had applied this freely to the groins of the child, which were badly irritated. The following day the cyanosis appeared. Upon the withdrawal of the drug the pulse and color became normal.

Respectfully,

J. A. BROBERG.

DELAVAN, MINN.

THE INDEX MEDICUS.

To the Editor of THE MEDICAL NEWS,

SIR: We ask permission to state that the plan proposed for continuing the publication of the *Index Medicus* having been successful, no more subscriptions can be received.

JOHN S. BILLINGS, M.D.,
ROBERT FLETCHER, M.D.,
Editors.

WASHINGTON, D. C., Nov. 27, 1895.

SOCIETY PROCEEDINGS.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in Washington, D. C., November 12, 13, and 14, 1895.

(Concluded from page 643).

Dr. A. Vander Veer, of Albany, N. Y., read a

REPORT OF SEVEN CASES OF ABDOMINAL SURGERY IN WHICH THE MURPHY BUTTON WAS APPLIED.

The first case was one in which an anastomosis between the upper end of the jejunum and the greater curvature of the stomach was made for carcinoma of the pyloric extremity of the stomach by means of a medium-sized Murphy button. The patient was comfortable after the operation, but died from exhaustion on the third day.

The second case was one of carcinoma of the sigmoid flexure, removal and end-to-end anastomosis. The operation consisted in removal of a mass three inches in length in connection with the sigmoid flexure, and an anastomosis of the large intestine by means of the button. The cause of constriction was found to be carcinoma. The patient died from exhaustion on the eleventh day, but was much exhausted and emaciated previous to operation.

The third case was one of removal of stones from the gall-bladder, using a long drainage-tube button. In this case recovery ensued.

The fourth case was one of removal of eight inches of the small intestine, together with a papillomatous ovarian cyst. End-to-end anastomosis was effected with the button and recovery followed.

In the fifth case an anastomosis was established between the gall bladder and the small intestine, with recovery.

In the sixth case operation revealed a tumor the size of a cocoanut in the immediate vicinity of umbilicus, a portion the size of a silver dollar implicating the umbilicus and being in a gangrenous condition. On making an incision there was found a strangulated hernia and many old and firm adhesions. The peritoneum was intensely congested and very dark in color. A loop of small intestines was included in the tumor and gangrenous for a length of ten inches. The vessels in the mesentery were secured and this portion of the intestine was excised. A Murphy button was used for end-to-end anastomosis. The button was passed thirteen days after the operation, and was followed by a large movement of the bowels. Uninterrupted recovery ensued.

In the seventh case a diagnosis of biliary calculi was made. The usual incision was made for exploration of the gall-bladder, which was found to contain about two ounces of bile. Through the walls of the viscus and down into the cystic duct could be felt a number of small calculi. There were some adhesions. The long drainage-tube button was introduced into the fundus of the bladder and the wound closed, after a careful examination for any possible carcinomatous mass, which, however, was not found to be present; the patient was then placed in bed. The use of the button in this case was regarded as a saving of time, leaving the patient in good condition for removal of the gall-stones later. Several days afterward the attending physician removed five irregularly shaped calculi, which Dr. Vander Veer exhibited. At this time the patient began to show marked symptoms of cerebral anemia, with delirium, finally passing into a comatose state and death resulting.

Dr. Vander Veer said that the cases reported, although not many, yet covered a field in which the Murphy button might be made use of readily and easily and with satisfactory results. The Murphy button will not answer for every lesion involving the intestinal tract; but it surely has its sphere of usefulness, as it is clean, easily handled, and saves the patient from a much longer operation, when time alone is the great desideratum.

Dr. H. H. Grant, of Louisville, followed with a paper entitled

INTESTINAL RESECTION AND ANASTOMOSIS.

He said that there had always been a division of judgment upon the question of immediate suture in acute obstruction or injury requiring resection of the intestine which even the improvements in technic and means of aid in operative work have not adjusted. What it is intended to do with the Murphy button it does well; but too often it does what is not intended, and disaster and death result. There is abundant evidence that it becomes a foreign body; that it occasions spreading necrosis, which involves the peritoneal coat; that recontraction takes place after lateral anastomosis; that fatal results are frequently directly attributable to its use, beside other less important objections.

Lateral anastomosis is now beyond all question the most acceptable method of resection in the continuity of the bowel, if we exclude the button. It is best accomplished by direct suture, and direct suture is difficult of execution except in very skilled hands. In order to facilitate direct suture, Dr. Grant presented a device for clamping opposing surfaces of the bowel, cutting off fenestra between them, and retaining them so opposed until the suture can be completed. He then demonstrated the *modus operandi* of this device.

He had experimentally used the clamp sixteen times with fourteen consecutive recoveries, but had had but one opportunity to use it in practice. On May 25th he operated on Mrs. E., aged 53 years, who had a fecal fistula at the right femoral opening, the result of a strangulated hernia, operated on eight months before. An incision was made just above Poupart's ligament, near the fistulous opening. The fingers easily liberated the intestine, which presented an opening occupying half its lateral surface and as large as a quarter of a dollar. The mesentery was greatly thickened; the distal segment of the bowel was reduced in size, the proximal dilated at the site of the fistula. The intestine was resected for a distance of about four inches; the blades of the clamp were applied opposite the mesenteric borders of each segment, and the anastomosis made in the manner described. After suturing, the communication between the opposing surfaces was found ample. The cut ends were then invaginated and the anastomosis returned; the abdominal wall closed with silkworm-gut sutures; the site of the fistula curetted and filled with iodoform-gauze; and the patient put back to bed in forty-

two minutes. There was very little shock. At the present time the patient is well.

The advantages of this method over the other aids, except the button, are manifest. Not only does it do away with the foreign body, but it makes an opening three or four inches long at the fenestra. It is as easily accomplished and takes less time. It is no more difficult to use than is the button, but the operation cannot be so quickly completed, as the invagination of the ends is not necessary after the end-to-end approximation with the button. The clamp merely makes direct suture easy to an ordinarily skilled hand.

DR. C. A. L. REED said experience would establish the fact that the Murphy button ought not to be used in approximation of the large intestine, for the reason that the intestinal contents were not sufficiently liquid to pass through the small opening in the button. In the small intestine the liquid contents will pass through the opening in the button and the approximation is satisfactorily accomplished. Dr. Reed reported a case of resection of the sigmoid flexure for malignant disease (which terminated fatally) in substantiation of his remarks, the anastomosis being made by means of the Murphy button. He commended the device presented by Dr. Grant, and, although he preferred the end-to-end procedure, he would try the device in the next case in which he performed lateral anastomosis. Cholecystenterostomy by means of the Murphy button was one of the easiest, neatest, and altogether most satisfactory operations known to surgery.

DR. JOSEPH M. MATHEWS, of Louisville, said that he had taken occasion more than once to call attention to the difficulty that attends the diagnosis of tumor of any kind in the sigmoid flexure. Time and again he had been mistaken, as he believed others had, in supposing that he had malignant tumor of the sigmoid when he had not, and supposing, on the other hand, that he did not have this when he really did. A few years ago a patient was brought to him from an adjoining State, and from evidence outside of palpation he believed that the man had malignant trouble of the sigmoid flexure. A few days thereafter he was taken to Chicago, was examined by a very eminent surgeon, who stated positively that there was no tumor of any kind in the flexure, and advised the patient to go home and go to work. In less than a week the man was dead. An autopsy revealed carcinoma of the sigmoid flexure. His reasons for opposing resection of the sigmoid and making anastomosis by the Murphy button were in substance the same as Dr. Reed's. Carcinoma in the sigmoid flexure was not only usually attended with systemic infection, but there is an involvement of other organs and tissues of the body. He would therefore ask, could a man live any longer after a surgeon had removed the tumor than he would if it was left untouched? Granting that there is total obstruction, would it not be better to perform colotomy and let the man live out his allotted days with carcinoma in a more pleasant way than he would if an operation were done? In lieu of this, it had occurred to him that the plan suggested by Dr. Bacon, of Chicago, of anastomosing the colon with the rectum, leaving the growth there, would be a more favorable operation than extirpation of the carcinoma.

DR. A. M. CARTLEDGE, of Louisville, said that in doing a cholecystotomy there was not much time saved by using the Murphy button, and it was not as useful as ordinary methods of suturing. He thought that this was well illustrated in one of the cases reported by Dr. Vander Veer, in which there was a passage of stones after the operation, and in which the button was necessary on account of the extremely feeble condition of the patient. In cases with numerous small calculi extending into the cystic and common ducts, he had made a comparatively large incision in the gall-bladder and sutured the margins to the peritoneum, when the stones could not be removed, and they would then pass for days externally through the drainage-tube. The orifice in the button is too small to permit the stones to pass, whereas they would escape through a drain and come out. He expressed himself in favor of Dr. Grant's device, and considered it an excellent one for lateral anastomosis.

DR. W. E. B. DAVIS believes that the Murphy button can be used to advantage in intestinal work when it is necessary to perform operations quickly; otherwise the method of stitching similar to that practised by Abbe is better, more certain, and accidents are not so likely to follow as from the use of a mechanic appliance which is non-absorbable. Cholecystenterostomy by the button should be resorted to only in those cases in which it is impossible to remove the obstruction in the common duct. The old method, as pointed out by Dr. Cartledge, is decidedly better in the other class of operations.

DR. VANDER VEER, in closing, was satisfied that end-to-end anastomosis with the button in the large intestine was not likely to be a satisfactory procedure on account of the reasons mentioned by Dr. Reed. He believed Dr. Grant had presented an appliance that would be of value to the profession. The fact that new devices for intestinal anastomosis were being presented from time to time before medical gatherings was ample evidence that we had not yet reached an ideal method. The Murphy button is an excellent device for the performance of cholecystenterostomy and other operations.

DR. GRANT believes that any surgeon of ordinary skill, after having the two surfaces of the bowel directly opposed, can with his device suture them without soiling the peritoneum or letting them slip away.

DR. J. MCFADDEN GASTON, of Atlanta, Ga., read a paper on

SURGICAL INTERFERENCE IN RECTAL DISORDERS.

He said that the practicability of eradicating rectal troubles of syphilitic origin by medication is a mooted point, and with the present light on the subject it seems justifiable to resort to such a surgical measure as the condition indicates, while constitutional treatment is being carried out in the case. There are instances of supposed development of specific disease in the form of stricture of the rectum, after the lapse of many years subsequent to any syphilitic contamination, and some authors claim their ability to diagnosticate specific stricture even without a previous history of primary syphilis. Strictures of the rectum from fibrous deposition in its walls call for division or excision of the structures involved. When carcinomatous induration of the rectal tissues is detected early there is encouragement to undertake an operation, but after the breaking down of the neoplasm, with infiltration of the surrounding structures, no benefit is derived from excision of the parts involved. The rectum affords material for surgical work of the

most important character, and it should not be relegated to those professing to deal with so-called "orificial" surgery.

The burning and urgent need of the surgeon is a definite settlement of the issue as to active interference in cases of pronounced carcinoma of the rectum. Shall we content ourselves with the palliative measure of inguinal colotomy and leave the diseased structures untouched, as urged by Dr. Mathews, or shall we endeavor to remove all the tissues involved by extirpation, as recommended by Dr. Gerster? The full statistics of results in the hands of skilled operators ought to be collected and a fair analysis made before a final adjudication of the question is reached. The materials for such a comparison should be obtained from special hospitals for the treatment of carcinoma in this and other countries, as well as from general hospitals receiving and treating this class of patients; being grouped together, a fair inference may be drawn as to the feasibility of active interference in any case of carcinoma of the rectum.

DR. J. M. MATHEWS said that he was glad the essayist had alluded to fissure of the rectum giving rise to reflexes, as to have such reflexes there must be a pathologic condition. The so-called "orificial" surgeons had run wild with reflexes from the normal rectum, and as a consequence many respectable citizens had lost healthy rectums. Dr. Mathews' observations had been that benign rectal stricture is very seldom met with. When found, it is simply an annular constriction of the mucous membrane, which is easily dissipated and does not require excision. When the surgeon introduces his finger into the rectum and finds a stricture it betokens one of three serious diseases—syphilis, tuberculosis, or carcinoma—and the patient should not be turned aside with a jesting remark that he has a rectal stricture. Dr. Mathews maintains that 60 per cent. of the cases of stricture of the rectum arise from syphilis or are the result of it. He had asked his professional friends to investigate this matter and make known their investigations. The responses he had received were nearly all in the affirmative. He regards syphilitic stricture of the rectum as more frequent than either carcinoma or tuberculosis. As in nearly every instance of carcinoma blocking the rectum to the sigmoid flexure we have systemic infection, can a cure be expected from surgical interference? It is to be wished that the rectum could be successfully removed for carcinoma.

DR. H. M. NASH, of Norfolk, Va., had seen a number of cases of ulcer of the rectum cured by dilatation of the sphincters and topical applications. He uses the Sims speculum, placing the patient in the exaggerated Sims position, which gives the operator all the room he wants for manipulation in the rectum.

Afternoon Session.

DR. GEORGE H. NOBLE, of Atlanta, Ga., read a paper entitled

ONE-HUNDRED-AND-SIXTY-SIX CASES OF CARCINOMA OF THE PREGNANT UTERUS OCCURRING SINCE 1886.

The author's attention was directed to this subject by four cases that came under his observation, and his success in dealing with them had encouraged him to look more carefully into the treatment. As a result he had collected one-hundred-and-sixty-six cases of carcinoma of the pregnant uterus which had occurred since 1886, the time of the Barr Thesis. Dr. Noble confined himself mainly to the statistics of the treatment and results, referring to Barr, Cohnstein, and others for information concerning the age, the period of recurrence, the period of abortions, etc. There were twelve partial amputations of the cervix in the seven months of pregnancy, averaging five-and-a-half months; almost all of the mothers recovered from the operation; 66.6 per cent. went to full term, one child dying subsequently; and 41.6 per cent. aborted. Two mothers had subsequent operations performed for removal of carcinoma, but there was recurrence in both cases. Another conceived a second time and died thirteen days after confinement, of peritonitis. Of the three cases of intravaginal amputation of the cervix, two recovered from the operation, giving a mortality of 33.3 per cent.; the children the same. One mother died of peritonitis; one died suddenly six weeks after confinement; and the third had two subsequent operations for the removal of the malignant disease, making an ultimate mortality of 66.6 per cent., and possibly 100 per cent. The intravaginal amputations give a combined mortality from operations: of mothers 19.3 per cent., of infants 40 per cent. Sixteen supravaginal hysterectomies were done prior to the seventh month, with a mortality of 6.2 per cent.; six had recurrences of the disease, three had no return, and seven were not observed. Of the sixteen cases in which the records were complete, thirteen cases were lost, a mortality of 81.3 per cent. Of the remaining three, one went to full term, and in the other two the result was not mentioned. One case aborted thirty-five days after conception, aborted again in forty days, conceived a third time, was delivered normally, and was well five years afterward. There were 23 vaginal hysterectomies. In two cases the results were not recorded, leaving 21 cases, all successful. There were seven cases of vaginal hysterectomy in the puerperal period from fourteen to twenty days after abortion or delivery; all recovered.

The total number of abdominal hysterectomies was 16; in 12 of these Freund's operation was performed; in one Mackenrodt's method was followed; the remainder are not described. Of this number 7 died from the operation, making a death-rate of 43.7 per cent. One case had enchondroma of the pelvis, another had return of carcinoma in one year, and a third had a return in a few months, and died seven days after an operation for ileus due to carcinoma of the intestines. These three are the only ones with complete records; therefore it is impossible to give an estimate of the ultimate recoveries. The products of conception were all lost.

Cesarean section was done forty-three times, as follows: Conservative (or Sänger), 26; Porro, 9; Freund's, 8 times. Of the 26 conservative operations 16 died and 7 recovered; in two the results are not recorded, and one was dead before the operation was performed.

The number of recoveries after the Cesarean-Porro operations was four, of deaths five, the mortality of 55.5 per cent. In eight Cesarean sections by the Freund method there were three recoveries and five deaths, giving a mortality of 61.1 per cent.

A short summary shows (1) that vaginal hysterectomy should be safe in the early months of pregnancy and the puerperal state, when there is a reasonable

hope for the mother. (2) That abdominal hysterectomy should be done when the uterus is too large to be rapidly and safely removed through the vagina. (3) That at or near the end of pregnancy Cesarean section should be resorted to, when the child's interest is to be considered. (4) That Cesarean section with Freund's operation is permissible when the disease is confined to the uterus and the child is viable. (5) That in doubtful cases cutting of the cervix and rapid delivery may be judicious when the incision can be made in non-ulcerated or non-infiltrated tissue. (6) That as there are four chances to one against the life of the fetus, and as an equal number of mothers may be ultimately cured in the early stages of the disease, the safety of the fetus should not be allowed to hazard the life of the mother; and that, upon the other hand, the futile efforts directed to the interests of the mother, when her case is hopeless, should not jeopardize the safety of the fetus in the latter months of pregnancy.

DR. HOWARD A. KELLY, of Baltimore, said that carcinoma of the pregnant uterus is rare. He had seen but three cases. If the new-growth is seen in the early stage, when it presents itself as a mere nodule on the cervix, not apparently extending into the broad ligaments, and pregnancy is approaching, it would be safe to let pregnancy go on to full term, and labor to take place naturally. On the other hand, if the carcinoma has advanced to such an extent that there is a possibility of involvement of the broad ligaments, the surgeon could not operate too soon, because under the conditions of pregnancy the growth of carcinoma of the cervix is much more rapid than it is ordinarily.

DR. VANDER VEER, of Albany, stated that four years ago he operated on a case, doing a vaginal hysterectomy. Pregnancy had advanced about four months. He felt happy about the case for two-and-a-half years, at the end of which time carcinomatous nodules presented themselves at the site of the cicatrix. Pregnancy had advanced to full term. The patient lived for a period of eight months. The pelvis was filled with a carcinomatous deposit. Dr. Vander Veer reported another case of carcinoma of the pregnant uterus, and, while the patient recovered from the removal of the uterus, she subsequently died from recurrence of the disease.

DR. E. S. LEWIS, of New Orleans, contributed a paper entitled

HYSTERECTOMY FOR FIBROIDS.

He said that hysterectomy for fibroids, now a justiable and recognized operation for the preservation of health, the prolongation and the saving of life through important operative procedures, minimizing the element of risk, had reached its present enviable position by the substitution of direct ligation of the uterine arteries for the unsatisfactory methods heretofore employed to secure immunity from hemorrhage, these measures often failing to prevent bleeding; and not infrequently there was exposure to infection through the region of the cervix. Complete hysterectomy, whether by the vaginal route in fibroids of moderate size, through the abdomen in certain cases, or by the combined abdomino-vaginal method in other instances, heralded a brighter era for the future of hysterectomy. That exceptions might occur with regard to individual cases, rendering the complete operation inadmissible, he was prepared to admit.

The author then reported eight cases in which the complete operation was practised:

CASE I was in a woman, aged fifty-three years. The tumor was of the size of a seven-months' pregnancy. Operation was performed March 11, 1894. An incision was made from the pubes to two inches above the umbilicus. The omentum was detached from the anterior surface of the tumor to which it was adherent; a portion of the omentum was ligated and cut off on account of free oozing. The sub-peritoneal fibroid attached to the fundus was lifted out, and the upper portion of the ligaments ligated and divided. The bladder was then detached, and the vaginal roof opened in front and behind. The lateral vaginal connections and lower portion of the broad ligaments were transfixed and ligated with a double ligature and the uterus freed. One suture was passed through the middle of the vaginal vault. The abdominal incision was closed, and the vagina loosely packed with iodoform-gauze pushed above the vaginal roof for drainage on account of some slight venous oozing. The tumor weighed 25 lbs. This patient made a satisfactory recovery.

CASE II was in a woman, forty-three years of age, who had profuse uterine hemorrhages. The uterus was as large as a five-months' pregnancy from the presence of an interstitial fibroid. The endometrium was curretted and iodin injected without relief. Hysterectomy by the vaginal method was performed, and recovery ensued.

CASE III was in a patient aged sixty-three years. A diagnosis of interstitial fibroid with carcinoma of the cervix was made. The uterus reached to the middle of the hypogastrium, and was about the size of the tumor in the preceding case. Its removal was easily effected in the same manner. The ligaments were secured with clamps. The fibroid, about the size of an orange, was not weighed. Recovery followed.

CASE IV was in a patient aged forty-four. The uterus was enlarged from the presence of a number of small fibroids. Vaginal hysterectomy was performed, and followed by recovery.

CASE V was in a patient aged thirty-five years. A diagnosis of uterine fibroid, reaching to the umbilicus, was made. Recovery followed operation.

CASE VI was in a patient aged forty-two, who presented a large uterine fibroid of the size of an eight-months' pregnancy. Vaginal hysterectomy was performed.

CASE VII was in a patient aged forty. A diagnosis of subperitoneal fibroid attached to fundus was made. The same operation was performed as in the preceding one.

CASE VIII was in a colored woman, who presented a fibroid affecting the body of the uterus, and as large as a six-months' pregnancy.

DR. HOWARD A. KELLY, of Baltimore, made some remarks on the

TECHNIC OF SUPRAVAGINAL HYSTERECTOMY.

He described a new method of hysterectomy, by which the uterus, ovaries, and tubes are removed through the abdomen. It is a modification of the Baer method. He had tested it in about one-hundred-and-fifty cases of all kinds, and had operated in the presence of hundreds of practitioners. While he had not heretofore described it, he had briefly referred to it before the Section on Ob-

stetrics and Diseases of Women at the last meeting of the American Medical Association.

DR. JOSEPH TABER JOHNSON, of Washington, D. C., followed with a paper entitled

SEVENTEEN CASES OF HYSTERECTOMY.

He said that the first successful hysterectomy ever performed was done by Dr. Burnham, of Lowell, Mass., in 1853. Kimball, who assisted Burnham in his first case, subsequently operated with success after a correct diagnosis had been made. In 1875 Kimball reported nine hysterectomies with three deaths. Burnham had then done sixteen hysterectomies with four deaths. These results were considered fairly good at that time. In 1878 Gusserow reported that up to 1866 Kœberle had lost all but eight out of forty-two hysterectomies, giving him a mortality of 81 per cent. Schrœder collected reports of 108 hysterectomies with a mortality of 85.3 per cent. Thomas, in his *Diseases of Women*, reports 24 cases with 18 deaths. Storer, in 1874, reports 10 American hysterectomies, all fatal. From 1874 to 1894 many changes were made in the technic, including asepsis, the Trendelenburg position, the intrapelvic but extraperitoneal treatment of the pedicle, the closure by suture of the separated edges of the broad ligament, drainage when necessary through the vagina after total extirpation, and these have all had their share in diminishing the mortality.

In the June number of the *Annals of Gynecology*, Cushing published a report of 1670 suprapubic hysterectomies done by American operators, with a mortality of 13.8 per cent. One of the improved methods of widening the scope of this beneficent and magnificent operation and greatly reducing its mortality was introduced, advocated, and practised by Dr. B. F. Baer, of Philadelphia, who is quoted in Cushing's article as having operated 78 times with 71 recoveries and 7 deaths.

Dr. Johnson presented his paper for the purpose of reporting 17 operations by Baer's method with 16 recoveries and one death.

DR. HENRY O. MARCY, of Boston, agreed with Dr. Johnson that the method of operating by the Kœberle clamp had been shown to be absolutely wanting in this type of operation; that it is not easier of execution except in very few and rare cases; that it is ill advised and subject to serious dangers.

In reference to the operation described by Dr. Kelly, he desired to refresh the memory of the members that in 1880 he published a paper in which he reviewed the various steps and pointed out the advantages of the operation which is now known as Baer's. In the International Medical Congress of 1881 he presented a second paper in which he emphasized the value of the operation. The advantage of leaving the stump was a great gain in the subsequent result, in that it left a sort of fixation-point between the uterus, rectum, and bladder. It is of value again in that it does not shorten the vagina —a question of paramount importance in reference to marital life and to the conditions that may follow in the subsequent history of the patient. He was sure that surgeons were working on the line of great and general improvement, and that when the technic of this operation has been developed more thoroughly the time will be when the removal of large fibroid tumors of the uterus can be accomplished with equal safety as the removal of large ovarian cystomata.

DR. RICHARD DOUGLAS, of Nashville, said that one advantage of the procedure described by Dr. Kelly was that the bladder was out of the operative field, the surgeon not having to handle that viscus; that the operator could open the broad ligament and remove intraligamentary fibroids without difficulty and without danger. Another important feature was that the risk of ligating the ureter was greatly reduced.

DR. W. E. B. DAVIS, of Birmingham, believes that most surgeons are now inclined to accept the intra-abdominal method of operating, although it was still a question whether we shall have a pedicle or shall go in through the vagina. A very important point related to the time of these operations. He has seen Dr. Kelly operate and admired his manual dexterity; but to take out the uterus in six or seven minutes meant very little, when it takes an assistant, or an operator himself, an hour or more to complete the balance of the operation. At the last meeting of the American Medical Association he saw Dr. Kelly remove the uterus by the method he had described in something like seven minutes, but it took an assistant one hour and twenty minutes to finish the operation. It was no reflection on Dr. Kelly's skill as an operator, but he thought the matter of time should go on record in a little different way.

DR. A. VANDER VEER, of Albany, remarked that in 1889 he removed the uterus somewhat in the manner described, the case having been already recorded. He had done the operation only twice since. He uses the Kœberle clamp because he thinks he can do the operation much more quickly and has no reason to regret its use.

DR. A. M. CARTLEDGE, of Louisville, believes it is an advance in pelvic surgery to remove the uterus in badly septic cases, whereas formerly only the tubes and ovaries were taken out.

DR. E. S. LEWIS, of New Orleans, remarked that his experience with total hysterectomy for fibroids was restricted to the cases he had reported. The operations that he had performed up to last year were cases in which a partial removal of the uterus was effected, leaving a portion of the cervix. He could not but think, however, notwithstanding that the majority of the gentlemen who had spoken upon the subject appeared to be advocates of the partial operation of leaving a part of the cervix, that total removal of the uterus was the best operation.

DR. KELLY said, in reply to Dr. Davis, that when he spoke of removing the uterus in seven minutes or less, it did not include closure of the wound, dressing, etc. He had never been so dishonest as to make the statement that the entire operation could be done in such a short space of time, nor would he like that impression made.

DR. JOHNSON remarked, in reference to taking out the cervix, that it prolongs the operation and necessitates greater mutilation and more stitching, and seems to be unnecessary in view of the successful cases that had been and are being reported. Patients get perfectly well without doing it. He concurred in Dr. Davis' statement that the time consumed in taking out the uterus did not amount to much, but that we should consider the matter from the time the first incision is made

until the last stitch is inserted, the wound dressed, and the patient off the table.

Dr. Joseph Price, of Philadelphia, contributed a paper entitled

ABDOMINAL HYSTERECTOMY.

Among other things he said that, had the same mortality attended the early oophorectomies that attended the first ventures in hysterectomy, there would have elapsed a longer period than forty or fifty years between the first successful oophorectomies and the date of the revival of the procedure. Both vaginal and supravaginal hysterectomy had been largely practised by those who had given pelvic surgery most attention. They are the men who have contributed the most to perfecting the procedure. Abdominal hysterectomy is the one procedure indicated in all cases of intrauterine malignancy, when the vaginal portion of the cervix is not involved; in all cases of uterine malignancy complicated with tubal and ovarian disease; and in cases of uterine fixation antedating the malignant development. Hysterectomy, vaginal or supravaginal, should be a simple, direct, and complete operation in every detail. When the operation is done with good surgical judgment and skill there will be comparative immunity from all risk of dangerous hemorrhage and avoidance of sepsis. The method of procedure that successful experience recommends as safe, the most satisfactory and complete in its results, consists in extirpation by lateral ligation, incision of the posterior vaginal fornix, circular incisions of the vagina to the bladder; and approximating the vaginal walls to and matching the peritoneum complete the simple procedure. Operations for malignancy by the upper method of dealing with omental and other adhesions lessen the risk of post-operative troubles and early recurrence. In all operations for malignancy Dr. Price advises the removal of both the ovaries and tubes, and says that an operation would be imperfect without this. The leaving of the ovaries sometimes results in the growth of small tumors, necessitating an additional operation. The toilet should be perfect. If the operation has been complicated by pus-accumulations in tubes and ovaries, with universal adhesions, irrigation followed by glass drainage will give the best results. Drainage should be used in all cases in which the adhesions are extensive, as oozing of blood and serum may be very free.

Morcellation, with a mortality of one in seven, cannot certainly be said to offer any very strong claim to consideration. Such a mortality does not compare favorably with the much-abused extraperitoneal operation with the Kœberle or elastic ligature. Dr. Price had no statistical reasons for complaining of any one of the four methods—intraperitoneal amputation, extirpation, supravaginal, extraperitoneal, or vaginal extirpation—as his results in all had been altogether satisfactory from the standpoint of recoveries.

Dr. A. M. Cartledge, of Louisville, Ky., read a paper on

HYSTERECTOMY IN ACUTE PUERPERAL SEPSIS, WITH A REPORT OF CASES.

He reported two very instructive cases, after which he summarized his conclusions with reference to acute puerperal sepsis, as follows:

1. From our present knowledge of the causation and nature of puerperal infection we may say that it is largely a preventable condition.

2. When occurring it is of the greatest importance to differentiate between puerperal intoxication or invasion of a piece of prutrescent placenta or blood-clot by saprophytic germs and true septic infection or invasion of living cells by pathogenic bacteria. Puerperal sapremia, though in many cases producing the most alarming symptoms, is usually amenable to energetic treatment by curettage, antiseptic irrigation, and satisfactory tubular drainage of the uterine cavity.

3. True septic infection should be treated by sterilizing the birth-canal at the earliest possible time, free elimination by purgation, and a prompt evacuation of superficial abscess-accumulations about the cervix. Such a course may save the patient from more radical measures.

4. The chief differential points between puerperal intoxication and true puerperal infection are the comparative absence of pain, tympanites, and abdominal tenderness, and the more sudden onset and severe character of the symptoms in puerperal intoxication. Hysterectomy as a primary measure is never justifiable in septic intoxication, and when necessary it can only be after the mixed or secondary infection which may follow in the track of a primary sapremia.

5. Progressive involvement of the deeper structures, as evidenced by daily elevation of temperature, probably 103° F. in the evening and subnormal in the morning, together with night-sweats, scanty secretions, ascending pulse, are indications for hysterectomy.

6. It is often impossible from the involvement primarily of the low pelvic structures to make a bimanual examination that will reveal the true condition of the uterine appendages; but in view of the fact that these structures are not so prone to be invaded in the acute violent type of the disease vaginal hysterectomy should be the operation of selection.

SECOND DAY—NOVEMBER 13TH.

Morning Session.

Dr. Richard Douglas, of Nashville, read a paper entitled

SPLENECTOMY STATISTICALLY CONSIDERED, WITH THE REPORT OF A CASE.

Gathered from all sources, the author finds on record 194 splenectomies. Of these 126 were in females, 57 in males, and in 11 cases the sex is not given. Furthermore, he finds that in forty cases the operation was undertaken for wounds or injuries. Of this number 26 were in males and 14 in females. If we deduct these we find that the ratio of splenectomies for disease is 31 in males to 112 in females, showing the latter sex to be much more predisposed to disease of this organ.

Dr. Douglas then reported the following case: Mrs. J. S., aged 33, housewife, multipara, and a native of Tennessee, had a good family history. She has suffered occasionally with menorrhagia, but more recently from amenorrhea. She had malarial fever when 12 years of age. For the last three years she has lived in the western portion of the State on the banks of the Mississippi, and has suffered during this time from frequent

attacks of malarial intermittent fever. About August 1st last she suffered from an acute pain in the left side. A tumor was then discovered in that region about the size of a fist. Physical examination revealed a smooth, elastic, movable tumor, filling the left lateral region of the abdomen, with its borders well defined and its edges sharp and notched. It frequently changed its form; at times it appeared flat and smooth; again it would rise up as a sharp ridge, extending from the ribs to the symphysis pubis. There was absolute percussion-dulness over the tumor. Vaginal examination revealed the uterus displaced forward and the pelvis filled with a smooth, hard mass, which upon change of posture disappeared from the pelvis and occupied the left iliac fossa. The woman suffered with paroxysmal pain, although not severe, with a sense of weight, a dragging in the left side, flatulency, nausea, and occasional vomiting. There was some emaciation and slight anemia. There was no edema, ascites, vertigo, or insomnia.

A diagnosis of malignant hypertrophy of the spleen was made, and after due preparation the abdomen was opened by an incision about six inches long at the outer border of the left rectus. The spleen was found displaced and free from adhesions. Its pedicle was secured by interlocking ligatures; and was severed close to the organ. As additional security against hemorrhage, ligatures *en masse* were employed; also individual deligation of the splenic artery. After removal of the spleen, bleeding from the abdominal incision became very profuse, and required several ligatures. The peritoneum was closed by separate silk sutures, and the abdominal wall was brought together with the usual interrupted silkworm-gut sutures.

The post-operative history of this case was a very stormy one, but one month after operation the woman was out of bed, and is now well.

DR. W. E. B. DAVIS, of Birmingham, contributed a paper entitled

SURGERY OF THE BILIARY DUCTS.

He reviewed the operative procedures practised on the biliary passages, and recommended for cases of obstruction from stone in the common and hepatic ducts that the obstruction should be removed, and that no attempt should be made to suture the incision in the duct or ducts. His experiments had demonstrated that the field of operation will be walled off, and that no general inflammation will occur after this treatment. He had tested the value of gauze in draining bile in injuries of the gall-bladder and biliary ducts, and reported cases in which he had removed the gall-bladder without tying the duct by packing with iodoform-gauze. The animals got well. In other instances in which he incised the gall-bladder and biliary ducts, and packed with gauze around the openings, no stitches being used, the animals recovered. Complete walling off of the general cavity was noted when the abdomen of the animals was reopened. The experiments of Dr. Davis demonstrate conclusively that the peritoneum is capable of taking care of a small amount of bile, but that large quantities or the constant extravasation of it will produce a fatal peritonitis, usually in from twenty-four to forty-eight hours.

DR. JOHN D. S. DAVIS, of Birmingham, Ala., read a paper on the

MANAGEMENT OF CASES WHICH HAVE RECOVERED FROM APPENDICEAL ABSCESS IN WHICH THE APPENDIX WAS NOT REMOVED.

He said that the practice of dealing with appendiceal abscess by simply evacuating the pus and draining the cavity thoroughly without any extensive search or the breaking up of adhesions in order to find the appendix has been adopted by a large number of leading operators for some time. More recently some surgeons have advocated that the operation should be made complete in all cases; that all adhesions should be freed and the appendix removed. One leading abdominal surgeon, who has perhaps done more work in pelvic surgery than any other man in this country, has advocated this plan of treatment in vigorous terms. In a large proportion of cases of pus in the tubes and ovaries gonorrhea has been an important factor in its production. Such pus is not septic, and is not calculated to give rise to so dangerous a general inflammation as an infection from an appendicitis or an appendiceal abscess. It is a notable fact that a ruptured tube or ovary will usually be followed by a circumscribed inflammation. It is the exception that a fatal general peritonitis results from such an accident. The most fatal forms of peritonitis are due to rupture of an appendiceal abscess. In fact, but few cases are saved when such an abscess ruptures into the general cavity.

An operation on an appendiceal abscess is usually one of the simplest of procedures, and is attended with almost no danger. When the inflammation is circumscribed and the drainage is thorough, nearly all cases recover. The records of operations for appendiceal abscess show that the great majority of cases are cured after evacuation and complete drainage. Recurrence of the disease in such cases is rare. The appendix, having ruptured in a large proportion of cases before the formation of an abscess, is completely drained through the abscess, with permanent cure. In others the appendix is destroyed by the inflammation, and there is nothing left of it when the abscess is operated upon. To make an extensive search for the appendix is liable to break up adhesions, and then allow escape of septic fluid into the general cavity. Thus a very simple condition may be converted into one of the most serious that could happen in the peritoneal cavity. Dr. Davis believes that there cannot be much need of breaking up adhesions, for they give way in a short time after the abscess is relieved. In breaking up these adhesions, in addition to the danger mentioned, the surgeon prepares a favorable condition for fresh adhesions, with the possibility of the bowel being fastened in a position that will produce pain and often obstruction. After the abscess is thoroughly cleaned out, gauze packed into the abscess-cavity and between the abscess and abdominal wall will completely shut it off, and the chances for recovery will be good in such cases. Dr. Davis does not favor the breaking up of adhesions and searching for the appendix in cases of appendiceal abscess.

(To be continued.)

Prof. V. v. Hacker, of Vienna, has been called to the chair of Surgery in the University of Innsbruck.

NEWS ITEMS.

Methods of Medical Teaching is to be the subject of a day's session of the American Academy of Medicine at its next annual meeting, in Atlanta in May, 1896. Ten minutes each are to be allotted chosen speakers treating of the following subjects, and the whole question is then to be open to general discussion by members in five-minute speeches:

1. The Preparatory Mental Discipline of the Medical Student.
2. The Subjects to be Known Before Beginning the Study of Medicine.
3. The Lecture and its Uses.
4. Text-book Recitation and its Advantages.
5. Laboratory Methods.
6. Manual Training.
7. Clinical Instruction.
8. The Seminarian Method.
9. "Electives."
10. Quizzes, Reviews, etc.
11. Pass-examinations.
12. The Final Examination.
13. Students' Medical Societies.
14. State Examinations.
15. The Best Methods of Teaching Anatomy.
16. " " " Physiology.
17. " " " Inner Medicine.
18. " " " Surgery.
19. " " " Obstetrics.
20. " " " State Medicine.

The St. Louis Academy of Medical and Surgical Sciences was organized on November 6, 1895. The constitution of the society subscribes to the code of ethics of the American Medical Association. The membership is limited to fifty.

No one can become a member of the Academy unless he possesses a good literary and medical education. As evidence of his literary qualifications and ability as a scientific worker he must deposit with his application a thesis, a pathologic specimen with descriptive text, a drawing of a normal or abnormal specimen with text, or some other evidence of his worth. The evidence will be passed upon by the committee on credentials. If the evidence is accepted the ballot is taken. Two negative votes will defeat a candidate.

The following officers were elected for the ensuing year: *President*, George W. Cale, Jr., M.D., F.R.M.S., London; *Senior Vice-President*, James Moores Ball, M.D.; *Junior Vice-President*, Arthur E. Mink, M.D.; *Secretary*, Emory Lanphear, M.D., Ph.D.; *Treasurer*, Wellington Adams, A.M., M.D.; *Orator*, Thomas O. Summers, A.M., B.S., M.R.C.S. Eng., M.D.; *Curator*, George Howard Thompson, A.M., M.D.

The Journal of Experimental Medicine is the name of a new periodical to be published from January, 1896, and to be devoted to original investigations in physiology, pathology, bacteriology, pharmacology, physiologic chemistry, hygiene, and practical medicine. Dr. Wm. H. Welch, Professor of Pathology in the Johns Hopkins University, is to be the editor of the new journal, and with him will cooperate a board of twelve associate editors, as follows: For physiology: Drs. H. P. Bowditch, R. H. Chittenden, W. H. Howell; for pathology: Drs. J. G. Adami, W. I. Councilman, I. M. Prudden; for pharmacy: Drs. J. J. Abel, A. R. Cushny, H. C. Wood; for medicine: Drs. R. H. Fitz, W. Osler, W. Pepper. In addition, a large number of the ablest of American investigators have consented to assist as collaborators. The new *Journal* will for the present appear quarterly, and the annual volume will contain from 600 to 700 pages. Messrs. D. Appleton & Co., of New York City, will be the publishers.

Dr. J. Edward Michael, a well-known surgeon and gynecologist, of Baltimore, Dean of the University of Maryland, and President of the Medical and Chirurgical Faculty of Maryland, died December 6, of nephritis, at the age of 47 years.

Prof. Læffler, the discover of the diphtheria-bacillus, has been decorated by the French Government with the Cross of the Legion of Honor.

Dr. Weller van Hook has been elected Professor of Surgery in the Polyclinic Medical School and Hospital of Chicago.

Dr. J. H. Wintrode, an esteemed physician of Marklesburg, Pa., died on November 17th at the age of 73 years.

SOME SALIENT POINTS IN THE DIAGNOSIS, PATHOLOGY, AND TREATMENT OF APPENDICITIS.[1]

BY JOHN B. DEAVER, M.D.,
OF PHILADELPHIA.

APPENDICITIS, owing to its unusual frequency and alarming gravity, has become the most important intraabdominal inflammation encountered by the surgeon at the present time. Occupying this position, the subject is one worthy of the gravest consideration and sufficiently warrants the presentation of a few facts which I have learned in the careful study and treatment of a large number of cases. As many of these points have not been brought to the attention of the medical profession, I desire to emphasize them as much as possible and give to them the prominence which I feel they deserve. I refer most particularly to the early recognition of the varied symptoms of appendicitis, to a proper appreciation of the possible disastrous results of such a morbid process, and to the prompt application to all such cases of the most advanced surgery. I believe the time has arrived when those of us who have had the opportunity of observing and operating upon a number of cases of appendicitis should declare ourselves without fear and without reservation concerning the operative treatment.

A glance backward over a period of 18 months shows that there has been a decided wave of progress in the diagnosis and treatment of appendicitis; and that there has been developed a keener appreciation of its dangers and a more uniform acceptance of operative treatment than before. Many have been brought to justly realize, only through the school of bitter experience, the gravity that a comparatively insignificant pain in the abdomen may suddenly assume.

A tempest of argument has been raised, a storm of protests has been hurled against what has been called too radical surgery, and, as a result, the sea of life is strewn with human wrecks, absolutely lost or crippled beyond repair.

It would be only charitable for us to believe that those who to-day, either by voice or action, place themselves in the ranks of conservatives on this question, have not encountered the experiences of many others in the treatment of this disease. Their apathy is the result of an inexperience which underestimates its destructive tendencies. Unseen and frequently unheralded save by a few premonitory symptoms, like ripples on the surface of calm water, the deadly process begins, but as those ripples broaden, so do the symptoms intensify until the whole body becomes agitated by the fury of the storm, and the question becomes one of life or death. I venture to say that among those present to-night there are some who can recall sad experiences with this foolishly styled "fashionable disease," appendicitis, in which the patient, who was supposed to be the subject of an acute attack of indigestion, in a few hours showed unmistakable evidence of a purulent peritonitis which resulted in death, or perhaps the peritonitis was confined to the right iliac fossa and terminated in an intraabdominal abscess, which when opened, the appendix not being removed, left the patient a chronic invalid from fecal fistula or subject to subsequent attacks, each one of which was attended with the awful uncertainty of death.

There are many cases in which inflammation of the appendix is so intense that necrosis sets in, and either perforation occurs or gangrene supervenes before there is even an attempt upon the part of nature to protect the peritoneum against infection. This is so common an occurrence that I am compelled to bring you face to face with the question, *Can you, or I, or anyone, presume to say when or where this condition will arise?*

In previous papers upon this subject I have laid stress upon the wisdom of early operation in acute attacks. A richer experience and a careful analysis of the knowledge acquired impel me to state again, in terms so strong that they cannot be misunderstood, that early operation is not only the safest, but the only sure road to recovery. Every case of appendicitis places one in the position of deciding immediately what is best to be done. The patient's life and future usefulness frequently hang upon the slender thread of your judgment. You may say that many cases get well without operation (that is, do not die from the attack), but should you rest content with a fair percentage of recoveries, when a much greater number would recover by operation?

I have been accused of being too radical upon the subject of appendicitis, of having removed normal

[1] Read at the meeting of the College of Physicians of Philadelphia, December 4, 1895.

appendices, but I have the courage of my convictions, and say to you that my statements are founded upon facts, and that if I can convince one of you, who may be skeptical, that what I say is true, then have my time and labor been well spent. In support of what I say I can produce the statistics of 200 operations performed between attacks, with two deaths, both of which deaths occurred in the first series of 100 cases.

Diagnosis. I wish to emphasize a fact I have already stated in former articles, that is, that the diagnosis of appendicitis is an easy one to make. There are three cardinal symptoms which when present warrant without exception a diagnosis: the sudden onset of acute abdominal pain with or without vomiting occurring in one who was previously well; rigidity of the right side of the lower abdominal wall; tenderness over the site of the appendix.

It is not my intention to go over the entire subject of the diagnosis, the pathology, and the treatment of appendicitis, but to discuss some salient points not touched upon in the paper I read before the College, May 2, 1894, and which I hope will throw sufficient additional light upon this subject to clear the horizon for those who are still groping in the fog of uncertainty and doubt.

The affections with which I have seen appendicitis most commonly confounded are typhoid fever, pyosalpinx, ovarian abscess, pyonephrosis, abscess of the kidney, and perinephric abscess. I cannot understand why appendicitis should be mistaken for typhoid fever, particularly in the early stage of either affection, and yet upon more than one occasion I have seen the surgeon forced to defer an operation because the consensus of opinion of the majority of the medical attendants was opposed to such a procedure. In the early stages of the two affections the characteristic symptoms are distinct. The sudden onset, the rigidity of the right lower abdominal wall, and the tenderness which is more marked and smaller in area, being limited to the position of the appendix, are pathognomonic of appendicitis. In typhoid fever the slow onset attended by lassitude, headache, nose-bleed, etc., the temperature-record, the general abdominal tenderness with the accompanying peculiar doughy condition of the abdominal walls, the enlarged spleen, and the absence of rigidity, should be sufficient to establish a differential diagnosis with absolute certainty. If, in connection with these differential points, a digital examination of the rectum demonstrate a sensitive mass, then any doubt which may exist in the mind should be at once dispelled. Spots may be found in either affection, but they are not of any diagnostic value, as I believe that in both cases they are of septic origin.

Follicular abscesses of the appendix are responsible for some of the mistakes in the differential diagnosis between appendicitis and typhoid. The minuteness of the collections accounts for the mildness and the prolongation of the sepsis and the lessened degree of the local symptoms. In this type of appendicitis we have a constant source of absorption with a small amount of tissue involved. It is not uncommon to find cases which have been supposed to be typhoid fever, in which an operation has demonstrated the presence of macroscopic follicular abscesses in the appendix, varying in size from a millet-seed to a mustard-seed, an eroded, mucous membrane, and a more or less infiltrated organ.

The difficulties in making a differential diagnosis between appendicitis and typhoid fever in the later stage are more fancied than real. The early history, the local symptoms, on the one hand; and the general abdominal symptoms, with the dry tongue; the sordes on lips and teeth, the temperature-record, and the characteristic diarrheal stools, on the other hand, are quite sufficient to make the differentiation clear and distinct. The spleen is enlarged in both affections; in both instances as a result of sepsis. The enlargement, however, due to septic infection from an active suppurative process like appendicitis is likely to be associated with pain caused by a perisplenitis from embolism.

The following case is related to illustrate the fact that follicular abscesses in the appendix are capable of causing a train of symptoms which suggest to the medical man the probability of typhoid fever:

One morning in the early fall, my friend, Dr. M., called at my office, saying that he was worried about his little girl, who was ill, because the nature of the illness was not clear to him. He came to the city with the purpose of having one of our medical men see the child. He related to me the history of the case and showed me the temperature-record, and I suggested that the symptoms resembled those of subacute appendicitis. An appointment was made with the medical man, and I was asked to accompany him. This being impossible, I suggested one of my assistants and Dr. F., of the German Hospital, who were accepted. The consultation was held, but a definite conclusion was not reached, as the medical consultant believed the trouble to be typhoid, while Dr. F. and my assistant thought it appendicitis. The following day I was asked to see the child and to operate if I concurred in the diagnosis of appendicitis. This I unhesitatingly did, and operated at once. The following conditions were present: The appendix was situated behind the colon, to which it was adherent; the mucous lining of the tip of the appendix, which was club-shaped, contained several follicular abscesses, the largest of which was the size of a split pea. The recovery was uninterrupted and rapid; the symptoms which had suggested typhoid disappeared immediately after the removal of the appendix.

Before directing attention to the points of differentiation between appendicitis and the affections attended with pus-formation which may be confounded with appendicitis, permit me to say that the occasion for making a differential diagnosis between appendicitis with pus-formation and other forms of pus-collections should never arise, as in all cases of appendicitis the appendix should be removed before pus has formed.

The presence in the rectouterine cul-de-sac of an inflammatory mass in intimate relation with the uterus, which renders it partially or completely immovable, and which can be clearly outlined by vaginal or combined vaginal and rectal examination, in connection with the history of a vagino-uterine infection, establishes the diagnosis of a pyosalpinx or an ovarian abscess. The essential thing in the differentiation between these two affections and appendicitis is the absence of a history of the three cardinal symptoms of the latter affection. This is also the essential point in the differential diagnosis between appendicitis and pus-affections of the kidney.

Too much stress cannot be laid upon the importance of urinary examinations, not only in the supposed kidney-affections before mentioned, but also in appendicitis. I have recently operated upon a case in which the urine contained pus and epithelium from the pelvis of the ureter, in which there was present a swelling in the right loin, accompanied by tenderness, extending in the direction of the attachment of the appendix, and in which a history of the three cardinal symptoms was elicited. I opened the right iliac fossa, finding the appendix, which was postcolic and contained pus, pointing north, adherent to and in communication with the pelvis of the ureter, through which the contents of the appendix were being emptied into the bladder, thus explaining the urinary symptoms. The recovery was uneventful.

In certain cases of appendicitis the pain is entirely referred to the left side. I wish to emphasize this point, as I have seen a number of cases in which the attending physicians who were familiar with appendiceal symptoms were totally misled. From my experience in operating upon a number of such cases, in which I invariably found the appendix holding a southerly position, I am prepared to make the statement that when the pain is referred to the left side, the appendix occupies the pelvis; also, that in this class of cases, when suppuration has taken place, resulting in a large pelvic collection, there is pronounced bilateral rigidity of the lower abdominal walls. Therefore when I am asked to see a patient, and the diagnosis of the ailment is not clear—with a previous history of the three cardinal symptoms, with the pain referred to the left instead of the right side, with a temperature denoting a hectic condition, and bilateral rigidity of the lower abdominal walls—I am convinced that the case is one of suppurative appendicitis, in which both the pus-collection and the appendix occupy the pelvis. A rectal and vaginal examination under these conditions, with the exception of great pain, elicits nothing but a sense of fulness. The contrast between this condition and that of suppuration in the pelvis dependent upon uterine infection, to which reference has been made, is marked. The following case will illustrate the importance of these diagnostic points:

During the past summer I was asked to see Miss ——, the history of whose illness was as follows: About two weeks prior to my visit she was suddenly attacked with what was at first supposed to be an attack of acute indigestion, which did not yield to the ordinary remedies. A provisional diagnosis of typhoid fever had been made, in view of the fact that the spleen was enlarged, spots were present, and the temperature was suggestive of an irregular case of typhoid. The suddenness of the onset, accompanied by acute abdominal pain with very decided bilateral rigidity of the lower abdominal walls, the temperature-record, the vaginal and and rectal examinations which elicited great pain with the characteristic fulness only, pronounced the case one of suppurative appendicitis with a pelvis full of pus. I advised operation without delay. Adverse opinion of other counsel delayed the operation for a period of two days, at which time the pelvis was found to be full of stinking pus; the appendix, which was perforated and gangrenous, occupied the pelvis. The appendix was removed and the recovery was uneventful.

The citation of one case occurring in the person of the son of a physician, a most excellent diagnostician, will serve to illustrate the importance of the pain being referred to the left side, as indicating the position held by the appendix, viz., the pelvis; the cardinal symptoms were present:

Master A., son of Dr. E., was suddenly seized with acute abdominal pain, vomiting, and rigidity of the right lower abdominal wall, which followed the ingestion of numerous articles of indigestible food. After a period of three days, symptoms of acute peritonitis developed, at which time his father consulted me. He remarked that he would have regarded the case as one of appendicitis if the pain had not been referred to the left side. I told the father that, with all deference to him, I regarded the case as one of appendicitis demanding immediate operation. Two days later I was hastily summoned to see the son, whom I found suffering from a diffused peritonitis of an active type, with a pulse of 130, leaky skin, constant retching and obstipation. I declined to interfere, advised the discontinuance absolutely of opium or any of its preparations, and ordered small and repeated doses

of calomel to be given to the extent of free purgation, believing this a wiser course to pursue than operation. The boy apparently recovered from this attack. I then advised operation in order to prevent a recurrence of the trouble, but the father could not agree to have his son operated upon when he was apparently well. Within ten days a second attack occurred; I was again summoned, but being absent from the city other counsel was sought; the operation was again deferred, and the result was an incomplete recovery from the second attack. I was again consulted and again advised operation. The boy was brought to Philadelphia. The operation showed that the appendix, the tip of which contained a pus collection, with an encysted abscess surrounding this, occupied the pelvis, being adherent to the floor of the pelvis and to the right of the rectum. The appendix was removed and the recovery was uneventful.

In those cases in which the pain is referred to the left side and the point of greatest tenderness is immediately above the pubis or in the left iliac fossa, the greatest intensity of the inflammation will be confined to the tip of the appendix. It is in this class of cases in which the appendix occupies the pelvis that bladder-symptoms, such as irritability, frequent micturition, and retention, are of value from a diagnostic point of view. The abrupt cessation of pain previously located in the region of the appendix, followed by fall of temperature, increased pulse-rate, and an anxious expression, indicates the occurrence of gangrene in that organ.

PATHOLOGY. The primary pathologic condition in an attack of appendicitis is catarrhal inflammation. The outcome of the attack after the catarrhal condition is established depends upon several important factors: 1st. Drainage of the organ; 2d. The character of the microorganisms present; and 3d. The presence or absence of fecal concretions or foreign bodies.

In a large percentage of cases the appendix holds a northerly position running up behind the cecum. This position favors, by gravity, the drainage of the organ. It also opposes the entrance of foreign matter and in such cases the primary attack is more likely to subside. The conditions are changed, however, in an appendix which has been the seat of an inflammation. In the process of healing of the mucous membrane lining the organ, strictures and twisting of the appendix due to contraction occur, which interfere with drainage and often entirely close its lumen. A condition I have met with is one of constriction with an enlargement on either side of the stricture, causing the appendix to assume an hour-glass shape. When the organ occupies any of the other positions than northerly, drainage is interfered with by gravity. An appendix which cannot drain itself and which becomes inflated is a menace to the life of its possessor.

The character of an attack varies with the association of the bacterium coli commune with the staphylococcus or with the streptococcus, the latter combination being by far the most unfavorable. When the bowel is red and excoriated the streptococcus is present, and the prognosis of a fecal concretion in appendicitis is a mere coincidence, and acts as a pathologic factor only by interference with drainage, thereby making perforation more likley, and also by constricting the entire lumen, and causing pressure and interference with the circulation, favoring gangrene of the organ to the distal side of the concretion.

Obstruction of the bowel is not uncommonly met in the various stages of appendicitis. Ordinarily this is due to bands, the result of the inflammation, or to the adhesion of the tip of the appendix to the adjacent bowel. I have recently met with a case in which the patient had been operated upon for the relief of a circumscribed abscess. The patient for ten days progressed favorably, and was considered to be beyond the danger-point. Suddenly symptoms of intestinal obstruction manifested themselves. The wound was reopened, and the obstruction found to be due to pressure upon the bowel, caused by the contraction of the abscess-cavity in the processes of healing.

Follicular abscesses of the appendix are frequently met. They are minute, often not larger than a millet-seed.

The postperitoneal lymphatics are sometimes affected secondarily, causing large retroperitoneal collections of pus. I have met with the pus of an appendicitis situated between the liver and the diaphragm, where it had burrowed behind the diaphragm and communicated with a bronchus, causing a purulent expectoration with an odor which indicated that gangrene of the lung was the cause of the patient's trouble.

I do not believe that leukocytosis is sound evidence of pus. I believe that ordinary means are sufficient to enable one to make the diagnosis, and that the time spent in demonstrating the leukocytes which prove nothing could be better utilized in liberating the collection.

TREATMENT. My paper has no doubt impressed you with the fact that in my opinion operation is the only treatment for appendicitis. The best results and the smallest mortality are obtained when the operation is performed at the earliest possible opportunity. The diagnosis can and should be made in a few minutes, and the operation should follow without the delay of days or even hours. If through doubt and delays immediate operation be impossible, then the quiescent period, that between attacks, is the next most favorable time. Operation at this period has been performed by me with a mortality of 1 per cent. in a series of two-

hundred cases, both deaths occurring in the first hundred. The added risks of operation for appendicitis when pus has already formed cannot be denied by any one who is familiar with the dangers which accompany such a condition of affairs. In fact, no surgeon or physician will deny that pus complicates and materially increases the danger of any operation, and particularly when that greatest of all absorbing surfaces, the peritoneum, is involved. Picture to yourselves the operation for the removal of an appendix before pus has formed—the clean abdominal incision; the removal of the diseased organ, with the closing in by serous flaps and the invagination of the entire stump into the cecum, with the subsequent closure of the abdominal wound, on the one hand; and, on the other, an abscess with its foul-smelling and infectious contents bathing the incision and contiguous parts; the unquestionably increased risk of infecting a peritoneum which nature has closed off by the removal of an appendix which has perforated and which is probably involved in the confining wall of the lymph; the necessity of drainage by gauze and tubes, with the increased likelihood of subsequent hernia, fecal fistula, etc. Can anyone who is familiar with these two conditions pretend to say that the former is not less dangerous and more desirable than the latter, or that the two conditions of operation do not bear the testimony of unbiased observers? There is, of course, a small percentage of recoveries following operations for abscess-cases in which the peritoneum has been generally infected; but this depends upon the amount and character of the pus and upon the operation being done before collapse has set in. I cannot say that I think it wise to operate upon a patient in collapse.

In operating upon pus-cases in which the appendix is involved in the wall of the abscess-cavity, I believe that it is possible and always advisable to make the operation a complete one, as in no other way is recovery assured. To leave an appendix which has sloughed off, or has a perforation in it, or which has been intensely inflamed by migration of microorganisms through its walls, with the certainty of fecal fistula or subsequent attacks, I believe to be bad surgery. It is my practice to remove the appendix in all cases. Certain it is that by the proper disposition of gauze and careful attention to technic, an appendix which is deeply imbedded in a wall of lymph, whether it makes a portion of the abscess-cavity or not, can be removed, and the dangers which attend its removal are far less than those which occur when it is allowed to remain. A practice which I believe is a frequent one is simply to evacuate the collection, there being no attempt made to remove the appendix if it be not plainly visible. This I consider, with all due deference to the surgeons who practice it, incomplete surgery. Cases of congenital absence of the appendix are reported, but the congenital absence probably exists only in the mind of the searcher. I have never failed to find the appendix in chronic cases, although many times I have been able to find it only after a prolonged search and a careful dissection.

I beg the privilege of a few more minutes to relate the report of a case upon which I operated November 23, 1895, and which will serve, I hope, the purpose intended, namely, to disabuse the minds of those among you who are still of the belief that a patient who has apparently recovered from an acute attack has safely passed the danger-point, and that operation is superfluous:

A boy of 13 was referred to me by my friend, Dr. P. Moylan, with a history of three attacks of appendicitis. During the last attack he was under the care of Dr. Moylan, who said to me that at the time of his first visit a general peritonitis was present, and was attended with so much distention that he was unable to make out by examination the cause of the peritonitis. There was apparent recovery from this attack. Operation was by incision through the right semilunar line, opening up a cheesy mass situated beneath the transversalis muscle. The peritoneum beneath the collection had been destroyed and the posterior wall was formed by the great omentum. The cheesy material was curetted away and the cavity antisepticized. The great omentum was tied off around the involved portion and the latter cut away. The cecum contained two perforations which were brought to view after the removal of the diseased and adherent omentum. The appendix lay postcecal, imbedded in a mass of lymph. It was perforated at its base. The pelvis contained a collection of pus which was confined by adherent coils of small bowel. The patient recovered.

In conclusion, I desire to say that an appendix that has been at any time the seat of inflammation will be a constant source of danger to the life of its possessor; that there is no medical treatment for the cure of appendicitis; and that, as Osler has so happily said, "the surgeon is frequently called too late—never too early."

1634 Walnut Street.

The Gonococcus as a Pyogenic Microorganism.—Bujwid (*Centraibl. für Bakteriol. und Parasitenk.*, B. xviii, No. 14, 15, p. 435) has reported the case of a man, 32 years old, with gonorrheal urethritis demonstrated bacteriologically, in which a severe chill occurred two days after a catheterization. Later, four intramuscular abscesses developed—in the neighborhood of the left shoulder-joint, in the right popliteal space, on the inner aspect of the left leg, and above the right external malleolus. The pus evacuated from these in small amount was odorless and reddish-brown in color, and upon culture on serum-agar proved to contain gonococci in pure growth.

LABORATORY STUDIES.

THE RELATION BETWEEN THE SPECIFIC GRAVITY OF THE BLOOD AND ITS HEMOGLOBIN-PERCENTAGE.

BY F. C. BUSCH, B.S., AND A. T. KERR, JR., B.S.,
UNDER THE DIRECTION OF

HERBERT U. WILLIAMS, M.D.,
PROFESSOR OF PATHOLOGY, UNIVERSITY OF BUFFALO.

THE investigation of the specific gravity of the blood has received more or less attention for a number of years. Among the first to study it were Nasse (1839), Davy (1839), Becquerel and Rodier (1844), Haro (1873), and Bizzozero (1879). Other investigators who have made valuable contributions to the literature are Schmidt, Senac, Boyle, Fano, Roy, and Arronet. In recent years most valuable researches have been made by E. Lloyd Jones, Schmaltz, Peiper, Siegel, Sciolla, Castellano, Copeman, Lyonnet, Hammerschlag, Hoch and Schlesinger, Sherington and Copeland.[1]

In 1890, Hammerschlag, after comparing the specific gravity with the hemoglobin-percentage in a large number of cases, constructed a table giving the percentages of hemoglobin for different specific gravities. In the winter of 1894–95 we began a series of observations to test the value of this table in the ordinary run of cases without limiting it to primary anemia. Hammerschlag neglects to state what method he used for the determination of the hemoglobin, but Hoch and Schlesinger give his table as based upon the Fleischl instrument. We have used for this purpose the methods of Fleischl and of Gowers, because they are in more general use than any others, take but little time, and are easy to manipulate. Henocque's spectroscopic method was not used because of the large amount of blood it requires, which would be especially an objection when used in connection with the other methods.

We made no count of the blood-corpuscles in comparison, but it has been found by Jones, Hammerschlag, Schmaltz, and others that the specific gravity corresponds more closely with the hemoglobin than with the number of red blood-corpuscles.

For determining the specific gravity of the blood a variety of methods have been used. One of the early ones was that of Haro (1873), who noticed that denser blood passed more rapidly through a tube of narrow caliber than did blood of lesser density. He noted the time it took bloods of different known densities to pass through a tube of certain caliber. He was thus able to estimate the density of an unknown specimen by noting the time it took to pass through the tube.

A good method of determining the specific gravity, but one which takes considerable time, is that with the pycnometer. This, as used by Schmaltz, is a capillary tube of 0.1 c.cm. capacity, which is first weighed empty, then when filled with water, and finally when filled with blood. The weight of the tube is subtracted and the specific gravity calculated from the weight of the blood as compared with that of the water.

Fano, in 1882, used a method which depends upon the principle that a body when immersed in a fluid will float indifferently in that fluid when the specific gravities of the two are equal. The fluid used was a solution of gum in water. To make this heavier he added a denser gum-solution. To make it lighter he added water. Blood was introduced into this and the liquid made to correspond in specific gravity to that of the blood. The specific gravity of the liquid was then, determined and thus at the same time that of the blood.

Roy, in 1884, devised a method applying this same principle. He used solutions of salt or other suitable substances ranging in specific gravity from 1.035 to 1.075. For making the test he used a modified hypodermic syringe. This had a small steel tube prolonged inward from the tip so as to be seen through the glass sides of the barrel. The syringe was filled with a salt-solution and a drop of blood drawn into it. As it emerged from the steel tube into the solution he noted whether it rose or sank. If it sank, a new solution of higher specific gravity was chosen; if it rose, one of lower specific gravity was taken. Finally one was obtained in which the blood neither rose nor sank, or two were found in one of which it rose and in the other sank. In the latter case the specific gravity of the blood was between the two.

Roy's method as modified by Jones is as follows: The apparatus consists of from 20 to 25 one-ounce glass bottles filled with standard solution of glycerol and water, differing one from the other by 0.001 specific gravity and ranging from 1.027 to 1.075; a number of fine glass pipets drawn out to a point and bent at right angles near the tip; a cylindric glass jar of about one-dram capacity; and a number of clean suture-needles. By means of the pipet the blood is introduced into the one-dram jar filled with one of the standard solutions chosen by guess from the appearance of the patient. It is then blown out gently, being given an impetus in a horizontal direction owing to the bent tip of the pipet. If it rises or sinks other solutions are chosen, as in Roy's method.

Landois used solutions of sodium sulphate ranging between 1.050 and 1.070.

Siegel has adopted a device whereby the frequent standardization with the Jones-Roy method is diminished. He covers the surface of his standard solutions with a layer of olive-oil, introducing the blood through this by means of a glass tube which is closed by a rubber-cap.

Dastre employs a mixture of olive-oil and carbon chlorid (CCl_4), which, he says, neither mixes with nor coagulates the blood.

The method which we have used is that devised by Hammerschlag. The necessary apparatus consists of a hydrometer-jar, a hydrometer, a pipet of small caliber, a glass rod, some fine steel pens, a bottle of chloroform, one of benzol, and a mixture of the two. The mixture of chloroform and benzol is poured into the hydrometer-jar. The finger, after being washed with bichlorid and alcohol, is punctured. A good-sized drop of blood is introduced into the chloroform-benzol mixture. If the drop sinks, the mixture must be made heavier by adding chloroform. If it rises, the mixture is too heavy and must be made lighter by adding benzol.

It is desirable not to divide the drop of blood into several, but, on the other hand, care must be taken to get the chloroform and benzol thoroughly mixed by stirring

[1] For a good account of the history of this subject see Castellano.

with the glass rod. In order to obtain this end it is better, when the liquid is too heavy, to add an excess of benzol, and then obtain the required density by adding chloroform slowly and carefully until the drop of blood floats indifferently in the mixture. When this occurs, the drop of blood is of the same specific gravity as the mixture, and by determining that of the mixture with a hydrometer we know the specific gravity of the blood.

We have found it most convenient to obtain the blood from the middle finger of the left hand, making our puncture to the side of the tip on the palmar surface. For this purpose we have used an ordinary steel pen, with one nib broken off. The pen was sterilized by heat and a new one used for every test. The blood was drawn up into a pipet of fine caliber, which was introduced into the middle of the chloroform-benzol mixture, and nearly all of the blood gently blown out. *We were careful not to blow out all of the blood, but left a little in the tip of the pipet, shaking off the rest.* The object of this was to *avoid mixing air with the drop and thus obtaining an incorrect result.*

The same chloroform-benzol mixture may be used repeatedly. After each test, in order to get rid of the drop of blood, it is filtered. The hydrometer-jar should be scrupulously clean. Otherwise some fine particles in it may adhere to the drop of blood and thus cause an error.

The hemoglobinometer of Gowers is usually manufactured with but one colored tube, which is for use with daylight only. There is another form in which there are two tubes, one for use with daylight and the other with artificial light. The one we have employed is of the former kind. In making the comparison with it one must hold the instrument against a white background, opposite the source of light, or, as recommended by Landois, between the eye and the light.

In the use of Fleischl's hemometer artificial light is necessary, and the test must be made in a room from which daylight is excluded. When tests are to be made with patients confined to bed, it is very inconvenient and causes loss of time to be obliged to run to a dark room in some other part of the ward or building every time a test is to be made. We have been able to obviate this difficulty by a simple device, enabling us to carry our dark room with us. A piece of ordinary cardboard is cut so as to fit over the top of the canvas travelling-bag in which we carry our instruments. The hemometer is placed in one end of the case and a small lamp in the other. A hole is cut in the cardboard to give passage to the lamp-chimney. Another small hole is cut so as to be directly over the well of the instrument. At the side of this hole a window, closed by a cardboard flap, is cut for the introduction of the hand in order to move the wedge of the instrument.[1]

Siegel showed that the glycerol-water and the chloroform-benzol methods gave practically the same results, and Hammerschlag found that the chloroform-benzol methods and the pycnometer differed very slightly. Therefore, it appears that the results obtained by the use of these three methods are essentially the same.

[1] The capillary pipets for each Fleischl instrument are graduated for that particular instrument. The capacity of these is indicated on the screw that binds the table of the instrument-stand to the supporting leg, as well as on the handle of the pipet itself.

The pycnometer requires a very accurate balance, such as is used for the finest chemic work. Such a balance cannot readily be moved from place to place. The glycerol-water method, though said to take less time than the chloroform-benzol method, requires the keeping on hand of twenty or thirty solutions which must be frequently standardized. The chloroform-benzol method requires little apparatus, is easily procured, inexpensive, always at hand, and needs no standardization.

It was found by Roy and Jones that the influence of room-temperature made no difference in their results. Hammerschlag also determined by experiment that room-temperature did not influence tests made with his apparatus. Therefore, we have in no case corrected for differences in room-temperature.

The specific gravity in health has been differently given by different observers.

Becker	1.057–56
Landois	1.057–55

Hammerschlag found that in healthy males (between the ages of twenty and forty years) the specific gravity varies from 1 057 to 1.0625, and in females from 1.0535 to 1.061.

Jones states that venous blood is denser than arterial blood. Sherrington and Copeland found almost no difference between arterial and venous blood. In passive congestion, as in a ligated finger, they agree that there is an immediate rise in specific gravity. This rise vanishes at once upon the disappearance of the congestion.

A characteristic property of the blood is to keep its specific gravity constant. Thus, after drinking large amounts of fluid, the change in the specific gravity of the blood disappears in from one-half to one hour. Sherrington and Copeland found that after injecting large quantities of salt-solution into the blood of rabbits the specific gravity of the blood returned to the normal in a very short time. It was discovered by Hoch and Schlesinger that a marked change in the specific gravity of the blood as a whole might take place without affecting that of the serum. Therefore, it appears that usually the principal factors in a change of specific gravity of the blood from the normal are in the cellular constituents.

Of the solid constituents of blood in man, the hemoglobin constitutes about 60 per cent. (according to Hoppe-Seyler). In females it is somewhat less. This being the case, variations in the percentage of hemoglobin must immediately affect the specific gravity of the blood. Hammerschlag maintains that it is possible therefore to determine from the specific gravity, accurately enough for clinical purposes, the percentage of hemoglobin for a given sample of blood.

The table of Hammerschlag, which it has been our object to test, is as follows:

Specific gravity.	Hemoglobin.
1.033–1.035	25–30 per cent.
1.035–1.038	30–35 "
1.038–1.040	35–40 "
1.040–1.045	40–45 "
1.045–1.048	45–55 "
1.048–1.050	55–65 "
1.050–1.053	65–70 "
1.053–1.055	70–75 "
1.055–1.057	75–85 "
1.057–1.060	85–95 "

According to Hammerschlag, this table holds best for cases of anemia, including chlorosis, tuberculosis, and malignant tumors. But in interstitial nephritis the specific gravity is relatively lower than the hemoglobin. In circulatory disturbances, even when edema is present, the specific gravity is generally normal. In fever it is relatively lower than the hemoglobin, rising after the fall of the fever.

We have investigated the specific gravity of the blood in 150 cases, at the same time determining the amount of hemoglobin by the methods of Fleischl and Gowers. These cases embrace a wide range of diseases, and hemoglobin-percentages varying between 12 and 110. Out of the 100 consecutive cases taken for comparison of the three methods, the amount of hemoglobin estimated from the specific gravity and as determined by the Fleischl method differed by less than 5 per cent. in 24 cases; between 5 per cent. and 10 per cent. in 24 cases; between 10 per cent. and 20 per cent in 26 cases; and more than 20 per cent. in 26 cases. The specific-gravity method ran below the Fleischl in but 15 cases and in 5 of these less than 5 per cent. Therefore the differences observed usually showed the readings higher by the specific-gravity method than by the Fleischl instrument.

In the same cases the readings of Gowers' apparatus differed by less than 5 per cent. from Fleischl's in 36 cases; between 5 per cent. and 10 per cent. in 21 cases; between 10 per cent. and 20 per cent. in 33 cases; and by more than 20 per cent. in 10 cases. As a general rule they were higher than with Fleischl's, but not quite as high as those estimated from the specific gravity. Comparing the percentage obtained from the specific gravity with the Gowers' readings, in 33 cases there was less than 5 per cent. difference; in 31 cases the difference was between 5 per cent. and 10 per cent.; in 26 cases between 10 per cent. and 20 per cent.; and more than 20 per cent. in 10 cases.

From the foregoing comparison, it appears that in approximately one-half of our cases the hemoglobin as determined from the specific gravity corresponded quite well with the hemoglobin as determined by the Fleischl hemometer; that this correspondence was fair between the specific-gravity determinations and the Gowers determinations in more than one-half of our cases; that there was a somewhat closer correspondence between the determinations from the specific gravity and the Gowers than there was between the Gowers and the Fleischl instruments; that the Fleischl instrument gave relatively lower readings.

The differences in the readings of the three methods may be due: (1) to errors in the specific-gravity method; (2) to the inaccuracy of the table giving the hemoglobin-equivalent for the specific gravity; (3) to the errors of the Fleischl and Gowers instruments.

We are convinced that both Fleischl's and Gowers' instruments, particularly the latter, are liable to err to a considerable degree. Osler says that the error in the Fleischl instrument may not be more than 2 per cent. in blood which is nearly normal, but he cites Neubert and Letzius as having shown that in a much impoverished blood the error may be as high as 20 per cent. In using two Fleischl instruments in comparison in the same cases, we have generally found a difference in reading between the two. In 30 per cent. of these comparisons the difference was as much as 10 per cent. We have also found that in about one-fifth of our cases we disagree in our readings of the same instrument. Forty per cent. of these differences were more than 5 per cent.

We feel some hesitancy in stating that in consecutive tests, made with the same Fleischl instrument, in the same cases, within a few minutes, we have found differences in readings of as much as 10 per cent. This occurred to us after having used the instrument almost daily for nearly a year, and after having used it many hundred times. Such errors can only be explained by acknowledging inaccuracy in technic, but a method so easily liable to such serious errors could hardly be relied upon for more precise results in the hurry of ordinary clinical work.

In the same series of consecutive tests, the specific gravity and the hemoglobin-percentage as determined by it, varied to an insignificant degree. The hemoglobin-percentages as determined by the Gowers instrument, in some of the tests, varied as much as 10 per cent. In our experience with the Gowers instrument, we have found it very unsatisfactory. It is often quite impossible to get the tint of the diluted blood to correspond with that of the standard 1 per cent. solution. Even when this is attained, a difference in shade may be produced by looking at the instrument somewhat from the side instead of from straight in front, by holding the paper for reflection farther away from or nearer the instrument, by holding the instrument between the eye and the window, or by moving farther away from the window. In the last case, in a number of instances, the differences produced by moving 20 feet away from the window became as much as 15 per cent. higher. Therefore it would seem that on a cloudy day readings would be higher than on a bright day. The differences in readings between holding the instrument against a white background and holding it directly between the eye and the light were as much as 10 per cent.[1]

As may be seen from the foregoing comparisons and the observations of others the Fleischl instrument is not

[1] See Limbeck, pp. 18, 19, for analogous observations.

entirely reliable; therefore Hammerschlag's table, which is based upon this instrument, must be inaccurate. Taking all these conditions into consideration, there appears to be quite a constant correspondence between the specific gravity and the percentage of hemoglobin, and we think that, with a table based upon a much larger number of cases and a more reliable estimation of the amount of hemoglobin, this method would be as accurate for clinical purposes as the methods now in vogue, and possibly more so.

If such a table existed, it would be extremely simple to construct a hydrometer with a long narrow stem having the scale of specific gravity on one side and the corresponding hemoglobin-percentage on the other. By using such an instrument the specific gravity and the hemoglobin could be determined at the same time with the greatest facility.

Incidentally in the course of our work we have had a number of cases of epilepsy. In 12 cases of that disease we found in all but one that the hemoglobin determined from the specific gravity was at least 10 per cent. higher than by the Fleischl hemometer. Jones says that the specific gravity is frequently above the normal in the post-epileptic state. In 13 cases of syphilis we found that as a rule the hemoglobin ran lower than in health. There was quite a constant correspondence between the estimation of the hemoglobin by the Fleischl instrument and with the specific gravity. Jones finds that the specific gravity in syphilis runs low.

In a case of splenic leukemia the specific gravity was 1.052, and the hemoglobin by Fleischl's hemometer 40 per cent., the hemoglobin by Gowers' 68 per cent., and hemoglobin calculated from the specific gravity was about 68 per cent.

In conclusion our results may be briefly summarized as follows:

1. The percentage of hemoglobin in blood in most cases may be predicted from the specific gravity with sufficient accuracy to be valuable for clinical purposes.

2. Fleischl's hemometer is liable to an error of 10 per cent.

3. Gowers' instrument is liable to an error even greater than that of Fleischl's.

4. The error in technic with the specific gravity method is likely to be very slight.

5. In following up a case with Fleischl's or Gowers' instrument very erroneous conclusions may be drawn. Mistakes may be made of 5 per cent. or 10 per cent., too low one day and 5 per cent. or 10 per cent. too high on another.

6. In following up a case the specific-gravity estimation seems to give very slight error, and even if from it the absolute percentage of hemoglobin could not be determined, yet the relative increase or decrease of hemoglobin from one day to another might be quite accurately estimated.

7. Because of its being based on the instrument of Fleischl, Hammerschlag's table is of necessity only approximately accurate.

"LIQUID PEPTONOIDS."

BY A. L. BENEDICT, A.M., M.D.,
OF BUFFALO;
LECTURER ON DISEASES OF THE DIGESTIVE ORGANS, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO.

"LIQUID peptonoids, beef, milk, and gluten perfectly digested. Contains the albuminoid principles of beef, milk, and wheat, entirely digested and ready for assimilation. It represents a valuable nutritive cordial, and

will be taken by patients who are unable to digest food in any other form, and in these cases it has been found of the greatest service"—so says the label on the bottle, which, by the way, was left at my office by an agent of the manufacturer, and hence is presumably at least a fair sample of the trade-supply. The preparation is sweet, aromatic, alcoholic, and altogether quite agreeable.

As this preparation has been recommended not only by the manufacturers, but by physicians who have employed it in typhoid fever and other conditions demanding easily assimilable food, I have been interested to know just what it contained. A letter of inquiry addressed to the manufacturers not having been answered, I have subjected two sample bottles to the following tests:

Boiling, with and without nitric acid: no precipitate, and hence no albumin.

Heller's ring-test, with cold nitric acid: No. 1, no ring; No. 2, slight cloudiness; hence a trace, at most, of albumin or albumose.

Addition of ammonium sulphate: no precipitate (No. 1), hence no form of albumin except possibly peptone.

Ring-test with alkaline copper-solution: no rose tint, hence no peptone or albumose.

Addition of iodin: slight reddish tint, hence no starch, but probably erythrodextrin.

Addition of tannic acid: abundant precipitate. This reagent is precipitated by so many substances that the significance is not apparent.

Boiling with alkaline solution of copper sulphate: abundant reddish precipitate, hence sugar.

On evaporation, 100 c.cm. of the "liquid peptonoids" yielded a sirupy mass which, on further drying at rather too high a temperature, gave forth the odor of caramel, and was evidently slightly charred. The dry residue weighed 7 grams, and was mainly composed of sugar. Dialysis left nothing but the charred particles. In order to make sure that the drying had not carbonized some of the proteids—a supposition that was improbable, as no characteristic odor was noted—a quantity of the original liquid was dialyzed for several days, the water in the dialyzer always yielding sugar, and the liquid that did not pass through the parchment-paper was tested. It still contained sugar, showing that the dialysis was not complete. On evaporation over a Bunsen flame a small amount of sirup was obtained, which was then allowed to evaporate at the temperature of the room and then redissolved in cold water. Although the temperature used in evaporating had been sufficient to precipitate ordinary albumins and gelatinous substances, there was no residue after redissolution. Tannic acid, however, still gave a slight white precipitate and iodin a reddish tinge, presumably due to erythrodextrin.

As the word *peptonoid* is not in official use, it would not be fair to insist that it should apply to true peptone. It suggests, however, some form of peptonized albumin or gelatin, and it must indicate the presence of some proteid in order to fulfil the claims made for the preparation as a nutritive. Yet the reaction with tannic acid is the only one that even suggests a proteid, even the xanthoproteic reaction being absent.

This report is not intended to condemn "liquid peptonoids;" even if the liquid contains nothing but sugar, dextrin, and alcohol it has some value, though it is manifestly not suited for sustaining life in typhoid fever or any other wasting disease. The burden of proof rests with the manufacturers to show why the tests enumerated do not reveal the presence of the albuminous substances which are implicitly claimed; they should certainly not ignore a specific inquiry as to composition when it comes from a possible customer.

Granting that "liquid peptonoids" contains all that is claimed for it, the medical profession should not accept and medical journals should not advertise a preparation whose true formula is not given. We are not children to be put off with such explanations as "This is nutritious," or "alterative," or "valuable in uterine troubles," or "composed of derivatives of the aromatic group," or "a combination of analgesics." The very fact that manufacturers can afford to market their wares on such generalizations shows that a large proportion of us are lacking in brains or backbone, or both.

POSTSCRIPT BY DR. HENRY LEFFMANN, OF PHILADELPHIA.

The examination of a sample of "liquid peptonoids" purchased in the original package in Philadelphia confirms the statements made by Dr. A. L. Benedict. The article is a clear, brownish fluid with a distinct vinous odor. It leaves, on evaporation by the steam-bath, 11.2 per cent. of residue containing much carbohydrates. The liquid portion contains much alcohol. There is no unconverted starch, and but a small quantity of proteids.

The "Beef-peptonoids" manufactured by the same firm was also examined, and found to contain much undissolved starch. Under the microscope numerous granules of wheat-starch can be seen. Some proteid matter in a soluble form is also present.

MEDICAL PROGRESS.

Syringomyelia of Morvan's Type in a Child.—THOMAS (*Revue Médicale de la Suisse Romande*, 1895, No. 11, p. 596) has reported the case of a boy, six years old, who presented himself on account of diarrhea, but whose hands were noticed to be large, though short, as well as cyanotic, and to display other peculiarities. The last phalanx of the left index-finger had almost entirely disappeared, a small fragment of nail remaining. The same phalanx of the middle finger was separated from the rest of the finger by a deep furrow. The extremities of the thumb, of the ring-finger, and of the little finger were swollen and the nails incurvated. The terminal phalanx of the right thumb had disappeared; the ring-finger and the little finger presented the thickened remains of nails. The thenar and hypothenar eminences were less well developed than the other muscles of the upper extremities, although not displaying marked atrophy. The muscles of the lower extremities were not well developed and the feet were cyanotic and cold. The skin over the knees presented a number of cicatrices from previous injury. The nails of the great toes were thickened; the last phalanx of the right little toe had been lost in consequence of a burn. In standing, the child had a tendency to incline the body forward; in walking, the legs were separated and the heels were trod upon. The station was unsteady. Tactile sensibility was normal, while painful sensibility was impaired upon

the hands and feet; there appeared also to be thermo-anesthesia. The knee-jerks were abolished. Urine was under control, but the sphincter ani was incontinent. Electric examination disclosed only quantitative changes, the muscles contracting in accordance with their volume. It was further learned that the child had been born asphyxiated at term, after a difficult labor. He had been nourished from the bottle and had suffered considerably from digestive disorders. His first tooth appeared at eighteen months, and he was not able to walk until he was five years old. At the age of four years he had been burned by a hot brick being kept too long in his bed. He had been operated upon for phimosis and had been twice cauterized over the sternum. He had also had measles and whooping-cough. The precise date of the onset of the disease could not be determined. It had, however, been noted for two years that the child burned himself frequently and had repeated destructive whitlows without complaint of pain.

Two Cases of Hereditary Congenital Night-blindness.—Atwool (*Royal London Ophthalmic Hospital Reports*, 1895, vol. xiv, part 1, p. 260) has reported the case of a young man who had never been able to see clearly at night. When out after dark he had to exercise great caution in order to avoid knocking against other people and objects in his path. The man related that this peculiarity had existed in different members of his family for at least three generations. He had two sisters and two aunts who were night-blind. His father and grandfather had been similarly affected. The patient's vision was 6/6 in each eye and accommodation was normal. The visual fields were normal, both for white and for colors, when taken by diffuse daylight; on lowering the illumination, they were much contracted. Direct vision did not appear to be excessively diminished on lowering the illumination. Appreciation and discrimination of color were perfect. Ophthalmoscopic examination disclosed only physiologic cupping of the discs, and pulsation in some of the retinal veins. A sister of this patient, a hospital-nurse, complained of the same difficulty of seeing in a bad light, to such a degree that she was afraid to venture out of doors alone at night. The right eye had been operated on for internal strabismus. The girl's refraction was hyperopic. The visual fields were normal except that those for green were slightly and uniformly contracted. The pupils were active; the media clear; the discs and retinal vessels normal. The ground of the fundus was dark and looked granular, but there was no pigment to be found in the retina; neither were any spots to be seen at the macula or elsewhere. The choroidal vessels were very apparent. Neither of the cases presented nystagmus. Both had dark hair and there was no lack of pigment in any part of the uveal tract.

Intrauterine Rupture of the Anterior Abdominal Wall.—Brothers (*New York Medical Journal*, vol. lxii, No. 23, p. 707) has reported the case of a newborn infant presenting partly developmental and partly acquired lesions of intrauterine origin. The mother was a multipara who had experienced no difficulty in previous labors. The pregnancy in question had been attended throughout with considerable pain, but there had been no known fall or injury. Labor was rather precipitate, the child striking the floor with some force after expulsion. It was alive, but presented, a half-inch to the right of the umbilicus, a rent of the abdominal wall an inch in diameter, through which from fifteen to twenty inches of the small intestine had escaped. The child was well nourished. The umbilical opening was entirely closed and contained the stump of the cord. The opening in the abdomen was somewhat ragged and along one margin presented distinct adhesions to the gut. The intestine was much congested and swollen and the mesentery discolored. Further investigation disclosed the absence of genitals and anus. Instead a large open space covered with mucous membrane, a little more than an inch in diameter, extended from the pubes to the coccyx. To either side of this cloaca (which represented the exstrophied bladder) were small projections representing the ununited halves of the clitoris. The child lived for twenty-five hours, the napkins showing that urine was secreted. The belief is expressed that the rupture of the abdominal wall and the eventration originated within the uterus, perhaps from some unnoticed maternal traumatism.

Dislocation of the Shoulder-joint of Unusual Origin.—Baxter-Tyrie (*Lancet*, No. 3767, p. 1165) reports the case of a man who was riding a horse that ran away up a steep hill. After going a few hundred yards the animal abated its speed, when the rider raised his hand to strike. The horse, catching sight of the whip, sprang forward, while the man felt an acute pain and a sense of something having given way at his shoulder. He did not fall off, but rode a little further and was helped to dismount. On examination a subcoracoid dislocation of the head of the humerus was found. The explanation is that as the weight of the whip was inconsiderable (four ounces) the inertia of the arm converted it into a lever of the first order. The coraco-acromial arch, instead of fulfilling its normal function of preventing displacement, acted as a fulcrum. The limb from the fingers to that point acted as the "long arm," and the head and part of the neck of the humerus served as the "short arm." The inertia of the arm, left behind as it were, supplied the power, while the ruptured capsular ligament and displacement of the head of the bone would represent the work done.

The Influence of the Antitoxin-treatment of Diphtheria upon the Duration of Intubation.—As the outcome of a careful clinical study, Bokai (*Deutsche medicin. Wochenschrift*, 1895, No. 46, p. 755) has found that the period of definitive extubation oscillates between two wide extremes, in his own experience, between a quarter of an hour and 360 hours. The average duration of intubation before the advent of the antitoxin-treatment of diphtheria was 79 as against 61 hours in the cases subjected to this treatment, a gain thus of 18 hours. In view of the fact that in 16.2 per cent. of cases in which intubation was successfully practised the period of intubation exceeded 120 hours, the recommendation to perform secondary tracheotomy to prevent pressure-ulceration in case definitive extubation cannot be performed in five days, is not to be indorsed. The time for performing secondary tracheotomy under these con-

ditions is a variable one. The undoubted existence of ulceration from the pressure of a tube is an indication for tracheotomy, but the fear of such an accident is not

The Transmission of Tuberculosis Through the Sexual Organs.—As a result of an extended study, DOBROKLONSKI (*Vratch*, May, 1895; *Revue de Tuberculose*, 1895, No. 3, p. 195) arrives at the conclusion that the existence of primary tuberculosis of the genital organs in men and in women is indisputable and that the presence of the tubercle-bacillus in the genital secretions is possible, so that infection may take place if the tubercle-bacillus comes in contact with the mucous membrane of the genital tract. It is probable, however, that infection will take place only when a tuberculous focus exists in the genital organs of a tuberculous individual. This latter condition is so uncommon that infection through this channel must be rare. Tuberculosis of the genital organs may remain localized and give rise to no symptoms for a long time, throughout which the danger of transmission naturally exists. Investigation has also shown that tuberculosis may be transmitted in sexual intercourse between those with pulmonary tuberculosis, even in the absence of tuberculosis of the genital organs.

The Microorganism of Measles.—CZAJKOWSKI (*Centrabl. für Bakteriologie u. Parasitenk.*, Bd. xviii. Nos. 17, 18, p. 517) relates that since his first observation in 1892 he has studied bacteriologically the blood of 56 cases of measles—in 37 only microscopically, but in 19 by culture and animal experiment—and he invariably found one special organism. This he describes as a slender bacillus with blunt ends and actively motile. Most frequently single organisms are found in the blood-plasma, often attached by one extremity to a red blood-corpuscle; less commonly irregular groups of bacilli are to be seen. The organisms vary in length, the smallest being not quite 5μ long and less than half as thick; bacilli measuring the diameter of a red blood-corpuscle are common. The organism stains with the usual anilin colors and not by Gram's method. Cultures develop upon various liquid and solid media containing albumin, with the exception of gelatin and agar. Their growth seems to be favored by the pressure of blood or hematogen. The best culture-medium is sterilized ascitic fluid. Rabbits proved refractory to inoculation; mice succumbed, with symptoms of septicemia, and the special bacilli were found in the blood and parenchymatous organs.

A Case of Intractable Galactorrhea.—TUSSENBROEK (*Nederlandsch. Tydsch. v. Verlosk. en Gyn.*, Bd. v, Afl. 2) has reported the case of a woman, 31 years old, married four years, who was unable to nurse her child on account of total absence of nipples. The use of atropin, potassium iodid, and electricity failing to control the persistent galactorrhea, which had existed for five months and which had resulted in great emaciation, the breasts were amputated and recovery soon ensued. Microscopically the milk-globules were of variable size; colostrum-corpuscles could not be found. The removed organs were large and soft, and presented histologically deviations from the normal that led to the view that the galactorrhea was due to increased secretion.—*Der Frauenarzt*, 1895, No. 11, p. 504.

THERAPEUTIC NOTES.

The Treatment of Eclampsia.—ZWEIFEL (*Centralblatt für Gynäkologie*, 1895, Nos. 46, 47, 48) details at considerable length the various plans employed at the women's clinic at Leipsic in the treatment of eclampsia, together with the results secured. This experience leads to the following conclusions: When the convulsions set in during labor, this is to be terminated in narcosis as speedily as possible. Should the cervix be softened but the external os not dilated, dilatation should be carefully effected with the aid of distensible rubber bags, or, at most, small incisions may be made. If, however, the cervix is not obliterated, although the os will admit a finger, rubber bags should be employed; longer incisions will now be required. Should the convulsions continue after the uterus have been emptied and hemorrhage not have been excessive, free venesection may be practised, especially if the arterial tension be high. Under the latter condition blood may be withdrawn even before labor if the cervix be unyielding. Nothing is to be given the narcotized patient to swallow; fluid may be introduced into the stomach through the tube; lavage is to be practised when digestive disturbance exists. Either chloroform or ether may be employed to induce narcosis. The most rigid asepsis is to be observed throughout, as infection may be responsible for a continuance of the attacks.

Poisoning with Nitric Acid.—MOSER (*Brooklyn Medical Journal*, vol. ix, No. 12, p. 755) has reported the post-mortem findings in case of poisoning with nitric acid. The mucous membrane of the mouth was yellow, that of the esophagus softened. In the latter the longitudinal folds were abnormally prominent, and covered throughout their entire length by yellowish streaks. The mucous membrane between these folds was a little reddened and soft, but not stained. The mucous membrane of the stomach, from its cardiac to its pyloric extremity, was converted into a thick, greenish black slough. The mucosa was thrown into prominent folds. There was no perforation. The mucosa of the duodenum was softened and yellow. The small intestine was but slightly affected, and contained a black fluid. The intestinal discharges were of a bloody character. The heart, the blood, and the spleen presented no change. The kidneys and liver showed parenchymatous alterations. The pancreas was the seat of parenchymatous inflammation, with punctate hemorrhages.

Surgical Uses of Kerosene.—SCHIRMAN (*New York Medical Journal*, vol. lxii, No. 23, p. 720) reports the satisfactory employment of kerosene as a local application to wounds and ulcers of the trunk and extremities. Ulcers, especially indolent and atonic ulcers, were smeared with commercial kerosene, either pure or diluted (from 35 to 50 per cent.) with alcohol, by means of a small camel's-hair brush or with a piece of gauze soaked in the solution. The appearance and character of the ulcers soon changed for the better, the discharge gradually diminished, and in from two to four weeks the rapidly granulating surface formed a scar without any contraction in the surrounding parts. The advantages claimed for kerosene are rapidity of action, economy of cost, and freedom from complications and toxic effects.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

PHILADELPHIA.

SATURDAY, DECEMBER 21, 1895.

THE SERUM-TREATMENT, WITH ESPECIAL REFERENCE TO DISEASES OTHER THAN DIPHTHERIA.

ABOUT a year ago the principles underlying blood-serum therapy were discussed at some length in these columns. At that time it was stated that in all probability not only had a real curative agent for diphtheria been found, but also that, as a consequence, the working out of similar therapeutic measures for many, if not for all, of the acute infectious diseases might justifiably be prophesied. The experience of the year just past has fully confirmed the most sanguine hopes entertained concerning the antitoxin-treatment of diphtheria, and to Behring and to the investigators in bacteriology who made his researches possible are due the gratitude of a world of mothers and fathers, in that a disease which perhaps more than any others is a household dread has been rendered when uncomplicated almost as innocuous as an ordinary cold. At the close of an article containing the masterly presentation of statistics already referred to in THE NEWS, Dr. Welch makes the following remarkable statement: "The results of the treatment of over 7000 cases of diphtheria by antitoxin demonstrate beyond all reasonable doubt that antidiphtheric serum is a specific curative agent for diphtheria, surpassing in its efficacy all other known methods of treatment for this disease. It is the duty of the physician to use it!"

The attempt of Gottstein to prove the fallacy of certain of the statistics concerned, although somewhat disturbing to "those of little faith," has been convincingly combated by Behring in his address delivered this summer at Lübeck, in which he carefully considers the different data in question, and makes strikingly evident by a series of graphic curves the real condition which prevailed. Behring claims that, taking everything into consideration, the mortality in diphtheria may be reduced by at least 75 per cent. by the application of the antitoxin-treatment. For example, according to the mortality-reports, there are in Germany, a country of 46,000,000 of people, on the average 60,000 deaths yearly from diphtheria. Of these, then, and they are mainly among children and young people, according to Behring, it would be possible to save the lives of at least 45,000.

There is no virtue in a skepticism which remains uninfluenced by facts. The reading of the two articles referred to, even without taking into consideration the standing of the authors, can hardly fail to convince any individual with a logical mind that the efficacy of the antitoxin-treatment of diphtheria has been definitely established.

Considerable advances have been made too in the matter from a technical standpoint, particularly with reference to the concentration of the serum. As a result of suggestions offered by Ehrlich, the serum can now be obtained in much more concentrated forms than before. The fear that the demand for serum could never be met by the supply has been dissipated. Behring has calculated that, should diphtheria continue in its ordinary prevalence in Europe and America, from one-million to two-million doses of the curative serum would be required yearly. The establishment at Höchst-on-the-Main, is already capable of an annual output of over one-million doses of five-hundred antitoxin-units each. If one institution can do this there need surely be no fear concerning the possibility of the production of a world-supply.

Though naturally most attention has been directed toward the antitoxic serum as a curative agent, its virtue as an immunizing agent has not remained unrecognized, and the injection of the fluid as a prophylactic measure is coming continually more and more into use. Now that many of the dis-

agreeable phenomena, *e. g.*, urticaria, can be obviated by beginning with smaller doses than those first employed, the objections to the employment of the serum are being removed. The results of experimental immunization have yet to be determined in a much larger number of cases and in various countries before the time will come for passing judgment upon this aspect of the subject. Behring believes that in the end, through the combined influence of the new therapy and prophylaxis, we may confidently expect that the dread of diphtheria will ultimately become a legend handed down from ancestors.

Concerning the exact nature of the immunity conferred by antitoxic serum, there is comparatively little to add to what could be said last year. The experiments of Freund, Grosz, and Jelinek, of Vienna, bearing on the relation of the effects of antitoxins to the processes of coagulation of the blood may be mentioned in passing. These investigators have found that neither nucleinic acid nor nuclein possesses the power of counteracting the effect of diphtheria-toxins when injected together, while on the other hand histon and other substances that have a tendency to prevent coagulation are capable of keeping animals alive after the injection of ordinarily fatal doses of diphtheric poisons. While by such injections these investigators have not, so far, been able to obtain results in animals as brilliant as those that the antitoxic serum can yield, they do not think these impossible of attainment, and conclude that at any rate there must be a very close relation between the processes of blood-coagulation and those of passive immunization.

In view of the settled success of serum-therapy in the treatment of diphtheria it becomes interesting to review briefly the steps which have been taken to apply the same principle to the treatment of other infections and intoxications. It is not surprising that a large number of workers should have turned the current of their research in this direction, and that attempts have been made to prepare specific antitoxins for a whole series of diseases. In the prosecution of the work, however, unexpected difficulties have arisen on many sides, and in no one of the other infectious diseases has any success at all comparable to the results in diphtheria been as yet attained. Vaccinia, smallpox, scarlet fever, tetanus, typhoid fever, cholera, the streptococcous infections, the bubonic plague, syphilis, and tuberculosis, as well as pure intoxications, such as poisoning by abrin, ricin, and venene, all have been studied to a greater or less extent, and with varying success. Ehrlich obtained in animals antitoxins for abrin and ricin in a high degree of concentration, but these antitoxins are naturally of limited therapeutic application in human beings, since cases of poisoning by abrin and ricin are extremely rare. The antitoxin of Calmette, Phisalix, and Bertrand, for rattlesnake-poison, has not yet been produced in a quantity or quality suitable for general application in cases of poisoning in human beings. The results with scarlet fever and syphilis so far offer but little of promise. The same may be said of typhoid fever, although in this disease Pfeiffer and Kolle claim that they have demonstrated in the blood of animals treated for some time with typhoid-toxins a substance in considerable concentration which has a specific bactericidal effect on the typhoid-bacillus. Beumer and Peiper, who injected a sheep at intervals during three months with sterile bouillon-cultures of the typhoid-bacillus, obtained from the animal a serum which possessed marked antitoxic properties, but no direct power (in contradistinction to the work of Pfeiffer and Kolle) of destroying the typhoid-bacilli. They found that when injected into small animals the serum possessed definite immunizing properties against the subsequent injection of the toxins of typhoid, and also proved that the effects of the toxins could be counteracted by subsequent injections of the serum. These observations went to prove, therefore, that the serum possessed healing or curative powers. They experimented sufficiently with human beings, they claim, to show that the injection of the serum was innocuous.

Yersin, Borel, and Calmette have recently been experimenting with the bacillus of the bubonic plague, and have been able to obtain from animals an actively antitoxic serum, which they hope may soon be made available in the treatment of actual cases of the disease.

As to smallpox and vaccinia the results are still conflicting. Kramer, Boyce, Straus, Copeman, Hlava and Honl, Sternberg and Reed are among those who have interested themselves in this subject. At the present stage the only important point definitely proved is that there exists in the serum of successfully vaccinated animals certain substances which possess some powers of neutralizing vaccine-lymph, and also of immunizing certain

moderately susceptible animals against vaccinia. The investigators in this field, like those experimenting with scarlet fever and syphilis, have to deal with a disease the etiology of which is unknown, and are thus working at a considerable disadvantage, since in order to obtain the toxins necessary to concentrate the antitoxic substance in serum it is highly desirable that the microorganism which causes the disease not only be known, but also be easily cultivated.

Le serum antistreptococcique of Marmorek is a product of Pasteur's laboratory in Paris. Marmorek obtained from rabbits a serum, 0.2 c.cm. of which sufficed to protect an ordinary rabbit against a subsequent inoculation with ten times the fatal dose of a culture of streptococci. The cure of an animal after the infection was under way proved to be a more difficult matter. Marmorek found when he worked with a virulent streptococcus, infection with which ran ordinarily a rapidly fatal course, that a rabbit infected three hours before with ten times the fatal dose could be saved by the injection of 1 c.cm. of the antistreptococcous serum. He found, on the other hand, that if five hours had elapsed as much as 5 c.cm. had to be injected in order to save the life of the animal, and that after six hours even quite large quantities of the serum were of no avail. In the case of infection with streptococci of ordinary virulence, however, the animals could be saved by injection as late as twenty-four or thirty hours after inoculation. The serum was proved, therefore, to have some curative powers, but whether its favorable effect was due mainly to germicidal or to antitoxic influences is not clearly stated. Marmorek claims that the serum is specific for streptococcous infections. He experimented with it in the treatment of 413 cases of erysipelas, 17 cases of puerperal fever, and a whole series of anginas and localized streptococcous infections, and thought that its use had brought about a marked diminution in the mortality. It has to be remembered, however, that in a disease like erysipelas, in which the ordinary death-rate is only about 5 per cent., before we are justified in passing judgment upon the efficacy of a new treatment, experience with a much larger series of cases is necessary than when dealing with a disease like diphtheria, in which the average mortality has always been very high.

The work of Gromakowsky upon erysipelas, done in Pawlowsky's laboratory in Kiew, with the serum of immunized animals, is of too limited an extent to add much to our exact knowledge upon the subject. The treatment of carcinoma and sarcoma with the "erysipelas-serum" of Emmerich and Zimmerman does not fall into the category with which we are at present concerned.

Were there only the foregoing results to report, the outlook could not be said to be so very encouraging, but there are three diseases, viz., tetanus, cholera, and tuberculosis, in which advances of greater promise have been made, and for which we have reason to hope that the very near future may yield results sufficiently satisfactory to warrant the use of new serums in the case of human beings.

The first experiments with the tetanus-antitoxin belong to the earliest researches bearing upon the presence of antitoxic substances in blood-serum. Indeed, tetanus was the first disease in which, as a result of animal experiment, positive immunizing and healing results after the use of antitoxin could be demonstrated. This may at first seem strange, in view of the fact that the results in the treatment of tetanus have not up to the present been more satisfactory. According to Behring, investigators had until recently been unsuccessful in obtaining a serum as rich in tetanus-antitoxin as he himself had been able to prepare nearly three years ago as a result of the introductory work done by himself and Kitasato. The greater field opened by the researches on diphtheria led Behring to abandon temporarily his investigations upon tetanus. The serum of Tizzoni and Cattani, which has been used in a number of human cases, is commonly recognized to be insufficient. In France, Nocard, Roux, and Vaillard, who have worked extensively on antitetanic serum, express the opinion as a result of their researches thus far that there is more hope of the serum proving successful as a prophylactic than as a curative agent. On the other hand, Behring stated in his address at Lübeck that Knorr had recently made such improvements in the preparation of the serum that the treatment of tetanus in human beings promises to enter upon a new era. Owing to the rarity of the disease and the expense of the preparation, however, there is some doubt as to whether the industry will ever be prosecuted on a large scale.

As to cholera, the extensive experiments of Pfeiffer have tended to show that the substances present in the blood of animals immune to cholera were not antitoxic to the toxins produced by the bacillus. Pfeiffer found in the serum what he called

Antikörper (anti-bodies), substances which were specifically germicidal to the cholera-bacilli; and while he did not claim that it is impossible to make antitoxins for cholera, they were, he thought, certainly not present in the serum with which he worked. The announcement of Ransom that he had succeeded in determining the presence of antitoxin in the serum of animals immune to cholera was objected to by Pfeiffer on the ground that Ransom's experiments were made with doses of poison only two or three times the *dosis minima lethalis*, so that the results could fall within the domain of the effects of normal serum. Pfeiffer has the hope that these germicidal *Antikörper* may be concentrated sufficiently for use as a prophylactic agent and as a curative agent in mild human cases. That they will be beneficial in the severe cases associated with severe intoxication he thinks improbable; nay, in such cases he suggests that they might even do harm, since by destroying a large number of bacilli they would lead to an increased absorption of toxins.

Much more hopeful are the later reports of Ransom's work. He now seems to have obtained an antitoxic serum which renders harmless from four to six times the minimal fatal dose of cholera-poison. He thinks that he sees his way clear to the preparation of a serum which will render harmless ten times the minimal fatal dose, and it is promised that when this serum can be obtained in quantities it will be made generally accessible, and we shall have the opportunity of trying it in cases of cholera in human beings.

Perhaps as interesting as any are the efforts which are being made toward obtaining a serum antitoxic for tuberculosis. A most important step in the process was made when Koch did his work on tuberculin, an advance the significance of which, owing to the disappointments of an impatient world, was temporarily clouded, and a discovery which, if the prophecy of Behring be correct, will be celebrated, in the not very distant future, with greater *èclat* than that of the toxins of diphtheria. Koch was the first to draw general attention to the fact that the disease was definitely infectious. He placed under the microscope the bacillus which caused it; he devised the means of cultivating it outside the diseased individual; he separated the toxins from pure cultures of the bacillus in the shape of tuberculin, to which he showed that animals and human beings could become accustomed, and thus put the means in our hands for the discovery of the antidote and for measuring quantitatively its strength.

Behring probably stated a great truth when he pointed out that the possession of the poison (tuberculin) is the absolutely necessary preliminary to the preparation of the future curative agent for tuberculosis. In his opinion the articles of Koch on tuberculin must be studied thoroughly by the man who will eventually find a cure for tuberculosis. Behring himself affirms that the whole serum-therapy is an outgrowth of Koch's work on tuberculin, and does not hesitate to acknowledge that he himself was led to enter upon his researches on tetanus and diphtheria simply on account of his conviction that it was possible to do with other bacterial poisons what Koch had demonstrated to be true of tuberculin. The explanation of the fact that animals could become accustomed to tuberculin was attempted at first by conceiving of a gradual development of insusceptibility on the part of living cells repeatedly subjected to moderate doses of poisons. After the brilliant researches of Behring and Kitasato with the antitoxins of tetanus and diphtheria, it became possible to think of the production of blood-antitoxins as a satisfactory explanation of the immunity which could be experimentally produced in animals to the toxins of tuberculosis.

As regards the immunization to tuberculin and tuberculosis in human beings much work has been done in various quarters. The results of Vargas, of Barcelona, with a serum prepared by Mataro, reported in a recent number of the *Revista di Ciencias Medicas*, are so remarkable that they do not seem to us to be worthy of serious consideration. Paquin's serum, obtained from horses after inoculation with cultures of the tubercle-bacillus, has for some time been on the market, and there are occasional reports concerning its use. The experiments made with it by Hewetson, in Trudeau's laboratory at Saranac Lake, would make it appear that this preparation possesses little if any power to check the progress of tuberculosis in guinea-pigs. Numerous reports have been made in Paris to the *Société de Biologie* on experiments relating to the serum-therapy of tuberculosis, but the majority of them contain but little which promises definite results.

Maragliano, in an address before the last meeting of the British Medical Association, spoke of his

experience with the serum obtained from dogs, asses, and horses, after inoculation with toxins of tuberculosis of hitherto unheard-of concentration. In this way he asserts that he obtained a serum which, when injected in suitable quantities along with tuberculin, prevented both the local and general reaction induced by tuberculin. He has used his serum in some seventy-six clinical cases of tuberculosis with, he claims, very satisfactory results. As regards circumscribed and afebrile forms of pulmonary tuberculosis, the results were exceptionally brilliant, and even in severe cases a remarkable amelioration of the condition could often be brought about.

During this year Wernicke, at Behring's suggestion, undertook to demonstrate the presence of an antituberculin in the blood of patients who had been treated for a long time with tuberculin. In this attempt he was successful, and quite recently Behring, in conjunction with Knorr, has been able to demonstrate the presence of antituberculin in the blood of animals rendered experimentally immune to tuberculin. Animals suffering from tuberculosis in a certain definite stage were given subcutaneous injections of absolutely fatal doses of tuberculin. In some, along with the tuberculin, the blood serum from an immunized animal was injected; in others the tuberculin alone was administered; all the former lived, all the others promptly succumbed. Having once determined in this way the existence of antituberculin, the next problem to be solved will be a technical one, and concerns its preparation and concentration, for then, and not till then, shall we be able to test the efficacy of antituberculin in cases of human tuberculosis. Of the experimental work of Trudeau in this country nothing has recently been made public, but much may be hoped for from this quarter.

It is obvious, therefore, that aside from diphtheria, serum-therapy offers as yet to the practising physician more of hope than of achievement. But, as Behring points out, it has always taken the world several centuries to discover a genuine curative agent, and seeing that thus far all the medicines worthy of the name can be written upon a single finger-nail, one should be content with serum-therapy did it yield no more for a long time than a cure for diphtheria. But with the combined force supplied by hygienists, bacteriologists, pathologists, and clinicians, in all quarters of the globe, we may hope that in a certain number at any rate of the diseases to which we have referred, practically applicable results of serum-therapy may be speedily attained.

"THE DEVIL."

Old-fashioned tuners of the piano were accustomed to banish the enharmonic discrepancies of the keyboard to one portion, which was called the devil. All the discords were thus shoved into one octave, which in playing was used as gingerly as possible. It was convenient, but very clumsy and unscientific. The naming of this musical (or unmusical) octave was doubtless in imitation of the theologic habit of ascribing all the inexplicable evil in the world to Satan, thus at one stroke relieving both God and man of the responsibility for sin.

It is hardly to be denied that the habit of mind illustrated by the piano-tuners and the theologians also obtains even in this scientific age in the actual practice of medicine. Perhaps we fall into the habit by accepting it from our patients who are perfectly satisfied if they may believe, *e. g.*, that all their pains and ills are due to "the nerves," or "the rheumatiz," or a "rush of blood to the head." It may be expressed in language more or less erudite and polite, more or less mystifying, and apparently scientific, but in a final analysis, whether we call it "neurasthenia" or "the nerves," it is all one—"Doctor, I've got the nerves, *bad!*" Or, "I'm sure if my stomach was all right, *I'd* be all right."

At such pathetic *sancta simplicitas* we may at first be minded to smile cynically, but we soon find our smile becoming sympathetic with the thought that we are all more or less "tarred with the same stick." We are just as absurd in much of our pathology—we mean the pathology of routine practice, not that of the lecture-room and scientific essay, although it is not entirely absent even there. But when the average physician cannot cure, and when he can account for a morbid tendency or fact in no other way, how common, how very common, it is to shove the difficulty away into some part of the body about which he knows nothing, or which he cannot possibly reach with his therapeutics. This organ or part we might as well call "the devil," as did the old tuners of the piano, for the habit is based upon exactly the same mental characteristics.

For generations the mystic organ of womanhood was the convenient octave of discords to which were ascribed all the ills of womankind. Hysteria,

as we know, is derived from ὑστέρα, the womb, and the etymology to-day indicates a commonly accepted pathology. But even those who have emancipated themselves from this gynecologic ὑστέρον πρότερον, often only do but generalize and expansify the "explanation," and ascribe to the popular but nonlocalized goddess, Hysteria, the woes otherwise inexplainable and incurable. It sounds, however, to expert ears, very like the old-fashioned "the devil take her!"

In the cases of men and boys, and often in women, the explanation of hysteria becomes too far-fetched, and we are prone to rid ourselves of the labor of a more accurate diagnosis, or to hide the impotence of our therapeutics by some cabalistic word, such as "cachexia," "heredity," "diathesis," or "neurotic history." But, frankly, is it not often the piano-tuner's trick over again?

One by one the mystic source and home of pathologic discords is invaded by the modern scientific spirit of medicine, and his Satanic majesty is incontinently driven to more recondite retreats. Just at present we are witnessing his expulsion from the stomach. It is true that we are still far from understanding the mysteries of the chemistry and physiology of digestion. But precisely because of these mysteries—greater far in the past than now—the stomach has been the favorite organ to which to ascribe all incurable or nonunderstood complaints. It was clearly felt that if "the devil" could be chained up there, everybody, patient and professor alike, would feel contented that duty had been done, and that further ills must be endured in a proper spirit of resignation. Of course, if one had anorexia, headache, palpitation of the heart, morbid sleepiness, or what not else, to say "it is the stomach" is perfectly satisfactory, and there the matter should rest. If you are not satisfied with this "explanation"—well, you are a strange person, that is all!

The habit of locating the source of mysterious evils in the stomach is an old one, as may be proved by consulting the history of medicine, where may be found naïve examples. For example, in Lanfrank's *Science of Cirurgie*, the old English translation of about 1400, in treating of cataract, we read: "Signes of the bigynnynge ben these. It semeth to the patient that he seeth bright thingis tofore him & him thinkith that oon thing is ii thingis or thre, & sumtyme it semeth to him that thing that he seeth to be ful of holis, & sumtyme these thingis may come of evil disposition of the stomac, & than it is not so greet drede therof; for whanne the stomac is curid, these signes wolen go awei. In this maner thou shalt wite wher it come of the stomac or of the eyes," etc.

When one considers the varying atrocities and outrageous abuses heaped upon the digestive tract by all nations, and especially by the lower classes of civilization, one is inclined to grow cynical when to the splendid stomach is ascribed a thousand multiform ills originating elsewhere. The conviction grows that much of all this is again a placing upon this maltreated organ the sins of discord belonging throughout the whole keyboard, and in reality modern medicine is so finding the matter out. Notwithstanding the awful dietetic and other abuses it endures, we are learning that, far from being a self-complaining organ, the stomach is wonderfully meek and long-suffering, and that, moreover, instead of only having its own evils to bear, it is made the scapegoat of the sins of many other organs. Considering the digestive function as a whole, its duty is the tremendous one of manufacturing the crude and often wretched materials given it into highly complex and perfect products for cellular nutrition. To this difficult task is often added that of caring for and getting rid of the drugs and dietetic crimes that are commanded by doctor or patient or quack, in the delusion that the stomach is at fault.

It is no exaggeration to say that tons of drugs and seas of "mineral waters" have been thrust into stomachs for headaches due solely to eye-strain. One would find it a humorously impossible task to estimate the amount of nux and cod-liver oil taken for anorexia and anemia really due again to ocular or other distant malfunction. In the minds of many physicians there will probably still long remain the habit of pushing the devil into the stomach, but the new application of the scientific spirit to diseases of the digestive tract is surely to result in finally driving him from that stronghold. In all such instances of lazy diagnosis it will more and more prove impossible to rest satisfied with this convenient bit of slipshodism. If due to the stomach, we are now coming to ask details: How? In what way? Why? How to be treated? The day has about passed when we can rest satisfied that all scientific and therapeutic duty has been done by giving a thing a name, and an inapproachable abiding-place. Test-meals, analysis of stomachal

contents, estimates of secretions, measurements, and all the rest are at last making it uncomfortable for the stomachal Mephisto. He doesn't relish the descent into his realm of "a string with a bucket-like thing." It is plain he will have to migrate to some more inapproachable abode—say the liver, or the spleen, or the medulla.

And so it is to whatever aspect of medicine we turn. The scientist is abroad in the land. His restless and unsatisfiable hunt for causes, his discontent with inaccurate and incomplete diagnoses, is fast driving the devil of disease out of all his retreats. This novel sort of "diagnosis by exclusion" is the order of the day, and the supposed evil spirit of morbidity is being hunted out of all the mysterious hiding-places consecutively given him by the laziness and ignorance either of patient or physician. Just as a scientific understanding of the laws of sound and of piano-construction banished the phonetic devil from the modern piano, so the same spirit of investigation and of thoroughness is driving his *alter-ego* of disease from any one and from all parts of the human economy. It makes the practice of medicine more onerous to the conscientious physician, and it slowly weeds out the nonconscientious and the easygoing. But this is self-evidently all the better for the profession, and especially is it better for humanity.

EDITORIAL COMMENTS.

State Children's Council of South Australia.—There are no orphan-asylums and no orphans in South Australia. This little State, with an area of 904 square miles and a population of 500,000, takes care of 1124 destitute children (Report of July 1, 1895); 996 of these children were placed out in families at an annual expense of £7976. There were 31 girls and 45 boys in the reformatory, and 50 other children in the schools for the blind and the deaf, in the lunatic asylum, and other institutions. Two children absconded during the year. During the last two years the number of destitute children has diminished. At the "Children's Court," 202 were charged with various offences during the year, an increase of 24 cases over the previous year. Only three children were found "residing in brothels." It is interesting to note the result of State care in families of children committed for criminal offences. During five years 104 girls have been "placed out," after brief training in the girls' reformatory. Of these, 62 are doing well, 25 are bad, 5 are doubtful, and 12 are not yet reported. Many of these bad girls have been enticed into the city after the expiration of their sentences, and thus easily fell into their old ways. In the care of the criminal boys a greater success has been attained. The sentence of 147 boys has terminated during the same period, and 137 are reported as doing well.

There is nothing new to report in relation to the system of placing children out. The Children's Council now has 1007 thus cared for; 616 are boarded out, 251 are licensed to service, 52 are adopted, 18 are placed out without subsidy, 49 are licensed to relatives, 2 are apprenticed, 8 are out of the colony with guardians, and the rest are in schools for defectives, in hospitals, and other places. The Council received during the year 7277 reports in relation to these children; 3382 from visiting committees; 2056 from inspectors; and 1839 from schoolteachers. In classifying these reports on the conduct of the children and condition of the home, 5104 and 5354 respectively reported good; 269 and 74, fair; 57 and 9, indifferent; and 8 and 1, bad. The reports of the teachers show that the children are carefully taken care of and apparently well treated, and that with few exceptions they are well behaved.

There were 368 applications made for children: 94 from Roman Catholic families, 77 from Church of England, and 197 from other Protestant applicants; 266 of these were approved.

In the savings banks the children had £2458, about $12,000, of their own earnings, at the beginning of the year. This has been increased by £726 deposits and £78 interest during the year; £523 has been paid to children.

Five children have died during the year. One was drowned. Rheumatic fever, congenital syphilis, lymphemia, and marasmus, each took off one.

The Children's Council was able to collect from parents £1096 for maintenance-fees and other similar fees sufficient to make a total of over £2237. The total income of the Council was £14,276, and the net cost to the State of the work of the year was £13,104.

It is unnecessary to mention the fact that in all the Australian provinces the system of "placing out" now prevails. The method is cheaper, better, and more humane than any form of huddling the poor and miserable together, and is attended with a lower death-rate and fewer defectives.

Epistaxis through the Eyes—A recent brief editorial note on epistaxis through the eyes develops what should be a well-known fact, *i. e.*, that many curious occurrences may escape an individual experience, however large. In response to our inquiry as to other cases similar to that referred to in THE NEWS of November 30th, we have received further reports from five correspondents.

Dr. T. L. Wilson, of Bellwood, Pa., relates the case of an old lady of seventy-eight whom he found with the blood gushing from the nostrils. After plugging the nares thoroughly with absorbent cotton dusted with tannic acid he was surprised to see the blood ooze out around the eyelids and trickle down the cheeks. This oozing continued for the greater part of an hour, being finally controlled by applications of ice to both sides of the nose.

Dr. F. L. Donlon, of New York City, reports the case of a married woman, about fifty years old, in whom epistaxis set in suddenly at 11 P.M., and had continued for several hours, when the anterior nares were plugged. In a short time the woman complained that she could scarcely see, owing to the welling up of blood into her eyes and trickling down her face. The bleeding only ceased when the posterior nares also were plugged.

Dr. G. A. Neal, of Alabama, N. Y., details the case of a housekeeper, seventy-five years old, who had had sev-

eral severe left-sided nasal hemorrhages during three days before she summoned medical aid. On plugging the affected nasal cavity, both anteriorly and posteriorly, blood immediately appeared in the corresponding eye in drops that would have trickled over the cheek had they been allowed to collect. The bleeding continued thus for several minutes. Some thirty-six hours later, and before the plugs had been removed, the woman felt more fulness than usual in the diseased nares, and blood soon again appeared in the eye. This time but a few drops passed through the lacrimal duct. The woman gave a history of having had nasal catarrh for many years, but never epistaxis, of any account at least; neither has the hemorrhage recurred.

Dr. T. G. Wright, of Plainville, Conn., narrates the case of a young man whom he found in the night bleeding profusely and having already lost a large amount of blood. Shortly after plugging both anterior and posterior nares the blood found its way through the lacrimal ducts to the eyes and trickled down the cheeks.

Dr. Charles W. Crumb cites the case of a man, sixty-five years old, with chronic nephritis, in whom a slight bruise of the nose was followed by epistaxis lasting twenty-four hours. When the nares were plugged blood escaped freely from the eyes. A cone-shaped bit of sponge, saturated with ferrous sulphate, was passed into each anterior naris, and another piece of sponge similarly medicated into either posterior naris. The patient had been taking various preparations of potassium, and it was thought that his blood contained a deficiency of fibrin. Upon removal of the nasal plugs a catarrhal inflammation developed which lasted a long time and was attended with considerable purulent discharge.

The William Pepper Laboratory of Clinical Medicine.—Philadelphia has recently been enriched by the addition to her scientific resources of the William Pepper Laboratory of Clinical Medicine, a gift to the University of Pennsylvania by the present incumbent of the Chair of the Theory and Practice of Medicine and of Clinical Medicine, in memory of his father, who occupied the same chair from 1860 to 1864, in which latter year his death occurred from pulmonary tuberculosis at the age of fifty-four years. The plans for the building were prepared by Dr. John S. Billings, the Director of the University Hospital (in especial conjunction with which the laboratory will be conducted) and Professor of Hygiene in the Medical Department of the University. Dr. Pepper will himself be the first director of the laboratory, who, together with the assistant director, is appointed annually by the Board of Managers of the University Hospital upon the nomination of the Professor of the Theory and Practice of Medicine and of the Professor of Clinical Medicine. The specific purpose of the laboratory is the promotion of the interests of the patients in the University Hospital "by the prosecution of minute clinical studies and original researches, and to advance the interests of science by the publication of the results of such work." Instruction will be given to graduates only of approved medical schools whose curriculum corresponds with that of the Medical Department of the University, and provision will be made for advanced workers engaged in original research.

Dr. Pepper has in the past been lavish to the University of Pennsylvania in the giving of time, energy, influence, and money to advance the interests and to secure the welfare of the institution with which he has for many years been so closely identified, but this last gift is the crowning act of a career marked by tireless activity and munificent generosity. He has created for himself a monument more noble than carving of stone or casting of bronze, and his example should be an incentive to others to further the great work which he has thus begun.

The University of Pennsylvania, as well as our city and State, is to be congratulated upon this welcome addition to her scientific armament from which mankind may expect so much of genuine benefit.

The Lying-in-hospital Business seems to be profitable and on the increase. The names of doctors by the dozen are appended to the circulars that frequently come to us. We have before alluded to this strabismic use of the profession. We do not say that all such institutions are bad, or indeed that any are, but it is noticeable that emphasis is always laid upon the phrases, "those who for any reason desire confinement away from home," and "a home is provided for the infant if the parents desire to part with it." It would seem from the experience of older countries in this delicate matter that there should be legislative and governmental oversight of these multiplying *lying-in* houses, or the name will degenerate into a very truth-telling pun.

SPECIAL ARTICLE.

A TRIP TO MEXICO.

BY DOUGLASS W. MONTGOMERY, M.D.,
OF SAN FRANCISCO, CAL.;
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA.

IN view of the International Exposition to be held in the City of Mexico next year, I have thought that a short account of my trip to that picturesque country last May might be of interest to the medical fraternity.

Going from California to Mexico by way of the Southern Pacific Railroad one crosses Arizona. There is no doubt of this Territory being a desert, and that the sun is mistress of the situation. She rises in the morning like "a fair, hot wench in flame-colored taffeta," and she retires at night in the same outfit. The glare is even worse than the heat, and it seemed to me that I had never seen people with more wrinkles around the eyes and with smaller "eyeslits," evidently caused by the effort to keep out the intense light.

While passing through Arizona I had the pleasure of meeting Dr. Helm, of Phœnix, who gave me an account of a disease of which Dr. George Chismore had first told me. It appears that a fly, the scientific name of which is unknown to me, deposits its eggs in the nostrils of those who lie unconscious in the sun—of a man who is dead drunk, for instance. The resulting maggots are pointed at both ends, and are called "screw-worms." Having secured lodgment, they give rise to a destructive inflammation of a most disagreeable, and, if unchecked, dangerous nature. Dr. Helm has had several cases of the malady, and says that the insufflation of calomel-powder for two or three days will destroy the pests. He had one case in which they

complicated a fracture of the lower jaw, but were quickly driven out by the treatment mentioned.

At El Paso we changed from the Southern Pacific to the Mexican Central Railroad, and here it is well to be prepared for a "cinch" of the kind that travellers in all countries are exposed to. If the Southern Pacific train reaches El Paso behind time, which I understand it frequently does, one is told that the Mexican Central train has already crossed the river to Juarez, and that one will have to hurry across after it in order to allow time for the examination of baggage. One is also told that the transfer-coupon on the through ticket is of no use in the present emergency, but that a baggage-transfer company will undertake the job of getting the embarrassed traveller and his luggage across for a consideration. It can easily be seen that this little matter had better be settled with the Southern Pacific Company on purchasing the ticket, as it is likely to be arranged more satisfactorily at that time. The Mexican Central Railroad running from El Paso to the City of Mexico is really an American road, owned in Boston, and having American officials and train-hands.

On the way down I asked the Pullman conductor how they got along in the recent Pullman strike. "Oh!" he said, "we didn't strike. President Diaz sent a proclamation along the line that if any trains were interfered with, he would put a law meant for brigands into effect; that any man caught stopping a train or diligence would be taken out and shot within twenty-four hours without trial. So we didn't strike." I spoke about the strike to every train-hand that gave me the opportunity, and the strange thing about it was that they very evidently bore Diaz no ill-will for his high-handed procedure. Diaz's mode of meeting the difficulty was as high-handed as unlawful, according to our ideas, and as arbitrary as the strike itself. These same trainmen, however, could not find words strong enough to express their disapprobation of the deliberate legal measures adopted in the United States. It all means that these men, who, in ordinary questions, are shrewd and fair enough, have not yet learned to know law when they see it. The capitalist has his way of making a fool of himself, too; but, as Rudyard Kipling would say, that is another story.

The sleeping-cars are not nearly so comfortable in Mexico as in the United States. It is said that the Pullman Company sends its oldest coaches into "the dusty Republic," and one can well believe it. I had a rather amusing experience in one of them. In going from Silao to Jimenez I took the drawing-room, and at first it was delightful, especially the *sans gêne* opportunity one had to wash one's self; but later on, when I went to bed, I found there was too much draft. I closed up everything, but still I slept in a tornado, and, being tired and sleepy, at last gave up the search for the mouth of the cave of the winds. Next morning I saw what was the matter. The drawing-room was at the forward end of the car, and there was a large space under the outer door of the coach, and a corresponding one under the door of the drawing-room. In order to be comfortable, therefore, the drawing-room should have been at the rear of the car. I had a first-class "cold" to pay for the experience; but this was not all. Either through some defect in the construction of the soil-pipe, or because the car was going wrong end first, each time the water-closet lid was raised a gust of wind swept up it and straight into the drawing-room. The odor complained of by Don Quixote on the night of the adventure of the fulling-mills was at least in the open country.

In buying money do not get the notes of any of the individual States, if you do not want a too practical acquaintance with the intricacies of the modern Aztec monetary system. In El Paso, which is in the State of Chihuahua, I offered some Chihuhua State Bank notes in payment for my sleeper to the City of Mexico, but the money was refused because they were State Bank notes. They, however, took Mexican National Bank notes readily; that is to say, perfectly good State Bank notes were refused in the very State on which they were drawn. I afterward disposed of this money in the City of Mexico at a discount of 4 per cent. This is the financial system many of our own long-haired financiers would have us adopt in reviving the wild-cat State Banks in this country. Mexican silver money is a weariness to the flesh. Nothing makes a man so spendthrift as lugging a lot of silver when it is down to its true value, as it is in Mexico. Forty dollars of it is a load for a jackass. We Yankees are in better luck. Uncle Sam is the jackass.

During my entire trip in Mexico it struck me that a change from a gold to a silver monetary basis in our own country would be disastrous in regard to medical fees, and this is a view of the question that naturally most interests us. The bulk of our income is collected in small amounts in the office. These fees are largely regulated by custom, and custom would dictate that what is now a five-dollar fee in gold would continue to be a five-dollar fee in silver. This custom for the rank and file of the profession, especially in the older States, would be unbreakable. A few of the great specialists in the large cities would possibly be unaffected by it, but even they would feel it for the first few years while values were being readjusted.

The high plateau, the flattened back of the Rockies, or the Sierra Madre, as these mountains are called in Mexico, which includes nearly the whole of the area of the country, is arid and dusty. The water-supply of the cities and towns is wretched. Guadalajara, for instance, which is a large, clean-looking, well-built city, with an air of industry and thrift, has still the vicious system of bringing drinking-water from outlying springs on donkey-back. The lazy water-carriers often draw their load from a nearer, and possibly infected, source. Dr. Orvañanos has given an instance[1] of a whole family attacked by diarrhea from drinking water that showed a large amount of organic matter. Their water-carrier afterward confessed that he drew his supply from a more convenient spring than he was supposed to use. In other words, it is a system requiring more than ordinary vigilance to secure good service.

The plateau is from 5000 to 7000 feet above the sea-level, and the consequent rarity of the atmosphere, together with the arid climate, causes a rapid loss of fluid by evaporation. This must be compensated by drinking enormous quantities of liquid. It is, therefore, all the more necessary that the water-supply be pure. All the water I drank was boiled either in the form of

[1] Ensayo de Geographia Medica y Climatologia por el Dr. D. Orvañanos, 1889, page 49.

tea, coffee, soup, or simply as boiled water, till Guadalajara was reached, where natural human carelessness asserted itself, with a disagreeable diarrhea as a result.

There is a number of medical schools in Mexico, but the one in the Capital is the largest, having from 350

FIG. 1.

Nervous type of leprosy.

to 400 students. The cost of maintenance and the salaries of the professors are borne by the State, the students paying no fees whatever. Five years are supposed to be occupied in preparatory studies before commencing the study of medicine, and five years in the medical school proper. They think of lengthening the time spent in the medical school to six years, which would be a mistake. Four years is long enough to give a man a good grounding in the main branches of the profession, and he should then be permitted to take his degree. After being out of leading strings he may elaborate his knowledge in any direction he pleases.

A curious and a very injurious feature of medical education in Mexico is the almost exclusive use of French text-books, or text-books translated into French. In Guadalajara, for instance, they use a French translation of Eichhorst's *Practice of Medicine*. I understand they have introduced one Spanish text-book into the school in the City of Mexico—Ramon y Cajal's *Histology*, which, if it comes up to some of the rest of that author's work, should be an excellent production. The students read the French works, but receive their lectures and answer their questions in Castillano. This continual use of foreign literature must be a clog to originality of research on the part of both professors and students, and consequently a great misfortune to both Mexico and the world, as each country has something peculiar to itself to bring to the general stock of medical knowledge.

The human foot is so tender and so liable to injury that the proper protection of it has interested many men, especially army-surgeons, who see the necessity of keeping the soldiers' feet in good condition on long marches. It has often been contended that the Mexican sandal is an ideal foot-gear for marching, as it allows freedom of movement in every direction, and does not scald the foot by retaining the sweat in a confined space, as the boot is prone to do. This *guarache* or *catle*, as it is called, resembles the apostolic sandal we are accustomed to see in sacred pictures. It is made of a thick piece of cow-hide, and is bound to the foot by leather thongs. The *guarache* is picturesque, and no doubt the Mexicans find it fairly comfortable, as they are a remarkably handy people in the use of leather for all sorts of purposes, and probably can bind on a sandal much better than we could. Even so, however, its superiority to the shoe is doubtful, and this opinion would seem to be reinforced by the fact that it is being gradually discarded in the Mexican army itself. One would think that the thongs would cut into the flesh on a long march.

The clothing of the ordinary Mexican is scanty. When he sits down in a wet place he finds the fact out at once. He wears cotton drawers, a cotton shirt, sandals, a blanket, and a hat like a circus-tent. Yet there is very little pulmonary tuberculosis, although the climate at times is severe enough. This absence of tuberculosis among the Mexican Indians is in marked contrast to the condition of our own aborigines in this respect. That light raiment is not a matter of choice, but of poverty, is shown by the way the richer people wear woollen goods. In the matter of food, too, the poor live on a vegetable diet almost exclusively, while the well-to-do indulge in a wearisome number of meat-

FIG. 2.

Tubercular type of leprosy.

courses. In reference to this an amusing incident occurred while I was in Mexico. It appears that a number of negro families had been induced to migrate from our Southern States to Durango. In a short time the pork and flour furnished by the company gave out. As

there were neither chickens nor hogs to steal, they had to come down to the diet of the country—brown beans. Sambo could not stand that and struck out for home. As I was going down through Mexico they were straggling back to the States along the line of the Mexican Central Railroad. A Mexican on the train, in speaking of the matter, maintained, and quite learnedly, that laborers did not need meat in the Mexican climate. He himself, however, ate meat at all meals, and I especially remember seeing a nice piece of ham on his plate. As far as I can make out man eats meat in every climate, if he can obtain it.

There is considerable leprosy in Mexico, and there does not appear to be either much fear of the disease or much effort to segregate it. In the Hospital de Belén in Guadalajara there were about half a dozen lepers scattered about the wards. One of them had the atrophies, deformities, and ulcerations of the hands and feet, such as occur in neural leprosy, but the trunk, neck, and head were entirely free from disease. In fact, Dr. Garciadiego, who kindly showed me the case, drew my attention particularly to the man's magnificent physique and to the clean skin of the trunk, head, and neck. Another case presented the tubercular type, and the lepra-tubercles formed huge symmetric masses on the face, giving the patient a most peculiar appearance. I had these two cases photographed, and have inserted reproductions in this article. I saw a leper of the neural type begging at the station at Jimenez; his fingers and toes were shortened, his palms flattened, and there was paralysis of the right orbicularis palpebrarum.

SOCIETY PROCEEDINGS.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in Washington, D. C., November 12, 13, and 14, 1895.

(Concluded from page 671.)

SECOND DAY, NOVEMBER 13TH.

Afternoon Session.

DR. JOHN A. WYETH, of New York City, delivered a memorial address on

DR. J. MARION SIMS AND HIS WORK.

He said it was safe to say that Marion Sims attained the highest position ever achieved in the history of the profession. He stands alone in this; his reputation as a surgeon was so world-wide that in any capital, in any country within the domain of civilization, he could have commanded at any time a lucrative practice. Assuredly, there does not exist in the history of surgery another such distinction. In New York, London, Paris, Brussels, Berlin, Vienna, Rome, Madrid, Lisbon, and St. Petersburg he found himself everywhere sought after, not only by the patients he could benefit, but by the leading members of his own profession, who were anxious to pay tribute to his wonderful genius. The study of his life should instil hope into the heart of every student. Born amid the most humble conditions in a backwoods county of South Carolina, he died the foremost surgeon of his country and of the world. What a transition from the log-cabin of the poor farmer in Lancaster District to the palace of Saint Cloud, where he was the guest of Napoleon III, the trusted physician to the Empress, as he was to the highest and lowest of those who sought relief at his hands in any part of Europe!

Toward the higher and purer civilization the progress of man is slow. As yet the shadows of barbarism linger about him. His heroes are the destroyers, the Cæsars and Napoleons, who covered the earth and buried beneath it lives, sacrificed upon the altar of personal ambition. But the time must come when those whose genius and works give life and health and happiness to the world will be the first in the heart of man. In this purer temple of fame, along with those of Jenner, Ephraim McDowell, Morton, Lister, Pasteur, and others, generations yet unborn shall read the name of Marion Sims.

At the close of Dr. Wyeth's address, remarks eulogizing Sims were made by Drs. Robinson, Wilson, Nelson, Marcy, Engelmann, Kollock, Vander Veer, Gaston, Tiffany, and Westmoreland, most of whom had enjoyed his personal acquaintance.

DR. GEORGE BEN JOHNSTON, of Richmond, Va., read a paper entitled

COMPARATIVE FREQUENCY OF STONE IN THE BLADDER IN THE WHITE AND NEGRO RACES.

He said that it is commonly stated by writers on urinary diseases that stone in the bladder is of rare occurrence in the negro race. This is so at variance with the author's experience that he has instituted an investigation either to prove the statement or to correct the fallacy. He selected the States of Virginia, North Carolina, South Carolina, Alabama, Georgia, Tennessee, Kentucky, Florida, Louisiana, Mississippi, Arkansas, and Texas as the field of inquiry, and corresponded with four-hundred representative practitioners in order to procure the necessary data. He received 338 responses, 94 of which contained information and the remainder were negative. He succeeded in collecting 1068 cases of stone in the bladder. Of these, 952 were in white subjects and 116 in negroes. It is at once observed that the negro cases represent 9.55 per cent. of all cases reported. This showing is quite sufficient to disprove the idea of immunity which the negro is supposed to enjoy.

Geographically these stones were distributed as follows: Alabama, 10; Arkansas, 11; Florida, 28; Georgia, 90; Kentucky, 56; Louisiana, 19; Mississippi, 9; North Carolia, 126; South Carolina, 66; Tennessee, 128; Texas, 98; Virginia, 430.

Sex is specified in 780 cases and is not stated in 280. Of those in which the sex is indicated, there were 691 in males and 97 in females, or about seven times more males than females.

There were 182 cases not subjected to operation, and 584 in which the stones were removed by the following methods: Lateral perineal, 249; median perineal, 100; suprapubic, 138; vaginal incision, 32; dilatation of the female urethra, 28; crushing, 35; in 5 the operation was not stated.

Of those operated on 541 recovered and 43 died. No report of operation was made in 304 cases. Dr. John-

ston's own cases are incorporated in the foregoing statistics. During his twenty years' practice he has made notes in 41 cases. Of these there were 35 in whites, 6 in blacks; 39 in males and 2 in females. Thirty-nine were operated on and 2 were refused operation on account of advanced renal disease. Both of these died. In 25 cases lateral perineal lithotomy was done, in 12 suprapubic, and in the cases of the two females the urethra was dilated and fragmentation practised. There were no deaths following his operations.

DR. L. MCLANE TIFFANY, of Baltimore, Md., delivered the

PRESIDENT'S ADDRESS.

He said that the aim of the Association was twofold, namely, first, to do advanced work, and, second, to bring it to the notice of and to aid other members of the profession. The Fellowship of the Association was a very extended one, embracing a large territory with infinite varieties of soil, temperature, environment, etc., yet the *Transactions* did not show those local records from which facts may be generalized, applicable to the area from which the Fellowship is drawn. It did not seem reasonable for him to suppose that a surgical operation done among the mountains of Western North Carolina would behave quite the same way that a similar operation would if done on the Gulf coast of Texas. It did not seem reasonable that similar surgical operations on the banks of the Mississippi and the central plateau of Tennessee would behave the same way. Accurately kept charts with exact and careful notes would unquestionably show differences not yet placed on record by anyone and from which much clinical information could be learned. Again, he questioned whether surgical operations undertaken during the great heat of summer, or after the long continuance of summer heat, would show similar charts or give like results when compared with operations upon patients not subjected to high atmospheric temperature, either temporary or long continued. No association had a membership better situated or more competent to carry on a series of such investigations.

DR. WILLIS F. WESTMORELAND, of Atlanta, made some remarks on

CYSTOTOMY FOR STONE.

He said that any surgeon of the present day who had had a long and extensive experience in operating for stone must acknowledge that the upper operation is better and safer. Unless there is a pathologic condition of the blood or infection of the bladder, as recognized by chemic or microscopic examination, the surgeon could decide before operation what course to pursue. Dr. Westmoreland said that the anatomy of this region, as laid down by the investigations of Strong and Peterson upon the cadaver and frozen sections, led the surgeon astray, and the observation of the surgeon is more to be depended upon than any literature we have thus far pertaining to the subject. In operations for stone, the author said that he does not care whether he sees the base of the bladder or not; that he depends upon touch, and that therefore rectal distention might be dispensed with. In the place of rectal distention he recommends that a vessel of water be suspended three or more feet above the patient according to the amount of distention necessary. When the surgeon desires to effect distention of the bladder by a vessel, if the bladder is ulcerated at any point, with a thickening here or a thinness there, it could be done without sudden force, and if the patient during an operation should sneeze or cough, or contraction of the bladder take place, instead of contracting upon a solid mass of fluid, the fluid is forced back into the vessel and there is practically no increase in pressure.

DR. CORNELIUS KOLLOCK, of Cheraw, S. C., read a paper on

ABDOMINAL PREGNANCY.

After referring to the pathology of extra-uterine fetation and the classification of its varieties by early writers, he reported the following interesting case: On October 18, 1894, he saw for the first time a dark mulatto, 34 years of age, the mother of three children, whose general health had been good until within the last fifteen months. The abdomen was very much distended, measuring at the umbilicus 63 inches. Fluctuation was evident and wave-tap very distinct. The patient affirmed that she was pregnant, and that she had gone four months beyond the actual period of gestation. After a thorough examination celiotomy was decided upon, and an incision was made four inches in length below the umbilicus. The walls were so thin that the instrument penetrated the cavity before it was certain that the abdominal muscles were divided. There was a sudden and copious discharge of offensive matter. An immense fibroid was removed from the anterior portion of the sac. The cavity also contained a fetus weighing 10 pounds. The placenta had undergone fibroid degeneration, with only a small part of the placental tissue remaining. The patient was extremely weak when operated on. She lived for five or six weeks after the operation, and Dr. Kollock thinks she would be alive to-day were it not for the unfortunate intervention of intestinal obstruction.

DR. J. T. HENRY, of Chester, S. C., reported

A CASE OF EXTRA-UTERINE PREGNANCY.

The abdomen was freely opened and a large, dark mass the size of the head of an adult came into view. The uterus was crowded very much forward. The mass lay posterior to it and was very much adherent to the fundus posteriorly and to the promontory of the sacrum. The fimbria of the right tube spread out over the covering of the mass. It was with some difficulty that the mass was freed from its attachments, except that portion at the fundus of the uterus, and it was thought best to remove the uterus with it; and this was done after tying and cutting the broad ligaments. The fetus was five inches long and lay between the placenta and the uterus, the cord being attached to the left margin of the placenta. The abdomen was thoroughly washed out with sterilized water and closed without drainage. The patient sat up on the fourteenth day after the operation, was out of bed in twenty-five days, and has gained 25 pounds in weight.

DR. HENRY O. MARCY, of Boston, read a paper on

THE TECHNIC OF THE BURIED SUTURE.

He said that constant receipt of letters, from all parts of the country, containing inquiries concerning a method for the safe application of the buried animal

suture, prompted him to make this communication. At the risk of seeming dogmatism, he would venture to assert that aseptic wounds, with very few exceptions, should be primarily closed by buried tendon-sutures and hermetically sealed with iodoform-collodion. Carefully selected tendons are to be preferred for buried sutures, as primarily their anatomic constitution makes them stronger, more compact, and, as a consequence, more resistant to the softening processes that must ensue when buried in the living structures. When properly preserved, they have not been subject to bacterial decomposition, and hence may be sterilized without detriment to their ultimate elements. When tendon has been chromicized, it is best preserved in a sterilized oily fluid. Experience has shown that by far the best preserving fluid is linseed-oil sterilized by heat, to which carbolic acid has been added. Tendon improves so much when thus kept that Dr. Marcy rarely uses it until it has been in carbolic acid from three to six months. A method far too common has been to preserve chromicized catgut and tendon in absolute alcohol boiled under pressure. There is no question but that such material is absolutely sterile, but the important factor has been singularly overlooked, that by this process the chromic acid is dissolved out of the tendon, thereby leaving it less valuable than if chromic acid had not been used.

The infection of wounds may never be absolutely prevented, but the experience of surgeons teaches daily to what a marvellous extent it can be minimized, and reduced in aseptic wounds to less than 5 per cent. Not long ago the author examined his own personal experience, reviewing 600 operations, with only 2 per cent. of septic cases—evidence ample to show the safety of the coaptation of wounds by means of the buried animal suture.

One of the interesting features of the meeting was the presentation to the Association of a gavel made from the leg of the operating table used by Dr. J. Marion Sims in his office for twelve years preceding his death. It was the gift of his son, Dr. H. Marion Sims.

The following officers were elected:

President, Dr. E. S. Lewis, New Orleans, La.; *First Vice-President*, Dr. Joseph Taber Johnson, Washington, D. C.; *Second Vice-President*, Dr. Richard Douglas, Nashville, Tenn.; *Secretary*, Dr. W. E. B. Davis, Birmingham, Ala.; *Treasurer*, Dr. A. M. Cartledge, Louisville, Ky.; *Chairman of Committee of Arrangements*, Dr. W. D. Haggard, Nashville, Tenn.

Place of meeting, Nashville, second Tuesday in November, 1896.

CORRESPONDENCE.

ILLINOIS STATE BOARD OF HEALTH vs. NORTHWESTERN UNIVERSITY WOMAN'S MEDICAL SCHOOL.

To the Editor of The Medical News,

Sir: In the July issue of various prominent medical journals appeared a letter from the Illinois State Board of Health, accompanied by a set of resolutions adopted by said Board. The undersigned, the Executive Committee of the Faculty of the Northwestern University Woman's Medical School, having carefully investigated this matter, desire to make the following report, in order that no injustice may be done to the State Board:

The resolutions adopted by the State Board are as follows:

Whereas, The Faculty of the Northwestern University Woman's Medical School adopted a set of resolutions criticising the Illinois State Board of Health for having issued to three non-graduate students of said college the State certificate entitling them to practice medicine, whom they claim were not entitled to receive them, and charging the Board with having adopted a lax policy in numerous other instances, thereby seriously detracting from the usefulness of the Board; and

Whereas, Although the resolutions were "ordered to be placed before the Illinois State Board of Health," they were furnished to the various medical publications of the country simultaneously with their presentation to the Board, and before the Board had an opportunity to make any defence; and

Whereas, The said college had not made any investigation of the methods or policy of the Board, and could not be in possession of information upon which to found such serious charges; and

Whereas, The Secretary of the Faculty admitted to the Secretary of the Board that the resolutions were adopted without due consideration, and were not so applicable to the present Board; and

Whereas, In the past two years no certificate has been granted to any applicant upon an average rating less than 80 per cent. on all branches, and the questions and examination-papers and a tabulated record of all examinations are preserved, and are matters of record in the office; and

Whereas, It is not in the province of the Board to adopt any policy regarding the admission to its examinations of non-graduates, the law prescribing that "non-graduates shall submit themselves for examination," and further prescribing that "the examinations shall be of an elementary and practical character;" therefore, be it

Resolved, That justice demands that the Faculty of the Northwestern University Woman's Medical School, and all others interested, inform themselves as to the methods and policy of the Illinois State Board of Health in conducting its examinations, with a view to the establishment of the charges made, or of making such withdrawal, alteration, or explanation of the charges as the facts may warrant; and, further, that the Faculty inquire as to whether any individual interest or personal animosity prompted the drafting and circulating of the resolutions.

(Signed)

B. M. Griffith, M.D.,
Sarah Hacket Stevenson, M.D.

The original resolution of the Faculty of the Northwestern University Woman's Medical School, to which the above refers, is as follows:

Whereas, On three occasions within the past three years the Illinois State Board of Health has licensed to practice medicine in this State students who have not properly qualified themselves for such duties, and whose incompetence has compelled us to withhold the degree of doctor of medicine; and

WHEREAS, By common report we are informed that the State Board has adopted a similar policy with reference to numerous other persons; therefore,

Resolved, By the Faculty of the Northwestern University Woman's Medical School, that the State Board of Health be requested hereafter to make its examinations so rigid that persons incompetent to obtain the degree of doctor of medicine from first-class medical colleges cannot obtain licences to practice from the Illinois State Board of Health.

Resolved, That the State Board of Health be urged to do all in its power to secure a modification of the State law, so that the privilege of examination for licence to practice in this State can only be obtained by graduates of recognized medical schools in good standing.

Resolved, That for the protection of the lives and health of our people we believe it is the duty of the State Board of Health to do all in its power to prevent the entrance into the medical profession in this State of any persons not properly qualified; and, further,

Resolved, That in the interests of humanity and medical science we believe the State Board should make its standard of qualifications as high as that of the best medical colleges in this country, and that it should do all in its power to aid and encourage the efforts of the profession and the people for thorough medical education and higher requirements of licentiates and for the degree of doctor of medicine.

(Signed) MARIE J. MERGLER,
Secretary.

Replying to the State Board of Health, we beg to state that after thorough investigation we find that not only the three incompetent undergraduates referred to in our resolutions, but others similarly conditioned from our school, have been granted licence to practice medicine; and we find, further, that it is believed by medical teachers and other members of the profession that the State Board of Health has frequently conferred the licence to practise in the State of Illinois on undergraduates whose requirements were not sufficient to enable them to obtain the degree of doctor of medicine from the medical schools of the State that are recognized as in good standing by the Board of Health.

This policy is not calculated to advance the standing and active usefulness of the medical profession or to protect the public from incompetent practitioners. The Board of Health and its individual members have been *repeatedly* urged to discontinue this practice; but as these remonstrances have heretofore proved unavailing, the Faculty of the Northwestern University Woman's Medical School determined by public action to bring the matter to the notice of the profession, hoping thereby to obtain their aid in securing a better policy by the State Board.

The Board is in error in thinking that the Faculty acted hastily or without investigation, for it was familiar with the fact of the licencing of incompetent persons, not only from among *its* students, but among students of other schools. This practice has been in vogue since the first organization of the Board; but the last cases were, if possible, more flagrant and inexcusable than those which preceded them.

The Secretary of the State Board of Health is mistaken in stating that the Secretary of the Faculty of the Woman's Medical School said that the resolutions were adopted without due consideration, though another member of the Faculty did admit to him that if his statements were correct, the criticisms were not so applicable to the present Board as to former Boards; however, the Secretary is not aware that the practices of the present Board differ materially from those followed by earlier ones composed of a different membership.

Shortly after the original resolution was passed, the Secretary of the State Board of Health interviewed several members of the Faculty, and on one of these occasions stated, in extenuation, that the particular individuals now in the State Board of Health constituted an entirely different Board from that of former years. We are aware that the State Board of Health changes more or less from time to time in its *personnel;* but one of the signers of the series of resolution under consideration has been a valued member of the State Board for many years, and we cannot understand why he should have allowed such a practice as granting licences to incompetent persons at any time without a vigorous protest.

If the policy of the Board as now constituted is better than that of former years in this respect, it appears to be only a degree, for the same official, in one of these interviews, stated that no applicants for licence were now passed on an average of less than 85 per cent. on all branches, whereas the resolutions printed above place it at 80 per cent.; but he also admitted that formerly applicants were passed on a grade of 50 per cent. It must be borne in mind that the grade obtained on an examination depends upon the nature of the questions, the fairness with which they have been given out, the honesty with which they have been answered, the care taken to prevent cheating, the fairness with which they have been marked, and the qualifications of the examiner. Questions may be peculiarly easy; proper care may not have been exercised to prevent them from falling into the hands of the applicant beforehand or to prevent communication by the interpreters or others at the time of the examination, or the examiner himself may have marked too high. For example, an examiner who knew very little of anatomy might consider a very poor paper on that subject of exceptional excellence.

The Secretary of the State Board explained to us his efforts to prevent cheating among applicants for midwives' licenses, and he led us to infer that similar precautions were taken for those taking the medical examinations. He asked if we questioned the honesty or ability of certain members of the Board of Health; but, as we stated to the Secretary thereof, we cannot understand how an ignorant person, unable to obtain a grade of more than 35 or 40 per cent. on an ordinary examination for the degree of doctor of medicine, can come before the State Board within three, six, nine, or even twelve months afterward and pass an excellent examination. Teachers know that it is impossible to acquire a knowledge of medicine with this rapidity; therefore the inference would be that 80 or 85 per cent. by the State Board of Health is equivalent to little more than 35 or 40 per cent. by the colleges. If this is so, the State Board should raise its grade still higher or mark more carefully.

It was also admitted, in one of these interviews, that

one of the persons referred to was in no way fitted to practice medicine; but it was claimed that the answers obtained from her in examination were excellent, and that the Board had no option in the matter. As a possible explanation of the excellence of the papers handed in by ignorant applicants, it was suggested that anyone could "cram" and pass a good examination on two or three subjects; and it was explained that it was the custom of the Board of Health to give those taking their examinations full credit for each and every branch in which they succeed in obtaining a passing mark, though they might utterly fail in all others. It will be readily seen that in an extreme case this policy would allow an applicant to pass one branch at a time every three months (we believe the examinations are quarterly) until the whole had been gone through, while at the time the licence was granted the person might not be able to obtain a general average of over 25 per cent. We are not informed, officially or otherwise, that the Board has even yet taken any step to correct this bad practice.

It is stated in these resolutions that the Illinois State Board of Health is not at liberty to adopt any policy regarding the admission of non-graduates to examination—that is, persons mentally or morally unfit to practice medicine must be admitted to the examination if they apply; but certainly the law cannot require the Board to issue licences to such persons. In our resolution we called upon the Board, if there were defects in the law, to make all proper efforts to have them remedied. We have not been informed, either publicly or privately, that it has made any effort in that direction.

In the resolutions by the State Board of Health we are told that the law demands that the examination shall be "elementary and practical." Though the law under which the Board of Health acts prescribes that examinations shall be of an elementary and practical character, it does not prescribe that the Board of Health shall confer on incompetent persons the privilege of practising medicine in Illinois; and the Legislature surely could have no such purpose in view when it enacted the law. If an applicant can pass a thorough examination in the elementary subjects of anatomy, chemistry, physiology, and materia medica, and a practical examination in pathology, obstetrics, practice of medicine and surgery, he would be able to pass the examination for the degree of doctor of medicine in almost any of the recognized colleges throughout the United States.

We deeply regret that the resolutions of the State Board of Health failed to remove the belief that their methods are faulty; and we personally know another student who obtained licence to practice during the past year who was unable to pass the examination for the degree of doctor of medicine this last spring. We have informed ourselves, so far as possible, of the methods and policy of the Board of Health, and we gladly embrace this opportunity to do it exact justice. The Faculty of the Northwestern University Woman's Medical School does not need to disclaim the suggestion that any individual interest or personal animosity prompted the drafting and circulating of the resolutions. This Faculty, individually and collectively, is friendly to the Illinois State Board of Health; but in the matter under consideration it has been constrained, as a matter of public duty, to question the wisdom and propriety of some of its acts. We will gladly be the first to give it credit when it corrects its faulty practice, and we will gladly aid it in securing any necessary legislation for elevating the profession and for the benefit of the people.

I. N. DANFORTH,
E. FLETCHER INGALS,
MARIE J. MERGLER,
Executive Committee.

A QUESTION OF NOMENCLATURE.

To the Editor of THE MEDICAL NEWS,

SIR: I have received from the publisher of a directory a printed postal card containing a request that I would furnish my name and address, with the addition, "Please state whether allopathic, homeopathic, or other school." Is it not time that the insulting epithet "allopathic," applied to the medical body that has existed for at least twenty-three centuries, should be disallowed and rejected? If others take pride or pleasure in a sectarian title, by all means let them wear it as a badge of disgrace, but let not physicians imitate their shameful example.

Yours truly,
Æ.

PHILADELPHIA, PA., Nov. 27, 1895.

REVIEWS.

DISORDERS OF THE MALE SEXUAL ORGANS. By EUGENE FULLER, M.D., New York. 8vo, pp. 241. Philadelphia: Lea Brothers & Co., 1895.

THIS new addition to the literature of sexual disorders of the male will excite the interest of the reader for the reason that it demonstrates the fact that the greater proportion of cases of sexual disturbance depend upon tangible and evident pathologic changes in the sexual apparatus, and are not all to be loosely relegated to the groups of neuroses or of physic affections, to which only the lesser proportion of them belong. The writer, who has devoted much time and labor to the subject he discusses, finds that in the seminal vesicles, the tissues surrounding them, and in the ejaculatory ducts are to be found most of the morbid changes that give rise to sexual disorders. An excellent chapter on the pathology discusses at length the nature and appearance of these changes.

The clinical features of acute, subacute, chronic, and tubercular seminal vesiculitis are thoroughly described, while the chapter on treatment and prognosis is both practical and satisfactory. For the subacute and chronic varieties the method advocated consists of digital pressure on the vesicles—"stripping"—through the rectum, a procedure in the execution of which it may be somewhat difficult to acquire dexterity, has certainly philosophic reasoning to support it.

The chapter on anatomy, with which the book begins, is most interesting, and contains the results of evident painstaking study of minutiæ of value, descriptions of which are not to be found in the ordinary work on anatomy. The illustrations, of which there are quite a number, are excellent, both as to faithfulness of representation and artistic merit.

The book is one that will command the attention not alone of the specialist, but equally of the general practitioner. It is well worth reading, and offers much in the practical way that will be of use.

DIRECTIONS FOR WORK IN THE HISTOLOGICAL LABORATORY, MORE ESPECIALLY ARRANGED FOR THE USE OF CLASSES IN THE UNIVERSITY OF MICHIGAN. By G. CARL HAUBER, M.D., Assistant Professor of Histology and Embryology. Second edition, 8vo, pp. 191. Ann Arbor, Mich.: George Wahr, 1895. Price, $1.50.

THIS admirable little volume should prove of real service to the student of histology as a guide and aid in his work in the laboratory. It is not intended to take the place of existing text-books on the subject, but is to be employed in conjunction with these, and, while arranged especially for the classes in the University of Michigan, it can be used most advantageously by others. Its arrangemeut is simple, its directions clear and concise, and the ground covered ample. Suitable space is left for notes and drawings. The work is divided into two parts. The first consists of 25 lessons, which deals successively with the histology of the individual cells and tissues. In the second part are detailed methods of laboratory work, including the preparation of tissues for study. A prettily executed colored plate exhibits the several varieties of blood-elements stained according to recent methods. The book is eminently practical in character, and just such a one as the laboratory student in histology needs, and its merit should secure it a wide sphere of usefulness.

PRACTICAL URANALYSIS AND URINARY DIAGNOSIS. A MANUAL FOR THE USE OF PHYSICIANS, SURGEONS, AND STUDENTS. By CHARLES W. PURDY, M.D., Queen's University, Professor of Urology and Urinary Diagnosis at the Chicago Post-Graduate Medical School, etc. With numerous illustrations, including photo-engravings and colored plates. Second edition. 8vo, pp. xix, 351. Philadelphia: The F. A. Davis Co., 1895.

THE early exhaustion of the first edition of Purdy's *Uranalysis* justifies the favorable criticism accorded this publication. For the same reason there has not been time for extended addition to the text, although discovered errors have been corrected and two more colored plates have been introduced. We cannot do better than repeat that "this contribution of Dr. Purdy's is a useful addition to the literature of urinary examination. It is well and intelligently written, and, while taking cognizance of new tests, indorses only those that practical experience has shown to be reliable."

ANATOMY OF THE HUMAN HEAD AND NECK; GRAPHICALLY ILLUSTRATED AND DESCRIBED. By DR. SCHMIDT. Revised and edited by WILLIAM S. FURNEAUX. 4to, ill. p. 16. New York City: Thomas Whittaker, publisher.

THIS work consists of a series of folding plates, representing the chief organs in their anatomical relation to one another, together with a descriptive text written in a simple and popular style. Technical terms have been avoided as far as possible to satisfy the requirements of the non-scientific, while, for the convenience of the students, a list of references to the plates has been inserted by the editor, which gives the scientific names of the various parts. The descriptions are accurate and clear, and the plates will be useful to practitioners for the purpose of explaining anatomical regions and operations to patients. The plates would be improved by printing the names upon the parts instead of using reference figures.

THE MEDICAL NEWS VISITING LIST, 1896. Philadelphia: Lea Brothers & Co., 1895.

THIS favorite list is now published in four styles—weekly, dated, for 30 patients; monthly, undated, for 120 patients per month; perpetual, undated, for 30 patients per week per year; and perpetual, undated, for 60 patients per week per year (without text). The first three styles contain 32 pages of text and 160 pages of blanks. The 60-patient style consists of 256 pages of blanks, wallet-size, with flexible leather cover, pocket, and pencil.

NEWS ITEMS.

The American Medical Review is the title of a new "monthly review of current medical literature" published in New York City, and edited by Dr. Daniel Lewis, in association with Dr. George B. Bradley.

Removal of The Medical News.—The editorial and publication offices of THE MEDICAL NEWS are to be removed to New York City on January 1st. Further particulars will be given in the issue of December 28th.

PROFESSOR OF PRACTICAL SURGERY AND CLINICAL SURGERY IN RUSH MEDICAL COLLEGE; PROFESSOR OF SURGERY, CHICAGO POLY-CLINIC; ATTENDING SURGEON, PRESBYTERIAN HOSPITAL; SURGEON IN-CHIEF, ST. JOSEPH'S HOSPITAL.

A RECENT visit to the ruins of Pompeii and the Naples Museum has enabled me to make a careful examination of the ruined homes and corroded implements of the Pompeian surgeons. A visit of this kind, with its wonderful revelations at every step, is a memorable event in the life of every student of ancient surgery who has enjoyed such an opportunity. Nearly two-thousand years have elapsed since the last surgeons of that ill-fated city practised their art. They perished or fled during that fearful eruption of Vesuvius that wiped out of existence so suddenly the two neighboring cities, Pompeii and Herculaneum, burying the former under a bed of burning ashes and incorporating the latter in a mass of lava. It is interesting to posterity that the city of Pompeii, with all its antique treasures, has been preserved for centuries under this removable mantle of the product of volcanic action, which has made it possible for the interested archeologists of the present century to unveil to us the works of art and science of two-thousand years ago. A walk through the streets of the recently uncovered city of Pompeii brings vividly to the mind of the visitor the life, works, virtues, and vices of its former inhabitants. The old aqueduct that supplied the city with pure water from the mountains is well preserved and remains as one of the marvels of engineering of that time. The pavements of the streets can compare favorably with those of our day. The bare walls of public and private buildings testify to the unrivalled perfection masonry had attained at that day. The crude stone mills operated by human power furnished the city with flour, which in the adjacent bakery was converted into bread.

The enormous wine-jugs, so numerous in places where wine was sold and drunk, remain as lasting mementoes that the Pompeians were by no means prohibitionists. The numerous houses of prostitution, both public and private, remain as silent witnesses of a vice which appeared to have been unusually prevalent at that time. The capacious forum, amphitheater, comic and tragic theaters that remain in a wonderful state of preservation, show that the people of that day—male and female, old and young—enjoyed the glittering stage and the bloody contests of the gladiators. The public bath-house is a marvel of its kind, and it is doubtful if in its artistic design and luxury it could be duplicated to-day. The private dwellings are all constructed on the same plan—masterpieces of comfort and sanitary construction. The numerous fountains furnished pure water for beast and man. The temple of Esculapius is one of the prominent landmarks of the former city, and fortunately time and the elements have dealt gently with its precious contents. In the center of the capacious anteroom stands the altar of pure marble, beautifully carved, at which the priests of old worshipped in the interests of suffering humanity. It is here where the sick, the maimed, and the injured sought relief. As I stood behind the altar where so many of the disciples of Esculapius had stood and performed their sacred functions, it seemed to me that I could hear the pitiable appeals of the suffering Pompeians and the sound advice and sweet words of consolation of the ministering priest. With the temple of Esculapius will always be associated the early history of medicine and the struggle between disease and its successful treatment.

A walk through the narrow, stone-paved streets of the uncovered part of the ruins of Pompeii is necessarily attended with serious thoughts of the past and present. The wider streets show deep grooves made by the chariot-wheels, while the narrower streets were reserved for pedestrians. The one-story buildings, both public and private, show a singular uniformity in their construction—evidence that the Pompeian architects and builders had in view more the comfort and health of their occupants than a desire to exhibit their talent. The many shops in the principal street were the homes and business-places of merchants who supplied the citizens with the luxuries and necessities of life. A large building on the corner of two streets served as a drug-store, where crude drugs were dealt out to those in need of remedial agents. The proprietor of this primitive pharmacy—living, as he did, next door to a

[1] Read before the Alumni Association of Cook County Hospital, November 18, 1895.

public house of prostitution—in order to protect himself and family against intrusion of an undesirable nature, found it necessary to place above the entrance a sign to indicate to the prospective customer the legitimate character of his business, and to direct him properly if he was in search of pleasure.

Before giving a description of the surgical instruments exhumed from the ruins of Pompeii, it is necessary to say something of the city of Pompeii and its destruction.

The temple in the leper forum at Pompeii, generally called "the temple of Hercules," is the oldest extant ruin in the city, and it is safe to say that it is of the same period with the Poestum temples, as it corresponds exactly with them in architecture; hence we may safely date it at 650 B. C., and the history of Pompeii is thus narrowed between that date and 79 A. D., when we know from reliable sources that the final destruction of the city took place. Our inquiry thus extends over a space of about seven hundred years. For the first three-hundred we are in the regions of conjecture; for the last four hundred we are in the realm of authenticated history. When the Greek temple was built at Pompeii the place was in the hands of the Oscans, a pastoral tribe who came down the plains in the winter and fed their flocks in the hills in the summer. The Oscans were driven out of Campania in 420 B. C. by the Samnites, a tribe of hardy mountaineers who attained the height of their power about 350 B. C. and built a great part of Pompeii. The Samnites practically built the city; and wherever we find houses built of large blocks of stone, neatly joined together without mortar, we may safely predict their Samnite origin. Their work was all in the Doric style, and it was the Romans who covered it with stucco, transformed it into the Ionic style, and decorated it with tracery and paintings. The Romans occupied Campania in 88 B. C., and thereafter Pompeii takes its place in Roman history, and is frequently mentioned by Seneca, Pliny, and other contemporary writers. Toward the close of Nero's reign—that is to say, in the year 63 A. D.—the whole region was visited by severe earthquakes, which made such havoc that the cities were deserted for several years. The rebuilding of Pompeii appears to have been begun about 69 A. D., ten years before its final destruction, which took place on the 23d of November, 79 A. D. and appears to have commenced in the afternoon. It is well to observe that although Herculaneum and Pompeii were destroyed by the same eruption, they were destroyed in quite different ways. The former was filled up by a flow of warm, muddy water, which filled it with a soft paste; and subsequent eruptions have covered it with molten lava no less than eleven times, rendering excavation exceedingly difficult and costly. Pompeii, on the other hand, was covered with loose ashes and pumice-stone, which were ejected from the volcano to a considerable height and blown into the city by the violent northwesterly gale which Pliny tells us was raging at that time. In short, Pompeii can be excavated with a trowel, but it takes a chisel to make an impression on Herculaneum.

Lord Lytton has given us in his fascinating novel, *The Last Days of Pompeii*, a graphic and what must be considered as a correct description of the destruction of Pompeii. He connects the beginning of the terrible catastrophe with a public play in which Arbaces, the Egyptian, was to be turned over to the lion by the angry assembled multitude. The helpless Egyptian heard the shouting of the bloodthirsty audience and the roaring of the hungry lions, eager for their human prey, when he stretched his hand on high; over his lofty brow and royal features there came an expression of unutterable solemnity and command. "Behold!" he shouted with a voice of thunder, which stilled the roar of the crowd; "behold how the gods protect the guiltless! The fires of the avenging Orcus burst forth against the false witness of my accusers!"

The eyes of the crowd followed the gesture of the Egyptian and beheld, with ineffable dismay, a vast vapor shooting from the summit of Vesuvius in the form of a gigantic pine-tree; the trunk, blackness; the branches, fire!—a fire that shifted and wavered in its hues with every moment; now fiercely luminous, now of a dull and dying red, that again blazed terrifically forth with intolerable glare.

There was a dead, heart-sunken silence, through which there suddenly broke the roar of the lion, which was echoed back from within the building by the sharper and fiercer yells of its fellow-beast. Dread seers were they of the burden of the atmosphere, and wild prophets of the wrath to come! Then there arose on high the universal shrieks of women; the men stared at each other, but were dumb. At that moment they felt the earth quake beneath their feet; the walls of the theater trembled; and, beyond in the distance, they heard the crash of falling roofs. An instant more and the mountain cloud seemed to roll toward them, dark and rapid, like a torrent; at the same time it cast forth from its bosom a shower of ashes mixed with vast fragments of burning stone.

Over the crushing vines, over the desolate streets, over the amphitheater itself, far and wide, with many a mighty splash in the agitated sea, fell that awful shower. No longer thought the crowd of justice or Arbaces. Safety for themselves was their sole thought. Each turned to fly—each dashing, pressing, crushing against the other. Trampling recklessly over the fallen, amidst groans and oaths, and

prayers, and sudden shrieks, the enormous crowd vomited itself forth through the numerous passages. Whither should they fly? Some, anticipating a second earthquake, hastened to their homes to load themselves with their more costly goods, and escape while it was yet time; others, dreading the showers of ashes that now fell first, torrent upon torrent, over the streets, rushed under the roofs of the nearest houses, or temples, or sheds—shelter of any kind—for protection from the terrors of the open air. But darker, and larger, and mightier spread the cloud above them. It was sudden and more ghastly night rushing upon the realm of noon! Darkness reigned, interrupted only by the occasional column of fire which escaped from the volcano and the frequent lightning that encircled and illuminated momentarily the mountain, which was the central point of the fearful panorama.

Pompeii had no street-lights. The frightened inhabitants brought their oil-lamps into requisition to expedite their flight. Frequently, by the momentary light of these torches, parties of fugitives encountered each other, some hurrying toward the sea, others flying from the sea back to the land; for the ocean had retreated rapidly from the shore—an utter darkness lay over it, and, upon its groaning and tossing waves, the storm of cinders and rock fell without the protection which the streets and roofs afforded to the land. Wild, haggard, ghastly with supernatural fears, these groups encountered each other, but without the leisure to speak, to consult, to advise; for the showers fell now frequently, though not continuously, extinguishing the lights, which showed to each other the death-like faces of the other, and hurrying all to seek refuge beneath the nearest shelter. The whole elements of civilization were broken up. Ever and anon, by the flickering lights, one saw the thief hastening by the most solemn authorities of the law, laden with, and fearfully chuckling over, the produce of his sudden gains! If, in the darkness, wife was separated from husband or parent from child, vain was the hope of reunion. Each hurried blindly and confusedly on. Nothing in all the various and complicated machinery of social life was left save the primal law of self-preservation!

It was under such circumstances that the city of Pompeii, with such of the inhabitants who failed to escape, was buried and preserved for futurity. The bodies of human beings and animals were charred by the heat, but their forms have been preserved as in a mold by the fiery ashes which fell around and upon them. We thus find in the museums at Pompeii and Naples the size and form of the victims of the eruption preserved to perfection by the substitution of plaster-of-Paris for the original mold. Without such a support the remains on exposure would crumble into dust. At the time of destruction, November 23, 79 A. D., Pompeii is said to have had about 30,000 inhabitants. The number of those who died and were buried in the ruins will never be ascertained. Up to 1824, 350 skeletons were found. Many have been discovered since that time, and many remain in the unexplored part of the city, while the remains of many have been removed with the detritus, unrecognized. It is, however, safe to assume that more than one-half of the population escaped the fiery death and sought shelter in the surrounding country. There is no doubt that soon after the disaster many of the Pompeians rescued a large portion of their valuables from their ruined houses, but the site of the city remained lost for many centuries.

Excavation. The first discovery of the ruins of Pompeii was made in 1595; and the first attempt at excavation was made in 1748. But it was not until 1860 that systematic exploration was pursued, and since then it has been scientifically carried on as far as means and opportunity have permitted. It is estimated that the whole of Pompeii will be cleared in about fifty years' time. At the time of my visit to the ruins, excavation was in active progress. With pick-ax and shovel the ashes and pumice-stone which cover and fill the streets and houses are loosened, and a small army of boys is employed to convey the same in baskets to hand-carts, which are propelled by hand-power, over a temporary railway-track. The workmen at this time were engaged in cleaning a large house, evidently an aristocratic residence, with walls and ceilings beautifully decorated by paintings, representing female beauty and animal life. The pictures are so well preserved that it seems almost next to impossible to realize that the artist and former owner are dead, and that they have been buried in the ruins for nearly two-thousand years. At this place the houses are about ten feet under the surface of the soil. The workmen exercise great care in bringing all objects of interest in as perfect a condition as possible to the surface, after which they are brought to the museum at Naples, where they are examined, classified, and deposited in their appropriate places. The Naples Museum has become a great treasure house, in which the students of ancient history for ages to come will have an opportunity to study the interesting lesson of the high civilization of remote ages.

The objects of special interest to the surgeon in this great collection of ancient art are contained in a glass case, and are properly numbered and described in the catalog. They are the

Surgical Instruments. These instruments were found in a house which has since been called the "Surgeon's House." They are made of bronze, and some of them show a high degree of artistic workmanship. Some of them show the destructive

effect of heat and oxidation, while others are in a state of excellent preservation, as will be seen from the illustrations. The illustrations are taken from specimens from the Naples Museum by Domenico Monaco and E. Neville Rolfe, Naples, 1895.

A quadrivalve speculum, which is one of the most interesting and perfect specimens of the collection, is, unfortunately, not among the illustrations.

a. Actual cautery. Length 10 in. (Off. No. 78,034.)

b. Bivalve speculum working on a central pivot. Length 6 in. Width, when open, 2½ in. (Off. No. 7831.)

c. Scissors with a spring-like shears. Length 4 in. (Off. No. 78,005.)

d. A male catheter which is almost a fac-simile of the one devised by J. L. Petit in the last century. At the closed end is an eye, as in the modern instrument. Length 10½ in. (Off. No. 78,026.)

e. Hook. Length 6 in. (Off. No. 78,056.)

f. Point of injection-syringe, with eight small perforations near the distal end. The other end was, no doubt, filled with a syringe. Length 6 in. (Off. No. 78,235.)

g. Pompeian forceps, formed of two branches, crossing and working on a pivot. Each branch is fitted with an engine-turned handle and a spoon-shaped blade. A powerful forceps, undoubtedly used for the extraction of foreign bodies. Length 8 in. (Off. No. 8 in.)

h. Forceps with serrated bite. Length 4½ in. (Off. No. 78,032.)

i. Cupping-glass of bronze. Height 6 in., diameter 3 in. (Off. No. 77,991.)

j. Medicine-box with medicines, 5 x 3 in. (Off. No. 78,199.)

k. Spatula for mixing ointments. Length 7 in. (Off. No. 77,726.)

l. Lancet for bleeding. Length 5 in. (Off. No. 78,003.)

m. Fleam for bleeding horses. Length 5½ in. (Off. No. 78,007.)

n. Forceps. Length 4½ in. (Off. No. 77,982.)

o. Toothed dissecting-forceps with the engraved name, A. C. A. A : G. L. V. S. F. Length 7½ in. (Off. No. 77,985.)

p. Trocar for tapping, with a hole at the end for the escape of the fluid. Length 5 in. (Off. No. 78,008.)

q. Small spoon with bone handle, ending in the head of a ram. Length 5½ in. (Off. No. 78,000.)

r. Female catheter. Length 4 in. (Off. No. 78,027.)

s. Bistoury, the blade oxidized and the handle in bronze. Length 5¾ in. (Off. No. 77,637.)

t. Trivalve speculum, an instrument which, like the bivalve and the quadrivalve, has been much discussed by archeologists and physicians. It is composed of three valves standing at right angles to the rest of the instrument, and jointly dependent on one another in the expansion transmitted only to one of them. By turning the screw one valve is drawn nearer the operator, and this forces the other two to open in a sidelong direction. The instrument can be held by the two curved handles with the left hand, while the right hand turns the screw. Length 8¼ in.; widest expansion of the valves 1½ in. (Off. No. 78,030.)

u. Spatula. Length 7 in. (Off. No. 78,733.)

v. A metallic case containing surgical instruments. Length 8 x ¾ in. (Off. No. 77,144.)

These are some of the most important instruments found in the ruins of Pompeii, and which were employed by our ancestors two-thousand years ago in the practice of surgery. I searched carefully, but without avail, for traces of needles or something else which would indicate that at that time wounds were sutured. The collection contains no saws, trephines, chisels, or any other instruments for operations upon bones. All of the instruments with the exception of the specula and catheters are diminutive in size as compared with the same instruments of less remote and modern times. The absence of saws and chisels is noteworthy, as among the agricultural instruments these tools are represented by specimens of a high degree of perfection.

In the writings of Hippocrates raspatories, mallet, and trephine are mentioned, and consequently must have been used in operations upon bones other than those of the skull. Hippocrates gives very minute directions as to the use of the trephine in the treatment of fractures of the skull: "With regard to trepanning, when there is a necessity for it, the following particulars should be known: If you have had the management of the case from the first, you must not at once saw the bone down to the meninx, for it is not proper that the membrane should be laid bare and exposed to injuries for a length of time, as in the end it may become fungous. And there is another danger if you saw the bone down to the meninx and remove it at once, lest in the act of sawing you should wound the meninx. But in trepanning, when only a very little of the bone remains to be sawed through, and the bone can be moved, you must desist from sawing, and leave the bone to fall out of itself. For to a bone not sawed through, and where a portion is left of the sawing, no mischief can happen; for the portion now left is sufficiently thin. In other respects you must conduct the treatment as may appear suitable to the wound, and in trepanning you must frequently remove the trepan, on account of the heat in the bone, and plunge it into cold water. For the trepan, being heated by running round, and heating and drying the bone,

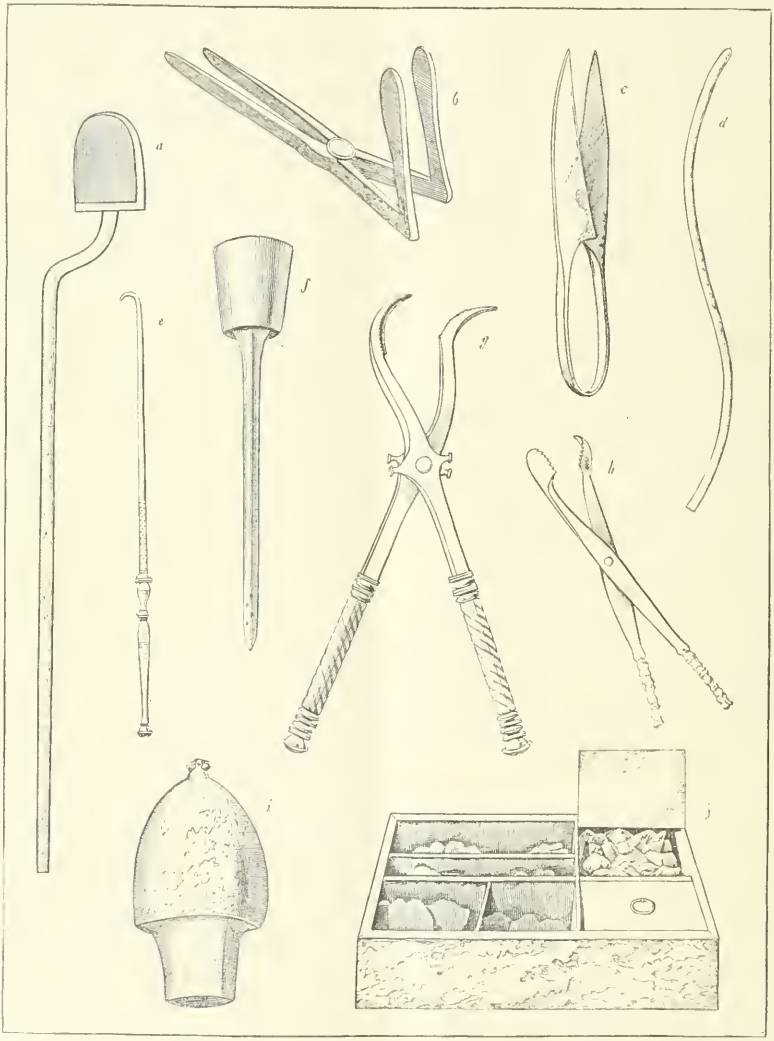
burns it and makes a larger piece of bone around the sawing to drop off than would otherwise do. And if you wish to saw at once down to the membrane and then remove the bone, you must also in like manner frequently take out the trepan and dip it into cold water. But if you have not charge of the treatment from the first, but undertake it from another after a time, you must saw the bone at once down to the meninx with a serrated trepan, and in doing so must frequently take out the trepan and examine with a sound, and otherwise along the track of the instrument. For the bone is much sooner sawn through, provided there be matter below it and in it, and it often happens that the bone is more superficial, especially if the wound is situated in that part of the head where the bone is rather thinner than in other places. But you must take care where you apply the trepan and see that you do so only where it appears to be particularly thick, and, having fixed the instrument there, that you frequently make examinations and endeavor by moving the bone to bring it up. Having removed it, you must apply the other suitable remedies to the wound. And if, when you have the management of the treatment from the first, you wish to saw through the bone at once and remove it from the membrane, you must in like manner examine the track of the instrument frequently with the sound, and see that it is fixed on the thickest part of the bone, and endeavor to remove the bone by moving it about. But if you use a perforator you must not penetrate to the membrane, if you operate on a case which you have had the charge of from the first, but must leave a thin scale of bone, as described in the process of sawing." As Hippocrates at one time lived and practised in Athens during a great epidemic, it appears strange that his teachings in reference to the treatment of injuries of the skull should not have reached Pompeii, as evidenced by the absence of trepans and other bone-instruments in the "House of the Surgeon."

If we judge the worth of the Pompeian surgeon from the collection of instruments he left behind him, it is evident that bloody operations were confined to bleeding, cupping, extraction of foreign bodies, and opening of abscesses. The metallic medicine-box, the spatula and spoon indicate that the surgeons of that time made free use of medicines and ointments in the treatment of injuries and disease. The instruments and implements of wood, splints, etc., were of course destroyed by fire and heat, and their absence in the collection leaves undoubtedly a large gap in the surgical resources of the Pompeian surgeon.

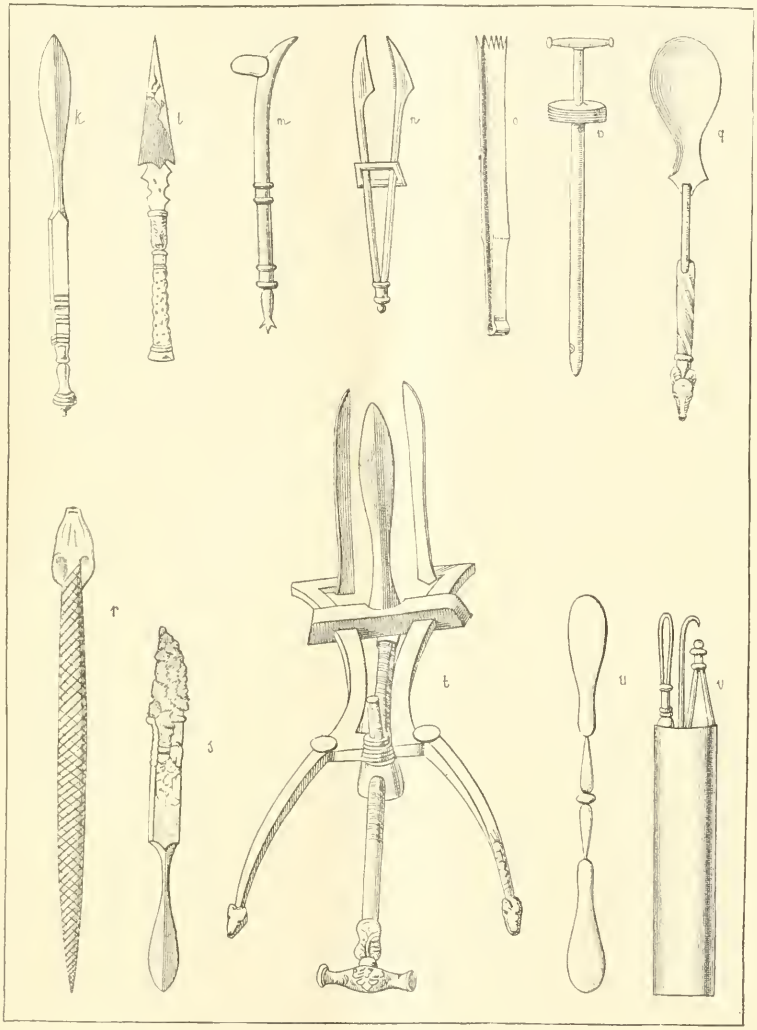
Surgeon's House. The surgeon's house does not differ from the private houses in its vicinity. It is roofless like the rest, all that remains being the bare walls. It is here that most of the surgical instruments were found. This house was undoubtedly occupied by the principal surgeon of Pompeii, who ministered to those in need of surgical aid. It is here that bleeding and cupping were practised for all kinds of ills, real and imaginary. It is difficult to imagine what transpired from day to day. That the surgeon was a busy man there can be but little doubt. Competition was then not as active and pressing as it is now, and it is therefore safe to assume that the capacious waiting-room was crowded day after day by patients anxious to be bled, cupped, or burned. These bare walls, if they could talk, could tell of many sad and exciting scenes. Fainting from loss of blood and writhing under the actual cautery, must have been frequent and familiar sights. How often the neighborhood must have been disturbed by the cries of the suffering and the shrieks of the tortured! How often the atmosphere and adjacent streets must have been stifled with the smell of burned human flesh! Let us hope that the master escaped, leaving in his haste his instruments of skill and torture as lasting mementoes of his so suddenly interrupted professional career. The house is deserted and silent now, a permanent reminder of the great antiquity of the art of surgery. If the last representative of Pompeian surgery could return to-day and behold the improvements in surgery which have been made since his time, he would indeed be astonished and amazed. What would be his surprise if he could visit one of our modern hospitals and inspect an aseptic operating-room. He would find his old occupation gone. No need now for lancet, cupping-glass, and actual cautery. He would find the science of surgery developed to a wonderful degree of perfection and its practice in consonance with its principles. He could make use of anesthesia to prevent pain, Esmarch's bandage to guard against hemorrhage, and operate under aseptic precautions to protect accidental and intentional wounds against complications the treatment of which made up a large part of the work of the ancient surgeon. He would perhaps be astonished to learn that since Pompeii was buried surgery not only came to a standstill, but retrograded for centuries, and that its present state of perfection is owing largely to the improvements and advancements made during the present century. Let us not forget, however, that our colleagues of the distant past, possessed of a primitive knowledge of anatomy, physiology, and pathology, and armed with few and imperfect instruments to practise their art, labored faithfully in the interest of suffering humanity, and unquestionably did much toward prolonging the lives and adding to the comfort and happiness of those who were intrusted to their care.

Pompeian Surgery. There can be but little doubt that the Pompeian surgeons practised surgery in accordance with the teachings of Hippocrates.

Hippocrates, who is justly entitled to be called the father of medicine, was born on the island of Cos, 450 B. C.; hence his lifework was contemporaneous with the early history of Pompeii. It is not difficult to conceive that his teachings penetrated to this city, or that some of its surgeons might have been his pupils. In all probability, Pompeian surgery was Hippocratic surgery. As has been remarked before, the instruments which have been recovered from its ruins so far seem to indicate that no major operations were performed at that time, and that the surgeon's work was limited to cupping, bleeding, the treatment of injuries, and the performance of minor operations. The discovery of a number of very ingenious specula in the "House of the Surgeon" furnishes us with positive evidence that at that time gynecology was not practised as a specialty, but constituted a legitimate part of the sur-



geon's work. Considering the character of the moral atmosphere of Pompeii, it is not astonishing to learn that diseases of the genito-urinary organs taxed the ingenuity and occupied much of the time



and attention of its surgeons, as shown by the different kinds of specula then in use and the wonderfully perfect construction of the male and female catheter. The numerous wine-shops and houses of prostitution, private and public, that constitute such a conspicuous part of the ruins of Pompeii, stand as lasting monuments of the debauchery and licentiousness of its former inhabitants, and furnish a satisfactory explanation of the prevalence of genito-urinary diseases among males and females, and which so often necessitated the services of a surgeon. The fleam for bleeding horses found in the instrumentarium of the Pompeian surgeon goes to show that he extended his sphere of usefulness to

the domestic animals, which furnished him with an additional field for observation and undoubtedly added materially to his income. That the surgeon of Pompeii was a man of means and good social position is amply testified to by the size and location of his house. This house is capacious, and is located in the aristocratic part of the city. A liberal income undoubtedly rewarded his labors and placed him in a position to enjoy the luxuries of life, which seems to have been the main object in life of the mass of the people at that time. The existence of a separate house occupied as a pharmacy shows that the people then, as now, had great faith in the healing powers of herbs and drugs, and the medicine-box found in the "Surgeon's House" was replenished from time to time from this source, and its contents were undoubtedly frequently made use of by the surgeon in the practice of his profession.

CLINICAL LECTURES.

REMARKS ON CERTAIN POINTS RELATING TO VAGINAL HYSTERECTOMY.

Being two Clinical Lectures delivered at the Suffolk Dispensary, October 12 and 19, 1895.

BY CHARLES GREENE CUMSTON, B.M.S., M.D.,
OF BOSTON, MASS.;
INSTRUCTOR IN CLINICAL GYNECOLOGY, TUFT'S COLLEGE; DIRECTOR OF THE DEPARTMENT OF GYNECOLOGY, TREMONT DISPENSARY; MEMBER OF THE SOCIÉTÉ FRANÇAISE D'ELECTRO-THERAPIE, ETC.

LECTURE I.

GENTLEMEN: The patient that I shall examine with you to-day is a woman of 42, a housekeeper; a *virgo intacta* who has led a most regular life. Her medical history is meager; she had smallpox at the age of four, the traces of which you may remark on her face. Her genital functions have always been accomplished with regularity and *without any complication*, since the age of 13. She comes to us with the vague symptoms of a "sore feeling in the pelvis, low down," which has been present for the past five weeks only. Let me impress upon you again that no leukorrhea, hemorrhage, or discharge of any description from the genital tract has been present at any time. The nervous, digestive, and urinary systems are apparently normal.

On examination I find the external genitals in perfect condition, with a hymen having a crescent-shaped opening just admitting my index-finger. The uterus is in normal anteversion, movable and of proper size. The adnexa are in every way normal. But on the right side of the cervix I find a growth about the size of a small walnut, which is fleshy to the touch. On withdrawing my finger I notice that a little blood-stained mucus covers it.

Now what does this growth signify, and in what way can we connect the soreness in the pelvis with the neoplasm on the cervix? I believe, and many similar cases which I have seen and operated on go to bear out this statement, that we are in presence of a carcinoma at its début, and my fears are still more increased from the fact that the patient's mother was afflicted with a malignant tumor of the breast from which she afterward died.

The soreness in the pelvis is probably due to an infiltration of the corpus uteri, the increase in the weight of which pulls on the broad ligaments, although the organ is not enlarged; at least palpation does not show this. The uterus is movable, the vaginal walls normal; consequently the disease is limited to the organ; the bowels are regular, and stools painless and free from pus or blood, showing that there is no metastasis in the rectum. In other words, we have here a case in which a radical operation will be crowned with success, and this operation is vaginal hysterectomy. I shall perform this operation before some of you next Wednesday at the hospital, as the patient has wisely consented to it.

Vaginal hysterectomy was first successfully carried out by the illustrious Récamier in 1829, and of late years has been revived by Péan, Segond, Richelot, Poucel, and other French surgeons. The Germans are also copying after the French and are having good results.

As the operation is commencing to be appreciated and performed in this country, and as I shall probably have the occasion to perform the operation before you quite often this winter, I would like to make a few remarks regarding certain points in this operation which are not to be found in the text-books, but which have a real importance. In the first place, let me speak of some of the indications and contraindications for its performance.

Generally speaking, this operation should never be resorted to in recent puerperal infections, in which case it is better to drain the pus either by the vagina or by the suprapubic region. The reason for this resides in the great softness of the uterus, which is one of the most serious complications met in vaginal hysterectomy, and this friability of the tissues attains the highest degree immediately after labor. All the pelvic tissues are in the same condition, and will tear and crush under the pressure of the clamps. Under these circumstances hysterectomy becomes a very difficult and dangerous operation, and will only be completed after serious tears have been made in the surrounding viscera. The prognosis is most bad.

I wish to emphatically state that vaginal hysterectomy will not cure *prolapsus uteri*, and in this opinion I do not stand alone, as Prof. Poucel, of Montpellier, Bouilly, and Richelot are of the same opinion. The latter expresses himself as follows: "The extirpation that I performed for a prolapsus showed me what I already suspected, viz., the relative ease and simplicity of the operation in cases of this kind; secondly, the possibility of a secondary prolapsus of the vaginal walls after extirpation, and consequently to consider the operation as a preliminary one." And further on the same author says: "If the prolapsus is simple, if the uterus is small, if the exuberance and flaccidity of the walls are not great, a well-performed colporrhaphy is the treatment *par excellence*. If there be doubt as to the success of a vaginal anaplasty on account of excessive relaxation of the tissues, if the uterus is large, if the hypertrophy of the cervix leads one to believe that the size and weight of the organ might interfere with reunion or favor a relapse, auxiliary means may be resorted to, the anaplasty remaining the base of the treatment."

The clinical signs of uterine carcinoma, that of the cervix, and still more that of the corpus, are more diffi-

cult of recognition than would be supposed. The pains experienced on the internal aspect of the thighs, the induration, hemorrhages, fetid discharges, are not pathognomonic of this disease even if they should all be present in the same patient. You may meet all these symptoms in cases of cervical metritis, with ulcerations, but this affection is not carcinoma, although, let me add, it certainly prepares the ground for a malignant growth more or less rapidly.

Now, gentlemen, it is precisely in these cases that an early vaginal hysterectomy gives wonderful results. These patients, who are sometimes prematurely in a state of cachexia as much from mental as from physical suffering, come back to good health with surprising rapidity after the operation.

In advanced carcinoma one of the greatest operative difficulties is caused by the invasion of the adnexa by the neoplasm, as well as from the slight cohesion of the uterine tissue, which in some cases is so very advanced that the cervix will tear away from the corpus when the former is seized and drawn down with the forceps. In these cases the operation is in no way justifiable, as a recurrence of the disease is sure to soon appear, but the thorough use of the curet is decidedly indicated and will go far in relieving the patient's sufferings.

But when the neoplasm is limited to the cervix and has not invaded the vaginal mucous membrane, the operation should be performed, with splendid results.

Another class of cases, few in number, it is true, requiring vaginal hysterectomy are those suffering from hemorrhagic metritis; but only when the patient is in a state of anemia due to prolonged hemorrhages which have resisted all other minor treatment, such as curettement, cauterization of the endometrium with a Paquelin, should this operation be resorted to.

As to fibroids, we have two classes: those having an abdominal and those a pelvic evolution. Those of the first class, unless they are small, are better treated, I believe, by the abdominal route. If it is decided to remove the uterus through the vagina, one will find that the operation will be greatly facilitated by an anterior hemisection. If the fibroid is in the pelvis, two alternatives present themselves. The neoplasm either projects into the uterine cavity and dilates the cervix or it grows up toward the broad ligaments. In the first variety one will easily remove the uterus by morcellement through the vagina; but, in the second, a selection between the abdominal and vaginal methods must be made, and which should be based on the mortality or the wedging in of the growth in the pelvis.

If you have to do with multiple fibroids, and if you are able to detect that they are scattered through the broad ligaments, I should advise the abdominal route, because the application of the clamps will be found very difficult.

There is a relatively frequent affection, and one most embarrassing for the surgeon to treat, on account of its benign nature, on the one hand, and, on the other, the gravity of the operation necessary for its cure. This affection is what I term microcystic degeneration of the ovary. This lesion is the cause of severe and always increasing pain. Usually only one ovary is the seat of this pathologic condition in the beginning, but soon the other organ becomes degenerated in the same manner. Now, when both ovaries are involved, vaginal hysterectomy is indicated, and when performed will give the patient rapid and complete recovery. When you have decided to perform a vaginal hysterectomy, and the reasons for the operation are considered sufficient, the question comes, At what time can and should this be performed? Of course, if the poor general health of your patient is the result of the lesion, there should be no hesitation on your part, for by putting the operation off until later you diminish the chance of success. But if the general condition depends on some intercurrent acute disease, you naturally should wait until all the symptoms have disappeared and then put your patient on tonic treatment before operating.

Scrofula and commencing tuberculosis are not contraindications for the performance of vaginal hysterectomy, for, as Ferrier remarks, it is only superficial wounds, involving the skin alone, that take on an abnormal evolution in these subjects. Deep wounds, on the contrary, heal normally.

It has been upheld by some surgeons that a surgical operation may cause an acceleration in the progress of a beginning tuberculosis, even inducing its development, particularly in the form of meningitis. I believe from certain cases that I have observed that this may be true of tuberculous lesions of the bones, but, when the general health of the patient is not too poor, I certainly think that no danger will result from the removal of the genital organs through the vagina.

As to syphilis, if it is considered as a diathesis, which is certainly the case in the congenital form, or as an intoxication, as the acquired form has the right to be considered, I think it well that every syphilitic patient who is to undergo a vaginal hysterectomy should be put on specific treatment *before and after* the operation. You will thus avoid secondary hemorrhage and the tenacious neuralgias that occur early or late after a surgical traumatism inflicted on syphilitics.

Malaria of any notable gravity is very infrequent in this part of the country; still, as some of you may hereafter practice in places where this disease is frequent, I will say a few words regarding it. A patient suffering from this affection should be given quinin in full doses, combined with strychnin and arsenic before and after operation, because malaria may produce local or general complications. For the first you have pain and hemorrhage; for the second, a simple intermittent, remittent, or even pernicious fever. In the period of malarial cachexia, erysipelas, gangrene, septicemia, or pyemia might be set up in spite of the most careful asepsis; consequently you would do better to put off the operation until the general condition of the patient is improved.

You have heard me often insist upon the absolute necessity of making a urinalysis in all cases demanding a surgical operation. The smallest wound may be the cause of death in diabetes; a pin-prick, removal of a corn, the extirpation of a chancroid of the face, may be followed by phlegmonous erysipelas or gangrene, soon resulting in death. I think, therefore, that diabetes is a contraindication for vaginal hysterectomy, or at least temporarily so; a considerable reduction in the amount of sugar must be obtained by well-directed treatment before performing this operation. There are, however, two classes of diabetic patients from the surgical point of view—firstly, those in whom a surgical traumatism will result in gangrene, and, secondly, those patients that are in no way influenced in their recovery by their dia-

betes. Those of the first class offer an excellent culture-ground for staphylococci and streptococci, although the result of their urinalysis in no way differs from that of the second class of diabetics who can undergo surgical interference without disaster.

It is, however, a safe rule never to perform vaginal hysterectomy on a diabetic subject, for you cannot tell beforehand to which class the patient may belong.

If you are in the presence of albuminuria, remember that any traumatism will increase it. The different renal diseases render the prognosis of a surgical operation more serious in direct proportion to their own degree of severity. Parenchymatous nephritis and amyloid degeneration are of far greater import than sclerosis. Bilateral hydronephrosis is, of course, more serious than when only one organ is the seat of the trouble, but even the latter condition renders the prognosis far from good. I would advise you to leave your patient alone if she presents any organic disease of the kidneys, as an operation of the importance of vaginal hysterectomy will in no manner improve her condition.

Among the diseases of the blood I wish only to speak of hemophilia as having any direct bearing on the operation under consideration. In subjects afflicted with this diathesis, primary and secondary hemorrhages are to be feared. The last mentioned are the most to be dreaded, and are more frequent than primary hemorrhage. They may occur when cicatrization is about complete. Hemophilia is a contraindication for vaginal hysterectomy, unless you have the time to build your patient up in order to forestand the shock. This is accomplished by subcutaneous injections of ergotin and artificial serum. Sulphuric acid in the form of a drink is highly recommended by Salvy as giving excellent results.

Pulmonary diseases, as bronchitis, influenza, etc., even when slight, may cause coughing-spells, which are very bad after vaginal hysterectomy; so that it is better to postpone the operation until the bronchial mucous membrane is less irritable. The only disease of the liver which concerns us as gynecologists is biliary lithiasis and congestion of the liver. The coexistence of the former affection with lesions of the uterus and adnexa is much more frequent than is usually supposed, and I wish here to call your attention to certain facts which have been put forth by Prof. Poucel, of Montpellier, as they are not generally known, and are certainly worthy of serious consideration.

The liver in a state of congestion compresses the vena cava, and in this way mechanically acts on the general circulation. We can thus explain the uteroovarian congestions nearly always present, and which predispose the patient to hemorrhages; acute metritis, with all its consequences; ulcerations, versions, degenerations of various types, congestive hypertrophy, catarrh of the uterus, with shedding of the ciliated epithelium, which latter is considered by Poucel as the most common cause of sterility. This chronic uteroovarian congestion is still better explained by the anastomoses existing between the veins of the cervix and the internal hemorrhoidal; it is the usual cause of abortion by apoplexy of the placenta, the same as hepatorenal congestion is the cause of puerperal albuminuria and eclampsia. Now, if these hepatic troubles are overlooked, the surgeon will often find that the pains which were thought to be due to lesions of the adnexa persist, even after the nicest operation, and it is for this reason that I wished to call your attention to this theory, which certainly is based on much observation.

Another important question to be considered is that of menstruation. If your patient has passed the menopause, any day will do for the performance of vaginal hysterectomy. But if the woman is still having her menses, the operation should *never* be performed during the menstrual period unless the case should be an urgent one, for instance, with an enormous quantity of pus and a generally bad state of health, in which case an immediate operation may have an excellent effect. However, if there is no urgent symptom, you should perform the operation about forty-eight hours after the menses have ceased. Otherwise your patient will be exposed to severe and obstinate hemorrhage. The studies of Cauchois and Louge on the pulse during menstruation have conclusively demonstrated that the increase of tension in the circulation is a constant phenomenon attending the menstrual periods. If this operation is performed two or three days before the menses, the vaginal incision will bleed very freely, and hemostasis is more difficult to obtain. The blood, moreover, appears more watery, and the uterus, too, bleeds to a far greater extent. But it is especially on removal of the clamps that the bleeding becomes serious, and may even necessitate a complete tamponade. Consequently, if you do this operation, do not forget to wait until menses are over, if they are near at hand.

A few words now regarding the instruments necessary and the preparation of the patient..

The instruments that are necessary are: two long and two short valves, four pairs of hysterectomy-forceps, 6 long clamps, 6 short clamps, 4 Segond's ligament-clamps, one pair each of stout curved and straight scissors, 6 pairs of long, thin clamps with *gold-washed* handles for tampons, and on the absolute necessity of these latter I particularly insist, as they save an enormous amount of time, to say nothing of trouble; and, lastly, a straight knife mounted on a long handle, Segond's curved knives for "*conoid excision*," and a Garceau's hooked sound-director, a most useful instrument which I have employed with the greatest satisfaction.

The number of tampons, which should be made of *gauze*, is as follows: 6 tampons 5 x 5 inches for pressing back the intestine, and 40 gauze tampons 3 x 3 inches for removing blood, etc., and keeping the field of operation clean, a most essential thing, because in vaginal hysterectomy you should see every organ and tissue before proceeding.

The tampons are then sterilized by dry heat at 100° C.

The sutures that I employ for this and every operation are of *silk*. The simplest way of rendering them perfectly sterile is to boil them for one hour in a 1 : 2000 mercuric-chlorid solution and *in the glass test-tube in which the spools are to be kept*. The spools are, as a matter of course, of glass.

You also must have two strips of a 5 per cent. sterile iodoform-gauze, each contained in a separate test-tube and measuring each 6 inches wide by 4 feet in length. These strips are used for packing the vagina after the operation.

The preparation of the patient is a very important and much-neglected point, and, with the exception of those urgent cases to which I have already alluded, should be

carried out as follows: I begin one week before the day of operation to put the patient on a light and easily digestible diet. The bowels are moved every day by means of a wineglassful of Carabaña water, taken just before breakfast. This particular water is, *par excellence*, the one that should be employed, as it acts on the entire digestive system in a most admirable manner and is, consequently, well suited for the preparation of a patient who is to undergo a vaginal hysterectomy.

Besides this, I am decidedly of the opinion that intestinal antisepsis is strongly indicated, and for this purpose I prescribe 20 cgm. of naphtol β in a cachet, one to be taken after each meal. If the patient is nervous, and she generally is with good reason, I would recommend the exhibition of strychnin, 5 mgm. before each meal. Another combination that I often employ for this class of cases is as follows:

R.—Strychninæ sulph. . . . 0.05
Tinct. valerian. 40.00
Syr. rubi idæi 50.00
Aq. dest. 70.00
M. S. — A tablespoonful to be taken after each meal.

A vaginal irrigation with two liters of a 1 per cent. solution of sulphonaphtol or of creolin as well as a hot bath should be given once a day for the four days preceding the operation.

On the evening before operation the pubis is shaven, a sublimate-bath given (3 grams of mercuric chlorid to the bath), and a 1 : 1000 sublimate-compress is placed over the abdomen and vulva and the patient put to bed.

At six the next morning the patient is given a cup of hot coffee and two tablespoonfuls of cognac, and an injection of 1 cgm. of morphin combined with half a mgm. of atropin is given subcutaneously a quarter of an hour before beginning the narcosis.

I will not insist on the asepsis of the instruments, hands, field of operation, etc., as they are the same as for any major or minor operation. In other words, they must be perfect. In the next lecture I shall speak of the technic of vaginal hysterectomy, the accidents that may occur during its execution, and, lastly, the ultimate results.

Lecture II.

Gentlemen: It is difficult to state precisely the average time that will be necessary for performing a vaginal hysterectomy, for it depends on two principal factors—on the one hand are the operative difficulties, on the other the acquired skill for performing this operation. There are often unforeseen circumstances rendering the operation more difficult to perform than was expected.

So soon as everything is ready for the operation the anesthetic is given. The room in which the operation is to be done should be kept at a temperature of about 78° F., thus avoiding any chilling of the patient. The woman is placed in the lithotomy-position. The operator should be seated on a low chair, so that the light may be good all over the field of operation. As you must see, a good light is absolutely necessary, for you are working in a cavity, so to speak.

I now come to the important question of the assistants, of whom there are *two*, not including the one giving the anesthetic. In the first place, let me speak of the assistant on the right of the patient. He should be seated near the flank of the patient, on a high chair or stand, if he so prefers, but when seated he can remain immovable, and bend easier when necessary. His left arm passes above and the right below the patient's thigh, his chief duty being to handle the upper and lower valves, keeping them constantly parallel, and pushing them more deeply into the vagina when necessary. If the patient should make an effort at defecation, as will sometimes occur, the assistant on the right should press the lower valve downward, sufficiently to prevent the fecal matter from escaping. During the clamping of the *left* ligament (of the patient) this assistant will make this easier by drawing the uterus outward to his side. When the clamps are placed on the *right* ligament (his side), he should watch to see that the labia majora and minora, as well as the vaginal walls, are not included in the clamps. When the ligament on his side is cut, he should hold the clamps parallel to the axis of the vagina, but without drawing on them, and by holding them between the thumb and first finger he will not occlude the light. When you wind the gauze around the clamps, after packing the vagina, this assistant should hold the labia apart.

I now come to the assistant on the left (of the patient). He should stand by the side of the patient, and if the vaginal arteries must be ligated it is his duty to catch them up and cut the ligatures for the surgeon. If there is any need of pressing the abdominal walls, for instance, for pushing down the uterus, a fibroid, or the adnexa, or to prevent the escape of pus into the pelvis after accidental rupture, or a pyosalpinx, he should exercise this pressure delicately and according to the directions of the surgeon. He should also have charge of the tampons, and keep the field of operation perfectly dry. His other duties will be similar to those of the other assistant, as well as to hold the lateral valve on his side.

There are four methods of performing vaginal hysterectomy: 1. Péan's operation, or hysterectomy by morcellement; 2. Segond's, by central conoid excision, or hemisection. This method is nothing else than morcellement, but differs from that of Péan in that hemostasis, excepting for the uterine arteries, is consecutive instead of preventive. The advantage of this method is that when terminating the operation you are not hindered by clamps; the only ones in place are those placed at the beginning of the operation on the uterine arteries. 3. The method of Müller-Quénu. Müller advised cutting the uterus vertically into two halves after having turned it out, or simply drawing it down. Quénu then took up Müller's ideas and made the operative technic methodic by incising the uterus little by little until hemisection is complete. This is an excellent method, and most serviceable in certain cases in which the uterus adheres to the bladder or rectum, or when the organ is prevented coming down by cystic ovaries or pyosalpinx. 4. The last method, due to Doyen, is that of anterior hemisection, but the details of which I will pass by. I will now describe to you the various stages of vaginal hysterectomy as it usually occurs.

The *first stage* is the *drawing down* of the uterus. If the cervix is conic you should grasp it with a pair of hysterectomy-forceps; but if, on the contrary, it is large

you will do well to catch it with two pairs, one of which is placed on the anterior, the other on the posterior lip; by this means you will obtain a better hold on the organ and will not be so likely to wound it. I think that it is well to curet the endometrium, thus removing any possible source of infection from within, after which the cavity is packed with iodoform-gauze. As this little preliminary operation requires about three minutes, I think the time well spent. Or you may simply cauterize the endometrium with a Paquelin and pack with gauze, as is recommended by Poucel.

The *second stage* of the operation is the incision of the vagina. The labiæ and fourchet having been widely separated by the valves held by the assistant on the right, and the cervix finally caught by the forceps, you give the cervix a movement of rotation from left to right so that the knife will pass over the right side of the cervix round to the posterior aspect; the same rotation is then made from right to left, thus completing the circular incision. Segond's lateral incisions over the broad ligaments are next made and should measure about one centimeter in length. I cannot insist too strongly on the necessity of these lateral incisions, as the operating space gained by them is enormous.

The circular incision should be made *as near the os uteri as is possible*, for by so doing there is less danger of nicking the ureters.

If there be much bleeding from the vessels of the mucous membrane it is well to catch them up and ligate them. There are usually four of these small arteries, and if they bleed much they will be a bother during the remainder of the operation.

The *third stage* of the operation consists in freeing the uterus. When the organ is not adherent you should remove it without hemisection or morcellement, for in this way you will diminish the chances of infection. There is no absolute rule for rotating the uterus when this is necessary, because some organs will come down more easily from above, while others will be more readily turned out through the posterior culdesac. When the cellular tissue uniting the bladder to the uterus is very resistant you should employ the curved scissors, because if you use your finger there is more danger of perforating the bladder. You will do the same, if from a perimetritis there are adhesions between the rectum and the uterus.

After you have freed the anterior and posterior aspects of the uterus for about four or five centimeters, and as much as possible before you open the peritoneum, you should place the lower clamps on the broad ligaments. You should use the long clamps for this, so that at least 4 cm. of ligament are caught up. The clamps should be placed at about 1 cm. from the uterus, and as well-made clamps are about 7 mm. broad it follows that, under these circumstances, you run no risk of including the ureter in the jaws of the clamps, because the ureters are at least 2½ cm. from the uterus. The first clamp should not be placed blindly. The first two fingers are inserted behind the broad ligament and act as a guide for the clamp.

You then cut the ligament *up to the end of the clamp*, and then the uterus will gradually come down in a remarkable manner. After this you draw down the uterus and open the culdesac. If the uterus is low enough to allow the first finger to hook the upper part of the broad ligament you place a short clamp from below upward, or from above downward, according to circumstances. The clamp will include in its grasp the uterine artery, the tube, and the ovarian ligament. If this clamp cannot be put on, you should ascertain if the uterus can be tipped forward, which is generally the case, or backward, and if one or the other is accomplished the instrument can be applied.

When the uterus will not descend, then you should perform either anterior hemisection or total median section or morcellement.

Anterior hemisection or total section will soon be master of the situation, and I can assure you that it is the greatest surprise to see how quickly the organ comes down after one of these maneuvers has been executed. And let me add that these sections are absolutely devoid of danger from hemorrhage.

The *fourth and last stage* of vaginal hysterectomy is the extirpation of the adnexa. When the tubes and ovaries are not adherent, delicate and firm traction should be employed. But if they resist, you should separate them with the greatest possible prudence. If they contain pus you must introduce tampons about them, so that these may receive the infectious material as fast as it runs out; and let me say that it is very difficult to detach a pyosalpinx without rupturing the sac.

Now if you find that the adhesions to the surrounding parts are very strong, especially if they are connected with the intestine, I would advise you to stop and go no further, and leave part of the pus-sac, after emptying all the pus, and excising as much of the nonadherent part as is possible.

After you once get the adnexa down you can then place a clamp on the upper part of the broad ligament, and the pedicle of the ovary and tube. When this is accomplished you separate the clamps into two clusters, those applied to the right and those to the left side. Then carefully look to see if hemostasis is complete, in which case you proceed as follows:

With a long forceps you pick up the end of one of the strips of iodoform-gauze, and carry this well above the ends of the clamps, in order to protect and support the intestine; then you pack in the rest of the strip not too tightly in the vagina. This gauze serves a double purpose; firstly, to prevent hemorrhage, and, secondly, to support the intestine. The second strip of gauze is then introduced in such a manner as to protect the vaginal walls from the contact of the clamps, as well as to prevent direct compression of the vulva. The clamps are then dressed in carbolized gauze, over which a sterilized napkin is placed, and the dressing is completed by a T-bandage.

I believe that I have omitted mentioning one particularly important point, and that is the emptying of the bladder just before beginning the operation, and again as soon as this is completed. Do not forget to do this.

I now come to the question of the after-treatment. The patient should be carefully transported to her bed, and placed with the head low, while a pillow is placed under the popliteal spaces in order to keep the thighs elevated and the legs flexed. A couple of soft towels are massed together and put under the clamps in order to support them.

I never employ a permanent catheter as some operators do, but have my patients sounded every eight hours

during the first day, and every six on the following days until the patient passes her water herself, which can generally be done as soon as the clamps are removed; in other words, after the first 48 hours.

A very good practice is that of Segond, who has an ice-bag placed on the patient's abdomen and kept there permanently for a few days. This is done not so much for the prevention of peritonitis as for its calming effect on the colic which you will often encounter in patients after this operation. I can recommend this practice, as it has done me good service, in controlling not only the colic, but reflex vomiting as well.

As to the feeding of the patient: You should only allow champagne and cracked ice for the first 24 hours, to allay the thirst. During the next two days continue the champagne and give bouillon, either cold or hot, according to the patient's desire.

The clamps are removed 48 hours after the operation, while the gauze should be removed on the fifth or sixth day. On the morning of the third day I order Rochelle powder, and when the bowels have moved I put the patient on milk and lime-water, equal parts, good claret, beef-juice, and light soup. I never allow solids in any form until the sixth day, and then a chop and dry bread may be given.

Six hours after the gauze is removed, an irrigation with a 1 per cent. solution of phenol is given, and should be continued once daily until all discharge has stopped. This usually is over by the fifteenth day, or in pus-cases by the twenty-first day.

I allow my patients to sit up in bed on the fourth or fifth day, and usually have them out of bed by the twelfth or fifteenth day after the operation, excepting in pus-cases and fibroid cases.

Now what is to be done if there should be a hemorrhage when you remove the clamps?

If it is slight, an oozing for example, do not under any circumstances try to apply a clamp. A vaginal gauze-packing is all that is necessary to control the bleeding.

But when the hemorrhage is severe, insert a Sims speculum, the patient being placed in the knee-chest position, as this insures plenty of light, and with mounted tampons you must endeavor to find the bleeding vessel, and, when this is found, place a clamp upon it, taking all necessary time, and, above all, do not work in the dark, as you will surely clamp some important organ along with this vessel if you do it blindly.

Sexual relations must not be begun until two months after the operation.

Regarding operative accidents: Even with the best operative care small vesical perforations may occur, even as late as eight or ten days after the operation. They probably are the result of the coming away of slough; but in all probability they are not due to pressure from the clamps, because Martin, of Berlin, who only employs ligatures, says that he has seen these small fistulæ appear during the first month. They get well of themselves, as a general thing. But if the fistula does not become obliterated it may be operated on; however, as Richelôt says, you should wait a little, firstly, because of its spontaneous closing up; and, secondly, on account of a too hasty operation.

Wounding the ureter during vaginal hysterectomy is exceedingly infrequent and will not occur if you will follow strictly what I have said regarding the vaginal incision and the application of the clamps. Among 400 vaginal hysterectomies performed for various lesions by Segond, the ureter was never wounded. Among 105 hysterectomies performed by Prof. Poucel, of Montpellier, only one case of uretero-vaginal fistula was observed, and this was greatly diminished by slight cauterizations with a Paquelin. In 139 more vaginal hysterectomies reported by Lafourcade, collected from the practice of various surgeons, the ureter was not injured in any case.

If your clamps are well made and tempered the chance of hemorrhage is very slight, if you will bear in mind what I said in the first lecture regarding the menses and general diseases.

I believe that in abdominal hysterectomy the intestine is wounded more frequently than in the operation under consideration. Poucel and Segond had only two cases out of a total of 405 vaginal hysterectomies in which the intestine was wounded, both occurring in the latter surgeon's practice.

Intestinal occlusion after vaginal hysterectomy is infrequent, and I am aware of only nine cases, one reported by Baudron and eight collected by Ashton. This accident was produced by the adhesions formed between the intestine and the borders of the vagina. The treatment is the formation of an artificial anus.

In debilitated subjects the sloughs always extend further than the tissue included in the grasp of the clamps, and this fact you must bear in mind when operating on weak patients, and apply the clamps *close to the uterus*, in order to prevent the slough reaching the ureter, then cut into the parenchyma of the organ when you divide the tissues.

Tuffier believes that utero-vaginal fistulæ are more often on the right side, and this is explained by Fournel by the fact that it is more difficult to apply the clamps to this side, because the separation of the uterus from the bladder is harder to accomplish and is usually incomplete.

Segond, Richelôt, and others believe that rectal fistulæ are due to the falling off of the sloughs.

One word more and I have finished. After vaginal hysterectomy the patients will, for a few months, complain of various troubles at the time of their menses. There are migraine, flushings, and, rarely, congestion of the breasts or liver, tinnitus aurium, etc. One of my patients was troubled by pain at each menstrual period for several months; the pain was seated in the place where her right ovary had been, was dull and lasted for three days each time, but this symptom subsided and she has been free from it now for some months.

Of course I have not covered the subject of vaginal hysterectomy in these two lectures; far from it. It has simply been my intention to mention some points on the subject that are not generally known or understood. Many other important questions relating to this splendid operation will come up for consideration before you this winter, and these remarks are simply intended as an introduction to the subject of removal of the genital organs by the vaginal route.

The College and Clinical Record will be hereafter known under the name of *Dunglison's College and Clinical Record*. A Monthly Journal of Practical Medicine.

MEDICAL PROGRESS.

Hysterical Vomiting in a Child.—WOOD (*Australian Medical Journal*, vol. xvii, No. 10, p. 460) has reported the case of a girl, ten years old, who during convalescence from an attack of typhoid fever, at the age of seven years, began to vomit after taking food, and had so continued to do with varying intervals. Immediately after the swallowing of food there was complaint of pain passing through the chest from front to back. The patient would then cry and refuse to swallow any more; in a few minutes the pain would abate, and she would resume eating. If the patient vomited during the existence of the pain, this would at once disappear. On one occasion she spent a fortnight with a medical friend, who insisted on her sitting at the table and eating everything put before her, and under this treatment she improved very much, but a return home was followed by renewal of the disorder. The child was extremely emaciated, but presented no evidence of organic disease. On admission to the Children's Hospital she ate and drank everything for twenty-four hours without vomiting, but on the next day she began to vomit. The food was retained for about eight minutes; the child's face assumed a pained, nervous expression during its retention; then vomiting occurred. Everything that had been swallowed was returned in one gulp, and no retching followed. On applying the ear over the stomach the sound of fluid falling into the stomach heard normally could not be detected. A few days later a bougie was passed into the esophagus, and a slight obstruction encountered at the cardiac orifice of the stomach. This yielded easily, and on repassing the bougie a minute later it could not be discerned. For the succeeding three days the child ate everything with greediness; no vomiting occurred, and the bowels acted naturally, although enemata had been used constantly during the previous two years. The vomiting returned from time to time, but was checked temporarily by the passage of the bougie. There was considerable gain in weight. The child returned to her friends, but failed to retain her weight, suffering from dysphagia, but not from actual vomiting. Later she was sent to a private hospital, where she once more improved. Afterward she was placed in a school away from home, and while much better she still had difficulty in eating in the presence of strangers. A peculiar symptom developed during this time—the occurrence of cough in the recumbent posture. A large amount of frothy mucus would collect in the pharynx, through which the air passed noisily in and out. At the expulsion of the fluid relief occurred, but the series of events was many times repeated.

Pylephlebitis and Abscess of the Liver Consecutive to Typhoid Fever.—LANNOIS (*Revue de Médecine*, 1895, No. 11, p. 909) reports a case of typhoid fever in the sequence of which there developed pylephlebitis and multiple abscesses of the liver, in the pus of which typhoid-bacilli were found. From a study of this case and of the literature upon the subject, he concludes that the complication is an exceedingly rare one. From the pathologic point of view three varieties of abscess of this kind are to be recognized: (*a*) metastatic, the abscess originating from a focus of suppuration in some distant part of the body, especially in the subcutaneous tissue; (*b*) from typhoid ulceration of the biliary passages; (*c*) in consequence of pylephlebitis, secondary to the intestinal lesion.

Landry's Paralysis, with Recovery.—BEHREND (*Deutsche medicin. Wochenschrift*, 1895, No. 47, p. 774) points out the differences in view that exist as to the nature of so-called Landry's paralysis, and reports a case of bulbar type terminating in recovery. This occurred in a man, thirty-seven years old, who, a day after drinking a pint and a half of rum, noted a peculiar feeling of coldness in the mouth and throat as if he had swallowed ice, together with a sense of numbness referred to the chin and neck. In the course of two or three days paralysis developed successively in the legs, trunk, and arms, with difficulty in swallowing and disturbance of speech. The nutrition was preserved, the temperature was normal, and the sensorium was clear. The pupils were equal and reacted sluggishly. There was diplopia due to paresis of both abducens muscles. Accommodation was not affected and the eye-grounds were normal. Hearing also was not deranged. In the cutaneous area between the lower lip and the hyoid bone sensibility was impaired. The expression was somewhat fixed in the distribution of the facial nerve, and the naso-labial folds were but feebly defined. The patient was unable to whistle. The tongue was protruded in the median line. There was some difficulty in chewing, and fluids drunk returned through the nose, a portion entering the larynx. The palatine velum was paretic. Pressure upon the spinal column and upon the nerve-trunks was unattended with pain. The knee-jerks could not be elicited. The electric irritability of the paralyzed muscles was preserved throughout. The sphincters were not involved. The spleen was not enlarged, and the remaining viscera presented no abnormality. The condition of the patient grew progressively worse and a fatal issue was feared; but, finally, improvement set in, and in the course of two months advanced to ultimate recovery. Treatment included warm baths, injections of strychnin and of camphor, and feeble induced currents.

Precocious Puberty.—At a recent meeting of the Clinical Society of London, CAMPBELL (*Medical Press and Circular*, No. 2591, p. 551) showed a lad, fourteen years of age, who had been under observation for upward of ten years. When only fifteen months old the mother had noticed that hair was beginning to grow on the pubes and that the external genitals were abnormally large; at two years of age they were fully developed and had not materially changed in the following years. The boy had at times manifested great sexual excitement. Between four and seven years of age he had frequent discharges of seminal fluid, but it had not been determined that this had contained spermatozoa. The muscular development was remarkable, the child having the muscles of a man of twenty-five or thirty. He had been in the habit of being shaved for several year. His education was defective from failure to attend school.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . .	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 28, 1895.

A FAREWELL WORD.

WITH this number THE MEDICAL NEWS leaves Philadelphia and passes out of its present editorial control. On January 1st, for business-reasons, the publishers will transfer the publication and editorial offices to New York City. The address of Dr. J. Riddle Goffe, the incoming editor, is Constable Building, Fifth Avenue and Eighteenth Street, New York City, to whom all editorial communications should henceforth be addressed.[1]

In severing relations with his contributors and collaborators the retiring editor deeply regrets the necessity of doing so, because whatever of unpleasantness and labor the office may have brought to him it has been the means of bringing a much larger share of things good beyond valuing—the friendship and sympathy, for example, of many noble men, and a clearer comprehension of the real dignity and loyalty of the great medical profession. There may be added the satisfaction of the consciousness of having striven faithfully to administer the trust for the benefit of scientific and ethical medicine. Hundreds of cordial letters received attest a certain measure of success in realizing this ideal, and no reply can adequately express the sense of gratitude felt for numberless courtesies and kindnesses spontaneously extended.

[1] The address of Dr. Gould is 119 South Seventeenth Street, Philadelphia.

SOME CAUSES OF NEURASTHENIA HITHERTO LITTLE DISCUSSED.

THERE are causes—and important ones—of some of the graver forms of neurasthenia that deserve more than the passing attention hitherto vouchsafed them. Without attributing to these causes more than their just importance, we are inclined to believe that those that we may describe as the conditions of a faulty education—conditions that we shall presently attempt to particularize—exert a considerable influence in disturbing the equilibrium of the nervous system, in altering the "*Gemeingefühl*," or mental perspective in which the patient views himself and the accidents that affect his thoughts, feelings, movements; which alteration in the primary functions of the understanding is a fundamental condition of the graver forms of neurasthenia, *e. g.*, the "*folie du doute*," the *delire du toucher*, the phobias; in a word, all the curious obsessions met in these strange maladies.

The fact, for instance, that a careless habit, once formed and persisted in, such as negligence in dressing, washing the person, in correspondence, in duties of the household, such as turning off the gas, putting a lighted match out, etc., etc., may develop into the painful obsessions of the "*folie du doute*," has been stated nowhere more definitely than in a paper by Dr. Höstermann.[1]

There are ideas, he gives us to understand, which originally produced in the normal course of thought, may become *dominant* in consequence of some external causes or conditions, as, for instance, evil experiences, natural timidity, habits. . . . Careless, disordely habits, although, properly speaking, not to be reckoned among the *obsessions*, may become identified with them. The thought that the door has not been completely shut, that the match was thrown in the neighborhood of inflammable material, etc., etc., may recur often to the mind and cause a certain anxiety and unrest, whence comes a desire repeatedly to observe if the door is really shut, the match really put out. The mind in which these incipient obsessions are produced is characteristically heedless. It is incapable at the moment of any particular action of strict attention. There is,

[1] Ueber Zwangsvorstellungen, Laehr's Zeitschrift, 1885, Bd. 41, p. 25.

therefore, the recollection of the thing done, but not of its attending circumstances.

Such heedlessness breeds accidents and their disagreeable consequences; which, in turn, may cause a fright, and, given an unusually impressionable mind, a lasting effect (*psychische Erschütterung*);[1] and by a curious reaction the particular event is ever afterward repeated with intense concentration, and fear of grievous consequences (as happened in the first case), repeated not once, but hundreds of times to verify the same fact, namely, that no harm has resulted. It is usual, indeed, for obsessions to arise suddenly. The instances in literature are now innumerable in which the curious reader may find some of great interest.[2] We can here only give a general sketch of these anomalies. A nervous woman, hearing unexpectedly of the dangerous prevalence of germs, and brooding much thereon, begins to wash her hands repeatedly, hundreds of times daily, spends hours in her room brushing her clothes, books, furniture, etc. After shaking hands with a guest she is anxious and *distraite* until they are washed again. Infection may have taken place meanwhile; and she is miserable. When walking out, if she passes anyone too near, she is afraid lest she has caught some contagion, and at once returns home to purify herself. At communion she doubts her fitness to take the sacrament. Has she, perchance, committed the unpardonable sin? (Under such circumstances the agony is very severe, even to fainting.) At table she does not pass anything for fear of infecting others.

Sometimes, forgetting, she passes a dish, and is straightway troubled by the thought that her hands may have been poisoned. Did she not touch the matches in her room before coming down? The matches are made of phosphorus, and phosphorus is a poison. Perhaps she has already poisoned somebody through her heedlessness. She would like to throw the matches away, but is afraid lest they poison somebody else. In short, everything terrifies such patients. We have even known one who was afraid to breathe, except through an apparatus, for fear of destroying the *animalculæ* which, it is said, exist in the air in great numbers.

It is a painful malady, though nothing in the experience of alienists is, perhaps, more curious and interesting. Krafft-Ebing,[1] to whom we are indebted for some of the most elaborate studies of this disorder, has given us many instances of obsessions arising from evil or shocking conditions in the life of a patient. "The most powerful causes," he says, "of imperative ideas (Zwangsvorstellungen) are impressions that intensely affect the mind and feelings by exciting ideas that persist until they become fixed in the fancy, wholly occupying it."[2] The subject of such obsessions are usually impressionable people of neuropathic constitution.

Impressions so powerful come early in the life of a patient. They are frequently made by the conditions of that life. One of the very best examples of the truth of this remark is to be found in Esquirol.[3]

In this case, a child—a little girl—wished to murder her step-mother; and had made the attempt with all the strength and passion she possessed. The idea had been produced in her mind by hearing the parents of her father discuss, somewhat too violently, the second marriage of their son. The examination of the child by Esquirol at Charenton revealed no dislike of the step-mother on any other grounds. No ill-treatment was alleged. The idea showed itself as a real obsession, with the uncontrollable impulse to murder. Esquirol paid great attention to this case, and the full report of it in his works is worthy of careful study. Such a case was formerly classed as *moral insanity*. It seems now more properly to belong to those obsessions that, given a neuropathic heredity, may develop from unfavorable moral conditions[4] (*Neurasthenisches Irresein*).[5]

A case of a milder description, in which the obsessions are distinctly of neurasthenic origin, is given by Dr. Thomsen, of Bonn. (*Archiv für Psychiatrie*, 1895, Bd. 27.) What is most interesting and apropos about this, is the fact that the patient, an intelligent lad of 16, himself described his

[1] Cf. Prof. L. Meyer: Ueber Intentions-psychosen, Archiv für Psychiatrie, 1888, Bd. 20.

The *Intentions-psychosen*, which are but conditions of neurasthenia, are probably caused in this way.

étourderie to "ill-breeding." Any attempt to correct him, any interruption of the current of his ideas in society, at home, about his avocations, would bring on a convulsive attack, such as has rarely been observed; "the eyes are turned to the right, the face twitches violently, the tongue protrudes, the foot stamps, he beats his neck with his right hand, uttering all the while abusive expressions," etc., etc.

This interesting case brings into clear relief the progression of the various stages of the disease, which, beginning in a neurotic child, from the early want of self-control, develops into incurable disorder. What better illustration is there to show the necessity of early inculcating a useful habit of restraining and curbing the passions and the excesses of the childish temperament if left to itself? And here we get a clue of no little importance, as it seems to us, to the great prevalence of neurasthenia in this country. The extreme social liberty enjoyed by the youth of both sexes is a cause of it, a social liberty that leaves the child too much to itself, rendering it impatient of control where some restraint is probably necessary to prevent the extremes of joy, grief, anger—a régime which, if continued long enough, is quite sufficient to vitiate the nervous system, to produce in it and the will the instability, the excitability combined with weakness, the alteration of the *Gemeingefühl*, that, as we have said, are fundamental conditions of neurasthenia, if properly understood.

THE BACTERIOLOGY OF THE HEALTHY NOSE.

There has been considerable divergence of view as to the presence or absence, and as to the abundance or scantiness, of microorganisms in the nose of healthy persons. Some of the investigations into this subject have been defective in failing to make a distinction between the entrance to the nasal cavity and its interior. In fact, it was for a long time assumed that the nose was a natural depository for microorganisms, but this opinion was based upon inadequate or untrustworthy evidence.

One of the first studies of the bacteria in the healthy nose was published by Jonathan Wright, of Brooklyn, in 1889, who found present a variety of microorganisms, and whose observations were confirmed by those of numerous other investigators; but none of these states that precautions were taken to avoid contamination from the vibrissæ or other structures of the nasal vestibules.

In the course of a series of researches into the bacteriology of the upper air-passages, Thomson and Hewlett[1] have determined that only exceptionally are microorganisms to be obtained from the mucous membrane of the healthy nose, the interior of the nasal cavity being in the great majority of cases perfectly aseptic. They found, however, that the vestibules of the nares, the vibrissæ lining them, and all crusts formed in them, generally swarm with bacteria. These experiments were conducted with great care, and every precaution was taken to eliminate all complicating factors and elements of doubt and to insure accuracy of result. No attempt was made to differentiate the organisms that were found present, the immediate object of the investigation being to determine their presence and numbers.

Of twenty-seven cultures made from the vestibulum naris, not one remained sterile; in three, a few colonies only developed; in three, from ten to twenty; and in twenty-one the growth was abundant. Microorganisms were found in all of fourteen cover-glass preparations from crusts or mucus; in two, they were scanty; and in twelve, abundant. Of seventy-six cultures made from the interior of the nose, sixty-four remained absolutely sterile; in seven, there was a scanty growth; in two, there were more than twenty colonies. In none of the twelve instances in which growth took place could this be called abundant, or were the colonies innumerable. Of thirty cover-glass preparations made from the nasal mucus, twenty-three showed no microorganism whatever; in five, a few organisms were found; and in two, they were numerous.

Among the whole number of one-hundred-and-fifty observations, in only three instances was there a visible quantity of dust on the nasal mucous membrane. It was found that in the rare cases in which dust is visible within the nose, it is usually deposited on the anterior portion of the septum or the anterior extremity of the middle turbinal.

The experiments from which the data recited were obtained were made upon thirteen individuals, varying in age from sixteen to thirty-six years, and who were on the whole up to the normal standard of health as regards the nose. Only seven, however, had never complained of nasal troubles. Of

[1] "Microorganisms in the Healthy Nose." Reprint, Medico-Chirurgical Transactions, London, 1895.

the whole number, three were females and three males examined in study-air; seven males were examined in the laboratory, where they had frequently spent one or two hours before submitting to examination. Microorganisms were encountered among the latter in much larger number than among the former.

This valuable investigation from which we have so liberally quoted closes with the following summary:

In all bacterioscopic investigations of the nasal fossæ, in all researches as to the action of the nasal mucus, etc., a clear distinction must be made between the vestibule of the nose and the proper mucous cavity. The former is lined with skin and is furnished with hairs and with sudoriferous and sebaceous glands; it is not a part of the nasal cavity proper, but only leads to it. The neglect of this distinction may account for the discrepancies in previous observations on the subject. Avoidance of contamination with the lining of the vestibule is difficult even when this source of error has been realized. The dust and crusts of mucus and *débris* deposited among the vibrissæ of healthy subjects are never free from microorganisms, which are as a rule abundant. The reverse is true of the Schneiderian membrane. While microorganisms must occasionally be present here, they are, under normal conditions, never plentiful and often entirely wanting. The occurrence of pathogenic organisms must be so infrequent that their presence in the pituitary membrane must be regarded as quite exceptional.

EDITORIAL COMMENTS.

The Color of Sin.—Where would we poor physicians and scientists be if it weren't for the newspapers? They are the true pioneers of scientific and medical progress nowadays, and we have all we can do to keep up with their rapid strides. One of them has just heralded a most brilliant advance, no less than an absolute physiologic test of guilt. It has discovered a scientist who has discovered that the various human emotions and passions, good and bad, each produce definite chemic secretions, which act upon the brain and cause vice or virtue, as the case may be, and are excreted by the skin in the perspiration, where they may be recognized by chemic tests. His name is Gates, and he claims to have isolated and distinguished no less than forty distinct "emotion-products." The products of evil and sinful emotions are "poisonous," while those of good and happy impulses are "life-producing" in their nature. This may in some measure account for the notoriously short lives of evil-doers, and furnishes a physical explanation of the pangs of remorse. "The worst of all these secretions is that of guilt"; and Dr. Gates' crowning discovery is that if a small amount of the perspiration of a person "suffering from conscious guilt," be placed in a test-tube and a few drops of selenic acid added, a pink color will immediately appear. Hence he is led to declare that the true color of sin is pink, and that Isaiah was merely indulging in rhetoric exaggeration when he spoke of it as "scarlet." How striking that Isaiah could come so extraordinarily close to the mark without even a test-tube to use in his experiments, and, of course, without selenic acid; and in a poetic composition, too! The Scriptural term "scarlet woman" is also found peculiarly apropos, indicating as it does a high grade of depravity. Positively another scientific verification of the verbal inspiration of Scripture!

But there is a fatal defect in this theory which does not appear to have occurred to the author, and that is that possibly these "products" themselves are the *cause* of the various emotions and their resulting virtuous or vicious action, and not the *effect*. May they not be due to some toxin or germ which attacks the body from without?

This would be something like a discovery; for then, by isolating the germ, it could be attacked in its native lair, cultures made for inoculation-purposes, and children vaccinated for murder, theft, and envy, as they are now for smallpox and diphtheria. Even if this should not be the case, as the products of the good and happy emotions are "life-promoting"—for instance, "laugh and grow fat"—why not collect them from the perspiration of happy and virtuous persons and inject them into the tissues of the criminal and the hypochondriac? May we not have here a scientific explanation of the well-known "healing-touch?" At all events, "honest sweat" has apparently not been ranked at all too high as a moral influence.

This discovery will be a great aid and comfort to the waning fortunes of the Lombroso school of criminal anthropologists, for it is just the kind of a straw upon which they love to build their most magnificent, if somewhat top-heavy, edifices. But it is a sad shock to our poetic sentiments to find that pink, which we have always somehow associated with the dawn, the moss-rose, and the blushing cheek of the sweet girl-graduate, is really the livery of sin. But such are the ruthless disillusionments of science.

The Newspaper-doctor.—The evils of hospitalism do not end with the direct result and the single offence. The advertising doctor and newspaper-medicine are its legitimate offspring. An Eastern city has recently suffered with an attack of acute hospitalism, and now comes the sequel. In this busy town there was a short time ago organized a new hospital, upon the staff of which was placed an irregular, not to say a disreputable, practitioner. The better men protested and declined such association, but without avail. The reprehensible selection of the board of managers of the hospital was only the beginning of worse things. In the local newspaper of a recent date, we find an advance notice of the performance "*in the presence of a number of invited people*," of a remarkable operation of "skin-grafting," in which "the skin of a Belgian hare will be engrafted upon the leg" of a patient who courageously offered himself, as a sacrifice if need be, upon the altar of science.

A detailed account of the successive steps of the preparatory treatment and of the operation itself accompanies this announcement, and editorially expression is given to the hope that the operation will be successful, "primarily for the patient's benefit and besides for the advancement of the science and *the fame of the physicians who will engage in the operation.*" In the account of the operation in the newspaper of the following day, it is stated that the patient "was removed to the sick ward with a live hare glued to his right leg. The only other person present at the operation, beside the physicians and white-hooded nurses, was Dr. ———." The question naturally arises how, in the absence of the ubiquitous reporter, such detailed description of the procedures adopted found its way into public print—whether through telepathy, telephony, or telegraphy, or through verbal or written communication. Under any circumstances the whole business is discreditable to the individuals concerned and an affront to the profession at large. Offences of this character can only be prevented by heroic treatment.

Business Enterprise is admirably illustrated in the ingenuity of the advertiser in our daily papers. Two instances have come to our notice within a week. To a big omnium-gatherum store in Baltimore belongs the honor of selling the medical service of "one of Baltimore's prominent doctors, a graduate of the Maryland University, who has practised among you for 11 years," etc. "He will accept our tickets for a visit any time you see fit to call him, day or night. We shall sell these tickets for 29 cents each. When the Doctor calls all you have to pay is the ticket you bought of us for 29 cents. These tickets are good for one year, and you can get as many as you wish to-day for 29 cents, and the Doctor will accept one ticket for each visit. It makes no matter what we pay the Doctor; you only pay 29 cents for a visit."

To Philadelphia is due the credit of another scheme. It seems to start from the doctor's office, but all the soda-water, crockery, and bric-a-brac drug-stores of the city are enumerated as filling this physician's prescriptions for 25 cents, and the "medical" man gives the "medical" advice and the "prescription" absolutely "free-gratis-for-nothing." Ponder for one minute the mental and moral conditions of these drug-store, grocery, and doctor men!

Information is desired concerning the "American Association of Physicians and Surgeons." We have before us the flaming page-advertisement of a newspaper-doctor who cures Bright's disease by "his great specific," etc., and who signs himself "Vice-President" (should not the hyphen be left out here?) "of Pennsylvania of the American Association of Physicians and Surgeons." Can any correspondent give us some information concerning this medical society?

Tuberculous and Tubercular.—The News has for several years discriminated in the use of the adjectives *tuberculous* and *tubercular*, applying the former to conditions related to the specific process, tuberculosis, and the latter to the histologic formation known as a tubercle. We are glad to find our position sustained by the *Lancet*, which makes an earnest plea for the practical adoption of this distinction, in order to insure lucidity and unambiguity of expression.

REVIEWS.

A Manual of Operative Surgery. By Lewis A. Stimson, B.A., M.D., Professor of Clinical Surgery in the University of the City of New York. New (third) edition. In one royal 12mo volume of 614 pages, with 306 illustrations. Cloth, $3.75. Philadelphia: Lea Brothers & Co., Publishers, 1895.

The arrangement of this edition is almost the same as that of the previous issue, but the additions to the book have been very numerous. Dr. Stimson has been largely aided in the preparation of the manuscript by Dr. Rogers, to whom, indeed, he has given full credit, both upon the title-page and in the preface. Among the new operations introduced in this edition are trephining for suppuration within the cranium due to middle-ear disease, puncture of the lateral ventricles of the brain, intracranial neurectomy for neuralgia, tenorrhaphy, open suture of fracture of the patella, laminectomy, the surgery of the thyroid gland, and many abdominal operations. The article on operations for the radical cure of hernia has been very much expanded in accordance with the progress in this branch of surgery. The new cuts introduced in this edition are numerous, and constitute a distinct addition to the text.

The article on the operative reduction of old luxations of the elbow is a suggestive one, and recalls the paper of Dr. Stimson on this subject, which appeared as a journal-article some years ago. The illustrations of cerebral localization taken from Starr are unusually satisfactory.

The conciseness of the descriptions may seem to some readers a disadvantage, since students and young physicians may find that it requires a certain degree of knowledge of the topics to make the methods advised sufficiently clear. So much valuable information is, however, contained in the volume, which is a small one, that the criticism, though in the main true, does not detract from the real value of this guide to operative surgery. Conciseness is so seldom found in medical textbooks that it is refreshing to find it here illustrated in its best form.

The directions for preparing aseptic materials for operations may be rather difficult for the general practitioner in country districts to carry out, but they are simple, easily understood, and avoid the elaborate details which have sometimes made antiseptic surgery a bugbear to those living at a distance from medical centers.

In this, as in all books, omissions are occasionally found of matters which it would seem ought to be included. Among these may be mentioned the omission of the use of cocain by incarceration for local anesthesia, as well as the infiltration-method of producing anesthesia advocated by Schleich. The fact that the latter is rather a new suggestion probably accounts for its not being mentioned. Less attention seems to be directed to the Esmarch method of producing artificial anemia and preventing hemorrhage than would be expected. The Petit tourniquet seems to be given an unnecessary and unwise prominence. It is almost a relic of the surgery of bygone days.

Stimson's *Operative Surgery* has always been a fa-

vorite with us, as it doubtless has been with many teachers and students of surgery. The new edition will sustain the reputation of the book, and add to the debt which the profession owes to the author and his less well-known collaborator, to whom English-speaking physicians are also indebted for the translation of Tillmanns' *Principles of Surgery*.

PEDIATRICS, THE HYGIENIC AND MEDICAL TREATMENT OF CHILDREN. By THOMAS MORGAN ROTCH, M.D., Professor of the Diseases of Children, Harvard University. Philadelphia: J. B. Lippincott Company, 1896.

IT is to be regretted that Prof. Rotch has chosen to cast his work in the form of a series of clinical lectures, which, though affording opportunity for the presentation of an enormous amount of clinical material and illustrations of cases, has naturally called for much of the unnecessary and tiresome verbiage of the lecture-room to keep up the illusion. Presumably the book is an elaborated report of the author's lectures to his classes, for to this method of compilation we must attribute the colloquial style and not infrequent inelegancies of expression to be noted throughout the volume. Judicious condensation in the matter of clinical histories might have been employed with decided advantage, and have allowed greater space for a subject like insanity, which has evidently been slighted for want of room.

Despite these drawbacks in the literary execution of the work, there is so much valuable material presented that the professional success of the volume is assured.

The results of Dr. Rotch's original work are most conspicuously recorded in the earlier pages which cover the whole period of infancy. The Infant at Term is a notable chapter presenting briefly and concisely much valuable material to be found in no similar work with which we are acquainted. Normal Development is also noteworthy for a like reason; but it is upon the section on Feeding that the peculiar value of Dr. Rotch's book will pre-eminently depend. This subject is treated at unusual length and with masterly skill, as was to be expected from Dr. Rotch's previously well-known contributions on this branch of pediatrics. The workings of the Walker-Gordon Milk-laboratory are here fully explained, and the methods of combining milk-prescriptions are completely set forth. As an addendum to this section that on Premature Infants demands praise for its valuable data and scientific methods of dealing with this long-neglected, because imperfectly understood, class of cases. The section on the Blood in Infancy and Childhood is likewise of unusual value. It embodies much original observation and presents a comprehensive view of the present status of knowledge of the blood in diseased conditions in early life. The section on Diseases of the Nervous System and the Myopathies occupies nearly two-hundred pages and is enriched with numerous photographic reproductions from the author's own practice. The remaining sections are well done, but call for no further special mention.

From the bookmaker's point of view the volume is not up to the standard of the illustrated medical textbook of to-day. The half-tone cuts in the text, as a rule, are indistinct or are spoiled by the quality of the paper—a fact which is strikingly emphasized by the contrast afforded by a number of inserted plates in the section on diseases of the intestine, which are printed on suitable plate-paper. The colored plates also are far from accurate in their tints, though special claims are made for them in the preface. An index of 17½ pages finishes the volume. It is unnecessary to say that for a technical work of over 1100 pages the volume is totally inadequate and necessarily very incomplete.

SURGICAL PATHOLOGY AND THERAPEUTICS. By JOHN COLLINS WARREN, M.D., Professor of Surgery in Harvard University. Philadelphia: W. B. Saunders, 1895.

THE work before us is a notable production. It contains some 800 pages. The illustrations are original, numerous, extremely handsome, and the book is more than worthy of them. It is evidently the product of years of patient study and laborious observation, and every line of it shows the comprehensive grasp of the scholar and philosophic thinker, and the rigid common sense of the practical operating surgeon.

The initial chapter deals with Bacteriology, and is one of the best and clearest of the numerous brief dissertations upon this difficult and most important subject. Here as elsewhere definitions are commendably brief, accurate, and clear. Hyperemia is next discussed and then Inflammation. Warren considers inflammation a condition, not a disease—not an increase of nutrition, but a diminution and perversion of nutrition, and he holds that the cellular elements of inflammation come from the cells of the part. He compares inflammation to a forest fire, which destroys but does not repair; though in its rage it carries destruction, it sweeps away also the pests which prey upon vegetation, and leaves in the ashes conditions and materials which favor a new growth of timber. Inflammation is set forth under the heads of Simple and Infective, the latter including Suppuration, Ulceration, Abscess, Fistulæ, Boils, Carbuncles, and Osteomyelitis, which last-named disease, the author truly asserts, causes most cases of necrosis. In treating extensive losses of bone from necrosis, Warren commends Schede's method (filling with a blood-clot) and Senn's method (filling with chips of decalcified bone).

In the chapter on Repair the author claims that repair need not be inflammation, but results rather from the power of renewal of undestroyed tissue. In repair cells which multiply by karyokinesis fill the leading rôle, and leukocytes play an unimportant part. Gangrene is fully considered, and Shock is studied in one of the most scientific of modern articles. The author differs from the view of Fisher and Gross that shock is a reflex vasomotor paresis, and gives adhesion to the belief of Hodge and Grœningen that it is a condition of fatigue and exhaustion of the ganglia of the cord and medulla.

The next sections deal with Fever, Surgical Fevers, Septicemia, Pyemia, Erysipelas, Hospital Gangrene, Tetanus. It is shown that the curative effects of tetanus-antitoxin do not fulfil anticipations; most reported cases are seen to be chronic cases, and the power of this agent over acute tetanus is doubtful. In the article upon Hydrophobia the truth of Pasteur's method is considered as proved. Next come articles upon Actinomycosis, Anthrax, Glanders, Snake-bite, Tuberculosis, Dis-

eases of Bone, Tumors, Aseptic and Antiseptic Surgery. Appended to the book we find set forth the blood-serum therapy for rabies, the preparation of erysipelas-toxin, and other valuable information.

A pleasing thing about this book is its scholarly and literary flavor, a flavor too often absent in medical works. Any Warren of Harvard has given bonds to greatness, and we cannot pay the book of John Collins Warren a higher compliment than to say that it is entirely worthy of his name and of his chair.

Surgery: A Practical Treatise, with Special Reference to Treatment. By C. W. Mansell Moullin, M.A., M.D. Oxon. Assisted by various writers on special subjects. With 623 illustrations. Third American edition. Revised and edited by John B. Hamilton, M.D., LL.D. Philadelphia: P. Blakiston, Son & Co., 1895.

If excellence of a book may be measured by popularity, then *Moullin's Surgery* must be so classed. Two American editions have been consumed since 1891, and now we have before us a third. This, like the second edition, has passed under the able editorship of Dr. John B. Hamilton, which fact by itself is ample guarantee of the primary worth of the book, as well as of its being properly modernized and fitted for the needs of the American practitioner and student. As the work of the editor has been placed in brackets, it is easy to see to what pains he has been to render the volume as comprehensive as possible. It has been found necessary to make a very general revision of certain parts, and to add much new material and many new illustrations in order to accomplish this result. While the claim of the preface that the book is "quite up to the date of publication" (October, 1895), as "it has taken but six weeks to pass through the press," is scarcely justified by examination of certain portions, yet, upon the whole, the result of the new revision is very satisfactory, and the work is certain to retain its position in the front rank of standard surgical books for study and reference. The colored plates of bacteria and tumors are beautiful, and many of the newly added original illustrations are of great value. The volume as a bookmaker's product is notably pleasing in all respects.

—

The Principles and Practice of Medicine. Designed for the Use of Practitioners and Students of Medicine. By William Osler, M.D., Fellow of the Royal College of Physicians, London; Professor of Medicine in the Johns Hopkins University and Physician-in-Chief to the Johns Hopkins Hospital, Baltimore, etc. Second edition. 8vo., pp. xviii, 1134. New York: D. Appleton & Co., 1895.

The favorable reception accorded Osler's *Practice* and the exhaustion of a large edition within three years speak more forcibly than any written commentary. The book is one of the most meritorious recently published, and its worth is the basis of its popularity. The numerous changes that have been found necessary in the revision indicate the rapid strides that have been made and are constantly making in the domain of medicine. Sixty-five pages have been added to the text, and the illustrations have been increased six in number. The article on Typhoid Fever has been thoroughly revised and amplified. Of the Brand bath it is said that it "has steadily advanced in favor both in hospital and private practice, and in spite of the difficulties and the unpleasant features necessarily connected with it there is no plan of treatment which gives such results. In the hospitals which carry out a strict hydrotherapy the death-rate is about 7 per cent., while in other institutions the death-rate is from 10 to 15 per cent." The article on diphtheria has been almost doubled in length and materially modified. Recent additions to our etiologic knowledge have been incorporated, and the antitoxin-treatment has received due consideration. Extensive changes have been made in the articles on septicemia and pyemia, and the subject of malarial fever has been largely rewritten. Entirely new sections devoted to the bubonic plague, and to foot-and-mouth disease, have been added, and the whole group of infectious diseases has been brought up to date. Descriptions of infantile scurvy, of hemorrhagic diseases of the newborn, of eczema of the tongue, of buccal leukoplakia, of affections of the mesentery, of anuria, and of parasitic infusoria have also been added. The section on diseases of the nervous system has been elaborated by new text and helpful diagrams. In fact, alterations and additions have been made throughout the book wherever these were rendered necessary by the increasing changes and developments of medical progress, and the result has been to keep the work in the front rank of text-books for the student and of reference-books for the practitioner.

Physiology Practicums. Explicit Directions for Examining Portions of the Cat; the Heart, Eye, and Brain of the Sheep, as an Aid in the Study of Elementary Physiology. By Burt G. Wilder, B.S., M.D., Professor of Physiology, Vertebrate Zoology, and Neurology in Cornell University, etc. Second edition, revised, with thirty figures. Published by the author. Presses of the Ithaca Journal, 1895.

Since physiology has become an experimental science, based largely on the facts of anatomy, it is highly desirable that all medical students, at the very beginning of their college-work and before entering on the study of physiologic phenomena, should be familiar with the general plan of organization of the human body. Inasmuch as this, at present, is impracticable, the study of the structure of some highly specialized animal-form should be insisted on as a necessary prerequisite. No animal presents so many advantages for a preliminary study in human anatomy as the cat; a practical acquaintance with the structure of this animal will afford the necessary data for a comprehension of the fundamental facts of physiology. To assist the student in this preparatory work, Prof. Wilder has, in his *Physiology Practicums*, given explicit directions for the examination of portions of the cat and of the head, eye, and brain of the sheep. It is safe to say that if the directions given by Prof. Wilder are faithfully followed the student will receive the best possible preparation for the subsequent study of human anatomy and for the comprehension of physiology. A teaching experience of twenty-five years has enabled Prof. Wilder to present

the subject in the most concise, explicit, and attractive manner, so that the student will have no difficulty in the conduct of his investigations. Every medical student at the beginning of his studies should provide himself with a copy of the *Practicums*, and conscientiously proceed to familiarize himself with its contents. The knowledge thus obtained and the technic acquired from this systematic dissection of the cat will be of inestimable value to the student in all his subsequent studies of anatomy and physiology. We are indebted to Prof. Wilder for this admirable guide, and trust that in the reorganization of the methods of education in our medical schools this preliminary work, as formulated by him, shall be regarded as an essential part of the curriculum.

A GUIDE TO THE PRACTICAL EXAMINATION OF URINE, FOR THE USE OF PHYSICIANS AND STUDENTS. By JAMES TYSON, M.D., Professor of Clinical Medicine in the University of Pennsylvania, etc. Ninth edition, revised and corrected, with a colored plate and wood engravings. 8vo, pp. 276. Philadelphia: P. Blakiston, Son & Co., 1895.

GUIDE POUR L'EXAMEN PRATIQUE DE L'URINE, ETC. Par le DOCTEUR JAMES TYSON. Huitiéme edition, revue et corrigée. Traduction de MM. E. GAUDRELET and A. S. CLARKE. Large 8vo, pp. 170. Paris: Société d'Editions Scientifiques, 1895.

WE can perhaps scarcely do better in detailing the reasons that have rendered necessary nine editions of this well-known and very useful manual than to quote from the preface to the French translation of the eighth edition which appears almost simultaneously with the ninth American edition: "Among the few publications in English devoted exclusively to urine-analysis the *Guide to the Practical Examination of Urine, for the Use of Physicians and Students*, by Professor Tyson, of Philadelphia, by reason of its success in America and England—having passed through eight editions—commends itself favorably to the attention of the French medical profession. . . . By reason of the minute details into which the author enters in his description of analytic processes the work is a most excellent one. The simplicity of the methods described give to the work a practical value. The examination of urine from the chemic, physical, and physiologic points of view is treated as completely as possible in the limits of a manual intended for physicians and students. Practising physicians will find of value the succinct but lucid portrayal of the differential diagnosis of diseases of the kidney." Not many changes have been necessary in this ninth edition, and the work remains, as it has long been, a trustworthy and complete presentation of the subject with which it deals and a reliable guide in urine-analysis to the student and physician.

DIET IN SICKNESS AND HEALTH. By MRS. ERNEST HART, with an Introduction by Sir HENRY THOMPSON, F.R.C.S., M.B. Lond. 8vo., pp. 219. London: The Scientific Press, Limited, 1895.

THE author of this book, who is the wife of the distinguished editor of the *British Medical Journal*, and who is well-known for her interest and activity in behalf of the Irish people, has been a student of the Faculty of Medicine of Paris and of the London School of Medicine for Women, and has already made a number of contributions to the literature of physiology and pathology. She thus comes well equipped to the performance of her present task. Within the limits that she has allowed herself, Mrs. Hart has succinctly laid down the principles of digestion and nutrition, and indicated the lines along which a suitable dietary is to be selected, both in the prevention and in the treatment of disease. Extended consideration is given to the diet of diabetes and to that of gout, and in many places explicit directions are given as to the preparation of various articles of food and various food-combinations. The book is written in a pleasant and entertaining style and printed in clear, legible type, and should realize the hopes of its author in proving "useful to those who are sick and to those who have to nurse, feed, and prescribe for the sick, and that it will aid the healthy to preserve health."

PHYSICIANS' VISITING LIST FOR 1896. LINDSAY & BLAKISTON. Philadelphia: P. Blakiston, Son & Co.

CONCERNING this well-known visiting list the publishers mention several improvements in the new edition for 1896. More space has been allowed for writing the names and to the "memoranda page." A column has been added for the "amount" of the weekly visits, and a column for the "ledger page." The reading matter and memoranda pages have been rearranged and simplified. The lists for 75 and 100 patients will also have a special memoranda page as noted, and hereafter will come in two volumes only, dated from January to June and from July to December. This does away with the risk of losing the accounts of a whole year should the book be mislaid.

THE MEDICAL RECORD VISITING LIST OR PHYSICIANS' DIARY FOR 1896. New York: William Wood & Co.

CONCERNING this excellent book the preface says: "It has been revised to increase the amount of matter calculated to be useful in emergencies and eliminate such as might better be referred to in the physician's library. The most important change is in the list of remedies and their maximum doses in both apothecaries' and decimal systems, and the indication of such as are official in the United States."

NEWS ITEM.

Rush Monument Fund.—Dr. George H. Rohé, Secretary and Treasurer of the Rush Monument Committee, acknowledges the following additional subscriptions:

INDEX.

ABDOMINAL wall, anterior, intrauterine rupture of, 683
Abortion, intra-uterine injection of lead acetate to induce, sudden death from shock due to, 153
Abscess, hepatic, following duodenal ulceration caused by a burn, 268
Acetanilid applied topically, toxic effects from, 555, 664
Acne vulgaris, for, 326
Addison's disease, 294
  case of, treated by ingestion of the adrenals of the sheep, 551
Adenoid growths, headache due to, 519
Adler, excision of coccyx for constant pain resulting from ununited fracture, 348
  extirpation and colotomy in cases of carcinoma of the rectum, 63
Adrenal, diseased, palpable, floating kidney with, 551
Advertising, medical, in Austria, 434
  new method of, 527
  for patients, 661
Akromegaly, 262, 458
  abortive, with macroglossia, 270
  treatment of, with pituitary extract, 630
  with temporal hemianopia and glycosuria, 241
Alopecia areata, treatment of, 214
Altruism, cellular, and physiologic history, 355
American Medical Association and patent medicines, 47
  profession, comparative standing of, 105
  woman, 123
Amygdophenin, 630
Amyl nitrite, the treatment of pneumonia with inhalations of large doses of, 611
Anastomosis-button, report of 111 additional cases operated upon with, 533, 569
Anemia, pernicious, case of, due to ileocolic disease, 573
  nature and treatment of, 42
  the heart in, 617
Anesthesia from ether and chloroform, some remarks on, 508
  -statistics, 582
  uninterrupted, in operations on the face and mouth, 566
  with chloroform and oxygen, 420
Aneurysm of the heart, 491
  treatment of, 104
  gluteal, spontaneous, case of, 652
Anthrax, serum-treatment of, 555
Antitoxic serum, the use of, for the prevention of diphtheria, 589
Antitoxin, bacterial diagnosis and treatment of diphtheria with, 1
  treatment of diphtheria with, 45, 156, 176, 242, 376, 406, 522, 555
Antivenene, more about, 586
Antivivisection for children, 181
  unlicensed, 612
Anus, vulvovaginal, 319
Aorta, tubercle of the intima of, 300
Apolysin, 350
Apomorphin in the treatment of opium-poisoning, 279
  use of, in narcotic poisoning, 447
Appendages, removal of, and ligation of uterine artery to utero-cervical junction, 170
Appendicectomy, successful celiotomy in a child of sixteen months with, 69
Appendicitis, 673
  chronic (relapsing), seventeen cases treated by operation, 564, 601
  some moot points in treatment of, 289
Arey, deterioration of diphtheria-toxin, 20
  toxic effects of trikesol, 68
  experiments relating to toxic nature of urine of diphtheric patients, 322
Arnold, three cases of rectal neuralgia, one with double mammillitis, 128
Arsenic subcutaneously, pseudoleukemia successfully treated with, 582
As others see us, 354
Ashburn, urethral calculus of large size, 579
Athletics, college-attendance and, 411
Atrophy, hemifacial, 604
Atropin-poisoning, case of, in which one grain was taken; recovery, 628
Auricles, prominent, new method for correcting the deformity of, 154
Auscultation of joints, 405
Autoclave, use of, for sterilizing nutrient gelatin, 349

BAGOT, nephrectomy for tuberculosis of the kidney in a patient always a resident of Colorado, 346
  urethral diverticula, 240
Ball, otitis media as a complication of pneumonia, 309
Barcus, sudden death from shock due to the intra-uterine injection of a solution of lead acetate to induce abortion, 153
Barkwell and Beckett, a new method for correcting the deformity of prominent auricles, 153
Bartholow, Dr. Robert's, 183
  cases illustrative of character and treatment of exophthalmic goiter, 542
Bashore, What shall we do with the old well? 260
Bath, warm, as a diagnostic measure, 376
Baths, cold, treatment of typhoid fever with, 214
Belladonna, use of, in pemphigus, 553
Benedict, "liquid peptonoids," 681
Bergen, general erysipelas occurring during the puerperium followed by popliteal thrombosis and gangrene, 424
